and XI. falls of 178,000 and 192,000, respectively, were noted. These cases can be ruled out as falling within the limit of error before mentioned, and if we are justified in assuming the fall in Case IV. to be due to the sepsis and pneumonia, we have three cases out of twenty-three showing a diminution in the number of red corpuscles, and that diminution less than 400,000 in each case. These cases, while not absolutely unfavorable, were all severe. Some of them were admitted at a comparatively late stage in the disease and were already anæmic. These latter cases showed a steady rise in the number of the corpuscles (Cases III., VIII., XI., XII., XIII., and XV.). In only five of the cases was it possible to examine the blood before the administration of the antitoxin, as they were usually admitted in the late afternoon and

received an injection of antitoxin at once. Two of these cases resulted in death, two were of moderate severity, and one was a mild case. Not one of them showed any appreciable reduction twenty-four hours after the administration of the antitoxin. In one case the blood was counted two hours after the injection (XVI.).

The amount of antitoxin injected varies from three to 41.5 cubic centimetres (Case XIV., in three doses). The largest single dose given was sixteen cubic centimetres (Case XXV.). The strength in antitoxin units varied from five hundred to six thousand and seventy-five units (Case XIV.). The greatest amount given at one dose was three thousand units (Cases XXV. and XXIX.). Of the three cases showing a diminution in the number of the red corpuscles, two

received large doses of antitoxin, both as to amount and strength. Case XXV. received thirty-two cubic centimetres, with a total strength of six thousand units, and Case XXIX. received twenty-six cubic centimetres with a total strength of six thousand units. The third case received only five cubic centimetres with a strength of seven hundred and fifty units. So that it is possible that large doses of antitoxin may, by virtue of their strength or amount, bring about or permit of a reduction in the number of red corpuscles. But it must be remembered that these were severe cases, which in the judgment of the attending physician required large doses of antitoxin and which would probably have shown a marked fall in the number of the red corpuscles if the antitoxin had been omitted. Case XIV., which received 41.5 cubic centimetres with a total strength of six thousand and seventy-five units, showed no reduction at all.

The microscopical examination of stained specimens revealed nothing abnormal. An occasional polychromatophilic red corpuscle was seen, but in the observer's opinion they were present much less frequently than in the cases of diphtheria treated without antitoxin. But, as before stated, this evidence of degeneration is untrustworthy except as confirmatory.

In twenty-seven out of the twenty-nine cases a leucocytosis was observed, ranging from 38,600 in Case XXV. to normal. The severe cases showed the greatest increase. But the severest case of all (XXVIII.), in which the patient was practically moribund on admission, showed no leucocytosis at all. The other case (XXVI.) showing no leucocytosis was very mild in character. But beyond the rough correspondence to the degree of severity of the case the amount of leucocytosis did not correspond to any particular clinical feature, nor could the observer form any idea from it as to the final outcome of the case. The leucocytosis is independent of the pulse, the temperature, or the amount of membrane. But while a high grade of leucocytosis is, as a rule, seen only in the severe cases, the ordinary clinical examination of the patient is of much greater value in forming a prognosis and in indicating the line of treatment than any information to be gained from the examination of the blood. The latter is simply confirmatory, never indispensable. As to the influence of the antitoxin upon the course of the leucocytosis, the cases here reported furnish no evidence that it has any effect whatever. True, the leucocytosis diminishes in the majority of the cases, but it does the same in the cases of diphtheria treated without antitoxin, as comparison of the tables will show. The leucocyte curve does not seem to have reached normal any sooner in the cases with antitoxin than in those without. In several of the cases ending favorably, the number of the leucocytes was greater twenty-four hours or more after the antitoxin was given than before (Case XIV. for instance). We have no explanation for the sudden and marked variations that take place in the course of the leucocytoses in acute diseases such as pneumonia and scarlet fever. These often amount to from 10,000 to 15,000 per cubic millimetre; such variations are seen in Cases III. and VI. of Table I. They can also be noted in the series of cases reported by Bouchut (*l. c.*), so that we would expect to see them in the antitoxin cases, and are hardly justified in ascribing them to its use. It is not denied that the injections of antitoxin may have some effect upon the number of the leucocytes. But such effect is immediate and transitory, appearing within the first hour and disappearing again by the end of twenty-four hours. In common with many other substances, the injections of antitoxin are stated to bring about an immediate reduction in the number of the leucocytes, the so-called hypoleucocytosis. But unless the injected sub-

stance be toxic and capable of producing a reactionary hyperleucocytosis, the number of the leucocytes promptly returns to normal, and no trace of any change is observable at the end of twenty-four hours. In the above cases no attempt was made to determine the immediate effect of the injections of antitoxin upon the leucocytes, some idea of its ultimate effect being all that was aimed at.

Stained specimens showed the same state of things already noted in the remarks on Table I. The polynuclear forms of the leucocytes were increased and the small mononuclear forms diminished, as also were the eosinophiles. Case XXVIII., the fatal case with no leucocytosis, showed a marked increase in the mononuclear and transitional forms, the polynuclear and small mononuclear forms being correspondingly diminished. No changes in the staining-reaction of the nuclei were observed, except in one case, which is not given in the above table. The child was practically dead when the blood was examined, the heart ceasing to beat five minutes afterward. Here all the nuclei of the leucocytes refused to stain, the leucocytes being heaped together and partially disorganized. Ewing states that by the use of six-per-cent. salt solution faintly tinged with an alcoholic solution of gentian violet, he is able to differentiate two classes of polynuclears in the blood in diphtheria, those with poorly stained nuclei and those with well-stained nuclei. This loss of affinity for gentian violet shown by the first class he holds to be due to the necrotic action of the toxins present in the circulating blood, and states that this loss of affinity is present in all cases of diphtheria that are at all severe. He also states that the use of antitoxin in favorable cases is followed by a recovery of this affinity, and hence that observation of this fact is of prognostic importance. The writer followed Ewing's procedures faithfully in the last seven cases in the above table, varying the amount of gentian violet and using different magnifying powers, but was unable to obtain similar results in any case. It is difficult, well-nigh impossible, to outline the nucleus, using the above solution and the hæmocytometer. The leucocytes are not flattened out, but globular, and take up the stain with such intensity that differentiation of the nucleus from the protoplasm is almost impossible, as above stated. Another point to be considered is that in normal blood the nuclei of the polynuclears exhibit the most varied intensity in their staining-reactions, from the colorless nuclei of the so-called "leukocytschatten" to the almost black-staining nuclei of the small polynuclear forms. No variations from the normal in the staining-reaction of the nuclei were made out in the dried and stained specimens.

A few words concerning the granulations of the leucocytes may be added here. There are four varieties of granulation stated by Ehrlich¹⁶ to occur in the protoplasm of the leucocytes in human blood.

1. The oxy- or eosinophilic; these take up only the acid stains, such as eosin, acid fuchsin, etc.
2. The basophilic; these take up only the basic stains, such as methylene blue.
3. The neutrophilic; these take up in preference a combination of the acid and basic stains. Hence the name.
4. The amphophilic; these take up either acid or basic stains, but not their combinations.

To the first class belong the eosinophiles, to the second some of the large mononuclear forms, to the third the polynuclear forms, to the fourth the so-called "mastzellen" of Ehrlich. These latter are excessively rare in human blood. The great majority of the mononuclear forms have no granulations; at least none have as yet been demonstrated. Ewing states that in diphtheria the granulations in a certain num-

ber of the polynuclear leucocytes lose their affinity for neutral stains and show a certain affinity for acid stains, such as eosin. These forms he calls pseudo-eosinophiles, and asserts that the change is due to the necrotic action of the circulating toxins; he thinks they are identical with the forms showing poorly stained nuclei, and so estimates their percentage by the salt-solution and gentian-violet method.

Now the statement that the neutrophilic granulations of the leucocytes in normal human blood are absolutely neutrophilic is not correct. They have an affinity for eosin, although it is a weak one, and the eosin is quickly washed away by water; it can be demonstrated by staining with a one-half per cent. solution of eosin in seventy-per-cent. alcohol, washing very rapidly in water, and drying immediately between filter paper. On examination the granules of the polynuclears will be found to be stained red. Again, if a specimen of normal blood after being hardened be stained in the above solution and then be passed directly into a strong aqueous solution of methylene blue, we have all the conditions present which are necessary for a neutral stain. That such staining does take place any one can demonstrate for himself. If, on the other hand, after staining with the eosin we wash the specimen thoroughly and carefully in water before staining with methylene blue, the granules will be completely decolorized and invisible. Now, the above procedures were tried upon specimens of blood from five healthy individuals and upon specimens of blood from six or seven of the severest cases of diphtheria in the Willard Parker Hospital. Both sets of specimens showed the granules in a certain number of the leucocytes to be stained when the washing with water was omitted, and all the granulations were unstained when the specimens were thoroughly washed in water before using the methylene blue. So that the writer was unable to differentiate these pseudo-eosinophilous granules and is inclined to believe them due to the

staining-methods used, rather than that they really exist as pathological entities.

Pane¹⁶ describes certain granules staining with methylene blue which he observed in the blood of animals injected with cultures of anthrax and pneumococcus. He demonstrates to his own satisfaction that these granulations are the remnants of the bacteria which have been taken up by the leucocytes. Three specimens from each of the last seven cases in the foregoing table were stained with methylene blue and carefully gone over with the mechanical stage, in order to see whether any of these granules were present. None were found, and it was not to be expected, even if the theory be correct, as few if any diphtheria bacilli enter the circulation under ordinary circumstances.

The hæmoglobin in these cases apparently suffered less reduction than in the cases without antitoxin. When a fall did take place, however, the return to normal was slow as compared to that of the red corpuscles. Even after the child was apparently well, and up and about, the hæmoglobin was below normal. This may be in part accounted for by the fact that children are confined to the house and do not get out into the open air. This pseudo-anæmia occurs in other diseases, and is often seen in the children in infant asylums. There is less need of hæmoglobin as a respiratory agent, because of the lack of exercise, fresh air, and sunlight. To show that these cases are not in reality anæmic, examinations were made in six cases (XIX. to XXIV., the incomplete cases) at varying periods after the beginning of the illness; eight, nine, fourteen, fourteen, twenty-one, and fifteen days after admission, respectively. In one case (XXIII.) the number of the red corpuscles was below normal. This was a very severe case, with involvement of the eyes, and the patient was still in bed at the time of the blood examination. In four of the six cases, the leucocytes were still slightly above normal. In all but two of the cases the hæmoglobin was below ninety per cent.

Remarks on Table III.—All the above cases, with the exception of I., were seen at the New York Juvenile Asylum. All were males and apparently healthy. The injections were given into the subcutaneous tissue of the abdominal wall. The corpuscles were counted in all the cases within an hour before the administration of the antitoxin. In the first three cases the blood was again counted an hour after the injection, but, as no change was observed, an interval of twenty-four hours was allowed to elapse in all the other cases. A diminution in the number of the red corpuscles was noted in seven of the fifteen cases. (I., II., III., VII., VIII., IX., and XV.). This diminution was most marked between the second and sixth day after injection and ranged between 974,000 and 217,000 per cubic millimetre. The fall of 974,000 was in Case I., the only adult in the series. Case VIII. was the only other one to show any considerable fall (932,000 per cubic millimetre by the fifth day). The diminution in all the other cases was less than 600,000 per cubic millimetre.

The case receiving the largest amount of serum and the greatest number of antitoxin units was the one to show the most marked reduction in the number of the red corpuscles (Case I.). Case II., receiving four cubic centimetres and four hundred units, showed a distinct reduction of half a million. All the other cases received small amounts of serum containing a relatively small amount of antitoxin. Some of these cases showed a reduction in the number of the red corpuscles, some did not. The red corpuscles returned to their normal number in from four to thirteen days. Case I. apparently did not do so for twenty-four days, but an interval of eleven days preceded the last count. The data furnished by the above cases are all too few to enable us to draw any conclusions as to the effect of the amount or strength of the serum upon the corpuscles. Microscopical examination revealed no abnormalities in the red corpuscles.

The leucocytes appeared to be absolutely unaffected by the injections. They rose to a point above normal in only one case (I.). Of the three cases examined directly after the injections, a fall in the number of the leucocytes was noted in only one instance (II.). In determining the presence or absence of a hypoleucocytosis, we are dealing with such small figures and such varying conditions that a large number of mutually agreeing observations are necessary.

In the stained specimens the relative numerical proportions of the various forms of leucocytes were apparently normal in all cases. No variations from the normal in the staining properties of the nuclei or of the granules could be made out.

The hæmoglobin was apparently affected to a less degree than the red corpuscles. It fell below eighty-five per cent. in only one case. But the diminution in the number of the red corpuscles was confirmed by the fall in the hæmoglobin in each case where such diminution took place.

Summary.—1. The red corpuscles of the blood in diphtheria undergo a diminution in number in cases of moderate severity and in severe cases. Regeneration is slow.

2. The leucocytes are increased in number in all but two classes of cases, exceptionally mild cases and exceptionally severe ones. As a rule, the amount of leucocytosis is directly proportionate to the degree of severity of the case. The leucocyte curve shows no correspondence to the clinical course of the disease. The number of leucocytes often remains higher than normal for days after all inflammatory phenomena have disappeared. The leucocytosis is similar in character to that seen in pneumonia and scarlet fever; the increase being in the so-called polynuclear forms.

3. The percentage of hæmoglobin falls coincidentally with the number of the red corpuscles, and to the same relative degree. But the regeneration of the hæmoglobin takes place much more slowly than that of the red corpuscles.

4. In cases treated with antitoxin the diminution in number of the red corpuscles is much less marked than in those cases treated without it; in a majority of the cases no such diminution takes place. The leucocytes are apparently unaffected by the antitoxin. The hæmoglobin is also much less affected in the cases treated with antitoxin, thus confirming the statement as to the red corpuscles.

5. In healthy individuals injected with antitoxin, the red corpuscles show a very moderate reduction in number in about one-half the cases. The hæmoglobin is correspondingly affected. The leucocytes are apparently unaffected by the injections.

6. No peculiar characteristic changes in the morphology of the corpuscles were to be made out.

7. It is improbable that any information of prog-

nostic importance is to be gained by examination of the blood in diphtheria.

8. The antitoxin treatment of diphtheria has no deleterious effects upon the blood corpuscles. On the contrary, it seems to prevent degenerative changes which would otherwise be brought about.

PUERPERAL ECLAMPSIA.¹

By S. SEABURY JONES, M.D.,

NEW YORK.

When Lever² in 1843 pointed out the connection between albuminuria and eclampsia, it was thought that the two conditions occupied the relative positions of cause and effect. After it had been shown experimentally that large quantities of urea could be injected into the veins of animals without producing convulsions,³ Frerichs came forward with his theory of the conversion of urea into ammonium carbonate in the blood and that this latter substance was the cause of the convulsions. Braun⁴ adopted the theory of the nephritic origin of eclampsia, as will be shown by the following quotation from his definition of that disease: "Eclampsia puerperalis is an acute affection of the motor function of the nervous system, characterized by a loss of consciousness and of sensibility, by tonic and clonic spasms, and occurs only as an accessory phenomenon of another disease, generally of Bright's disease*in an acute form." This definition clearly shows that Braun was a strenuous defender of the theory that puerperal eclampsia depended upon impaired kidney function for its cause.

As observations began to be made more carefully, however, cases of eclampsia were recorded which could not be explained by the hypothesis of nephritis. Thus Schauta,⁵ in twenty-eight fatal cases of eclampsia, reported three in which the kidneys were quite normal. Ahlfeld⁶ found in seventeen cases two in which the kidneys were normal.

Vinay⁶ reported that the results of microscopic examinations proved that in a rather large number of cases of eclampsia the disease can hardly be attributed to renal lesion. Kaltenbach⁸ says: "The prodromal gastric and cerebral disorders, the rapid and profound disturbances of the action of the brain, the post-partum elevations of temperature, the character and frequency of disorders of the nervous system which follow and which are similar to the neuroses of typhus and diphtheria, probably caused by a toxalbumin, are best explained by accepting the hypothesis of toxæmia."

Rivière declares eclampsia to be a form of intoxication, and Auvard adopted¹ the same theory. This

theory of auto-intoxication rests upon the hypothesis that there are constantly developed in the normal physiological processes, and especially in woman during pregnancy, substances which must be destroyed or eliminated by various organs, as the liver, skin, lungs, and kidneys, and that the failure to destroy or eliminate causes auto-intoxication. In this process the kidneys naturally play a very important rôle. We might say then, as Auvard suggests, that there are hepatic as well as renal eclampsias.

Stumpf,² quoted by Winckel, advances the theory that acetone or a body resembling it may cause at once the nephritis and the convulsions, thus explaining those cases in which the convulsion has preceded the albuminuria.

Playfair³ does not consider the albuminuric theory as clearly proven, and Parvin states that while in exceptional cases the kidneys may be normal, yet in the great majority they present changes characteristic of all the forms of nephritis, but that the eclamptic manifestations are not in proportion to the gravity of the lesions found post mortem.

Time of Attack.—Eclampsia may attack the patient before, during, or after labor. It may be preceded for many weeks by a severe albuminuria, or it may come without any or with slight warning. About fifty per cent. of attacks come first during labor; next in frequency are the attacks which precede labor, and least frequently come the attacks after labor.

Prodromal Symptoms.—There are three prodromal symptoms which, one or the other, or all together, are characteristic of this disease. They are headache, epigastric distress, and disturbances of vision. The headache may be very severe and is often extremely so, but frequently it amounts to only a feeling of fullness and a moderate pain either frontal or temporal. The epigastric symptom may amount to almost a crisis, so that it sometimes seems as if the stomach were eliminating the poison. Thus, one of my patients who had convulsions after her second confinement suffered only from the former symptom in her first, but to such a degree that for several days no food at all could be administered. The sensation is at times one of most intense burning. The eye symptoms may amount only to a dimness or haziness of vision, or to complete loss of sight, or only to flashes of light.

The loss of sight may be sudden and complete, and transient, or there may be retinal lesions more or less lasting. In those cases where a sudden blindness quickly passes away the cause is thought to have been an œdema, retinal or central.

The attack itself may be described as a short tonic followed by a longer clonic convulsion, which in its turn gives place to unconsciousness more or less profound, amounting in some cases to a decided coma. The first stage lasts from a few seconds to a minute, the second stage lasts a few minutes, while the last stage may be prolonged for hours or may be followed soon by another convulsion. The convulsions are more likely to attack the patient in her first confinement, and twin or triple pregnancies predispose to the disease.

Heredity has been mentioned as an element in the causation of this disease. Thus Parvin quotes Elliott as reporting the case of a mother and four daughters, all of whom had eclampsia. The evidence seems, however, on the whole rather weak and is negated by my own experience, for I have had under observation two sisters, one of whom has had two normal labors, and the other four. Both sisters came into the

world prematurely, while their mother suffered from puerperal convulsions.

It would seem fair to conclude that the occurrence of puerperal convulsions depends upon two elements, viz., the intensity of the toxæmia and the susceptibility of the patient, such susceptibility consisting of the greater or less excitability of the motor centres, and depending upon those blood changes which we know characterize the gravid state. We know too that there is an individual susceptibility characterized by a hyperexcitability of the nerve centres. Then again, the suddenness of the onset of the albuminuria or toxæmia seems to play a rôle in the causation of convulsions. The nervous system has had no time to accommodate itself to the poison circulating through its centres, nor has nature had an opportunity to perform one of those marvels by which compensatory functions and changes come to the aid of damaged organs. In this way one patient may be overwhelmed by the first acute attack, while another, who has had albuminuria before, and who has a chronic nephritis, may escape.

Mortality.—When we come to consider the maternal mortality in this disease, we meet with many and contradictory statements.

It seems pretty certain, however, that it has materially diminished in the course of the last thirty years.

This diminution may no doubt be attributed to the abandonment of the more heroic treatment of former times, to the introduction of antiseptics and cleanliness into midwifery, and to the use of chloroform and kindred agents.

Phillips, in Guy's Hospital Reports for 1871, quoted by Barker, put the death rate at fourteen per cent., and attributed the improvement to the use of chloroform and the abandonment of blood-letting.

Dorn¹ reported 747 cases collected, with a mortality of 29 per cent.

Hofmeier¹ reported from Schroeder's clinic 104 cases, with a mortality of 32 per cent.

Braun¹ reported 73 cases occurring from 1869 to 1878, with a mortality of 26 per cent.

Coming down to more recent times, Zweifel² reports 126 cases, observed in the maternity of Leipsic. Of these 43 were brought into the hospital unconscious; of the others there were: primiparæ, 66, with a mortality of 17 per cent; multiparæ, 17, with a mortality of 6 per cent; but of the latter there were 13 in whom the convulsions occurred before or after, not during, labor, all of whom recovered, while of the 4 in whom convulsions occurred during labor, 1 died.

In the primiparæ, the greatest death rate occurred in those who had convulsions before labor.

Zweifel divides these cases into two classes, those occurring from April, 1887, to January, 1892, which were treated expectantly, and those occurring after January, 1892, which were treated more energetically, as by Dührssen's incisions, forcible dilatation, and accouchement forcé. The expectant treatment consisted in the use of eliminatives, but did not include the protracted use of chloroform nor the use of morphine or pilocarpine, the two former being considered as tending to promote fatty degeneration of the heart and the latter to induce pulmonary œdema. Under the expectant plan 49 cases were treated, with a mortality of nearly 33 per cent; while under the other plan 80 cases were treated, with a mortality of only 15 per cent.

Zweifel does not consider Dührssen's method as free from danger and quotes one fatal case of hemorrhage, while in several sutures were necessary to check the flow of blood.

He also warns against the use of iodoform gauze

for intrauterine tampons as being dangerous, in view of the impaired kidney function. He attributes part of the good results achieved by Dührssen's method to the loss of blood and states that he regrets the disuse of blood-letting in eclampsia, as he has seen much benefit from it, and looks forward to its revival. In this statement he decidedly disagrees with Winckel,¹ who states that he has never seen any good derived from it and that he has abandoned it. Perhaps the most important question we have to decide in the treatment of puerperal convulsions, actual or threatening, is the one of active interference. Braun says: "Promote labor only when the life of the mother is in imminent danger." Leishmann says: "If the os is dilated or dilatable rupture the membranes and wait." Forcible dilatation and accouchement forcé are procedures which can scarcely be admitted as warrantable under any circumstances.

Kaltenbach¹ regards the Cæsarean section as preferable to accouchement forcé after Dührssen's incisions.

We must not forget, he says, that the convulsions may cease and pregnancy go on to term. Leishmann does not mention the induction of premature labor at a favorable time in the interest of the mother and child, when convulsions are threatening.

Playfair quotes Gooch as saying, "attend to the convulsions and let labor alone."

Schroeder says: "Especially no kind of obstetric manipulation is required for the safety of the mother," but admits that it may be advisable to hasten labor to save the child.

Forcible dilatation and turning are, says Playfair, strongly contraindicated. He does not mention the induction of premature labor as a prophylactic measure. Ahlfeld² and Charpentier state that accouchement forcé should be reserved for exceptional cases in which medical treatment has failed. In support of this statement they quote the following statistics: After spontaneous labor in eclampsia the mortality is 18.96 per cent.; after induced labor 30.74 per cent; after accouchement forcé 40.74 per cent. Dührssen's claim that convulsions cease in 90 per cent. of cases after the uterus has been emptied by his method is not confirmed by Zweifel, who found that they persisted in 48 per cent.

Barker states that induction of labor is justifiable when the life of the mother seems imperilled, and that it may be necessary also in the interest of the child. He says that he has never regretted advising it and feels that valuable lives have thus been saved.

Lusk is an advocate of active interference in threatened or active convulsions. He especially recommends the induction of premature labor at a time favorable to mother and child, when the condition of the patient demands it. In the actual presence of convulsions he does not so strongly advocate the acceleration of labor, but admits that the weight of authority is against him and says that non-interference has been uniformly disastrous in his experience, while some have been saved by active interference. Lusk quotes Flaeschler's statistics based upon the observation of one thousand pregnant women as showing that only about one in eight of pregnant women having albuminuria will have convulsions.

Blood-Letting.—Blood-letting has very few advocates to-day, save as a measure to be appealed to in exceptional cases, to relieve œdema pulmonum or to avert a threatened apoplexy. We have already alluded to Zweifel's approval of it and his regret at its disuse, and to Winckel's abandonment of it as useless.

Playfair,³ Ahlfeld,³ and Kaltenbach³ make about the

³ Parvin.

same statements regarding it, namely, that it may be beneficial in exceptional cases. In fact there is only now and then an indorsement of this procedure based upon a limited experience. It is quite possible that the advocates of blood-letting do so in ignorance of the fact that the great majority of women who suffer from puerperal eclampsia should get well under rational and conservative treatment.

I cannot but believe that many who appeal to radical measures in this disease before having exhausted less heroic ones, do so with an exaggerated idea of its actual normal mortality, if I may use the term.

Treatment by Drugs.—Chloral and chloroform are admitted by all to be of great benefit in the treatment of eclampsia, but the danger of using chloroform in any but a careful manner has been pointed out by Kaltenbach,¹ Ahlfeld,¹ Dührssen¹ and Runge, as tending to promote a rapid fatty degeneration of the heart.

Pilocarpine has been abandoned, I believe, by all as tending to produce edema of the lungs and other internal effusions. Clarke, of Oswego, and G. Veit, of Bonn, advocated large doses of morphine administered hypodermically, as much as a grain being recommended to be used for one injection, to be repeated as required. This recommendation is in a line with that by Loomis in 1873,² that uræmic convulsions should be treated by morphine hypodermically administered. Used in more moderate doses than those recommended by Clarke and Veit, and especially combined with veratrum viride, it has many advocates.

The Treatment by Veratrum Viride.—We come now to the consideration of the treatment of eclampsia by veratrum viride. In the July number of the *Southern Medical and Surgical Journal* for 1859 Dr. Baker, of Eufaula, Ala., strongly advocated the use of this drug in puerperal convulsions and reports one case of his own and several from the practice of colleagues, in which it had been used with prompt success.

Norwood's tincture was used and given in doses of fifteen drops, followed by doses of ten drops every two hours as long as required, the aim being to reduce the pulse in frequency to fifty or sixty a minute and to diminish arterial pressure. Dr. Baker especially notes the tolerance to large doses exhibited by patients suffering from eclampsia and the consequent absence of dangerous symptoms unless the very large doses originally recommended by Norwood have been used; still he recommends that the initial dose of ten to fifteen drops should be followed by frequent doses of five drops, as being equally efficacious and less liable to produce disagreeable symptoms. He speaks of being frightened at first by the depression which sometimes follows very large doses, but declares that the patients always recover. Since Dr. Baker's paper many observers have lent the weight of their approval to this treatment. In the Transactions of the American Gynecological Society for 1887, Jewett says, "Experience seems to justify the statement that no convulsions will occur while the patient is sufficiently under the influence of veratrum to hold the pulse below sixty. Dr. T. G. Davis,³ of Bridgeton, N. J., has reported six cases successfully treated by the use hypodermically of six minims of Norwood's tincture and one-third grain of morphine combined, the injection to be repeated as required, the aim being of course to reduce the pulse in frequency and tension. There seems little doubt that in this way all may be attained that is achieved by blood-letting, without the disadvantages of the latter method.

Dr. Reamey, of Cincinnati, reported to the American Gynecological Society at Baltimore in May, 1895,

six cases of puerperal eclampsia treated successfully with veratrum viride, with or without morphine. Dr. Reamey had given as much as twenty-five minims hypodermically and believed that morphine controlled its unpleasant effects. Love, of Orange, N. J., has also strongly advocated the use of veratrum viride in this disease in large doses, and claims never to have been obliged to have recourse to radical measures for the induction or acceleration of labor in eclampsia and to have carried his cases safely through. He has employed large doses, even a teaspoonful frequently repeated. These large doses when given per os, generally produce vomiting, and probably are not entirely absorbed, while, when doses of more than fifteen minims have been used hypodermically, especially without the controlling influence of morphine, distressing symptoms have sometimes been met with. These symptoms have, however, seldom if ever led to disastrous results. It would seem, therefore, generally best to combine a moderate amount of morphine with the veratrum and to use the latter drug hypodermically in small doses of five minims, as being more certain in effect and permitting quicker repetition.

When given in this way one need not hesitate to repeat the injection in half an hour, while if given by the mouth it would not be safe to repeat the dose until a much longer time had elapsed.

At a meeting of the Society of the Alumni of Bellevue Hospital held on October 2, 1895, Dr. C. C. Barrows¹ gave the histories of two cases of puerperal eclampsia treated by rapid delivery followed by the hypodermic use of veratrum viride in doses of five minims. He attributed excellent results to the use of the drug and this opinion was indorsed by Dr. Edgar and others in the discussion which followed the reading of the paper.

Cases.—As illustrative of what I have written, but not at all conclusive with reference to methods of treatment, I will briefly allude to two cases which have occurred in my practice within a short time.

CASE I.—Mrs. A.—, primipara, twenty-four years old, first consulted me in June of last year, with reference to her confinement which was due about September 15th. The patient gave a history of diphtheritic nephritis in childhood, with a second attack in her sixteenth year. The urine was found to be free from albumin and remained so until July 28th, when a considerable quantity showed itself. The amount of albumin increased so that in a few days it amounted to one-half in volume. The quantity of urine voided in twenty-four hours varied between twenty and forty ounces. There was general anasarca and almost constant headache, and ocular symptoms were complained of. The patient was apprehensive, as she had lost two friends from eclampsia and dreaded its advent in her own case.

The usual diet and tonics had been prescribed, and small doses of veratrum viride given. On August 15th, about three or four weeks before the end of normal pregnancy, premature labor was induced and on August 16th within twenty-four hours the mother gave birth to a well-developed child weighing eight pounds. The puerperium was uneventful and the mother nursed her child.

CASE II.—Mrs. K.— first came under my observation about the end of November, 1895, and expected to be confined about January 6, 1896. This was her second pregnancy, her first confinement having been two years before. Albuminuria had shown itself only a few days before her first confinement, which had been a little premature. The child had presented by the breech and was still-born after a protracted labor. For several weeks afterward the patient had suffered from the most intense nausea and a burning sensation in

¹ Loomis: New York Medical Journal, August, 1873.

² New York Medical Journal.

³ Philadelphia Medical News, 1893.

¹ New York Medical Journal, November 23, 1895.

the epigastrium, which her attendant had attributed to uræmia. During her second pregnancy the urine remained free from albumin until December 8th, when it appeared coincidentally with uterine pains and threatened premature confinement.

The pains subsided but the albumin persisted, though in moderate amount. There were absolutely no other uræmic symptoms, but on December 14th, one week after the first appearance of albumin and about three weeks before full term, the patient was rather precipitately delivered of a healthy living child. The placenta came away spontaneously and there was no untoward symptom until 6 A.M. on the 15th of December, twelve hours after delivery, when the patient was seized with a convulsion which was soon followed by another. One-quarter of a grain of morphine was at once injected by the nurse. When I saw the patient at 9 A.M., three hours after the first convulsion, they had not returned, but she was delirious and could be restrained only with difficulty. The pulse was tense and over 100 beats per minute. I immediately injected fifteen minims of Norwood's tincture hypodermically.

In half an hour the pulse had fallen to 60 and was soft, and the skin had become moist.

Consciousness returned in a few hours and the patient made a good recovery. Smaller doses (five minims) of veratrum were given at intervals as demanded by the patient's condition, and other measures, such as the use of chloral by rectum and large saline enemas, were employed with great benefit. The albumin disappeared eight days after confinement.

The Induction of Premature Labor.—It seems advisable to say a few words as to the method of inducing premature labor. Many methods have been recommended, such as the prolonged douche, the use of electricity, forcible and quick or slow and gradual dilatation of the cervix, the tamponade of the vagina, and, last, the introduction of some substance or instrument into the uterus with a view to promote its contraction. Among the latter one of the most recent methods was that of Pelzer who advised the injection of glycerin. This method and its modification, by means of which the glycerin is injected into a condom attached to a catheter, after the latter has been introduced into the uterus, may be useful in certain exceptional cases but have many disadvantages, and the injection of glycerin is certainly not without danger. It seems to me that except in case of urgency, which does not exist when labor is induced as a prophylactic measure, all other methods must yield to the introduction under the most careful antiseptic precautions of bougies or catheters into the uterus, combined with tamponade of the vagina. The patient and the vagina having been thoroughly cleansed, the cervix should be exposed by speculum and one or more bougies of about 22 F. in size, which have of course been carefully sterilized, introduced along the anterior uterine wall for about eight inches.

It is well to introduce more than one bougie, in order to ensure more prompt uterine contraction. A small strip of iodoform or other gauze may be now passed up just through the internal os and packed around the bougies, while a larger piece of gauze is used to tampon the vagina snugly but not uncomfortably. When the cervix has been found to be well dilated, after about twelve hours, the bougies and tampons may be removed or they may be left until expelled by the labor pains. If further stimulus to contraction seems desirable the vagina may be again tamponed.

Résumé.—From the foregoing it would seem that one is justified after weighing all the best available opinions in concluding

That puerperal eclampsia is due mainly to the non-

elimination from the system of the pregnant woman of toxins which are the direct and natural product of the physiological processes incident to her condition, or to the conversion into toxins of such products and their non-elimination, and that the nervous tension of the pregnant woman predisposes to the disease.

That while albuminuria during pregnancy should lead to grave apprehension, yet many women who present this symptom escape convulsions (about seven out of eight), while convulsions may be met with in women whose urine has remained free from albumin until the onset of the convulsions.

That he who saves four out of five women who have been attacked by eclampsia before or during labor may consider that he has been fairly successful.

That we have medicines powerful for good, and that they should be given a fair trial before resorting to accouchement forcé in actual convulsions.

That at a period when the fœtus is viable, especially at the end of the eighth month, if the patient suffers from severe premonitory symptoms, such as anasarca, severe and persistent headache, and the eye symptoms, and particularly if the evidences of nephritis have persisted for some time in spite of treatment, premature labor should be induced in the interest of the mother and child.

That in the actual presence of convulsions we should endeavor to overcome them by the use of proper medicines and remedial measures, notably by the use of veratrum viride, morphine, chloral, and chloroform, rather than appeal to the rapid emptying of the uterus.

That in veratrum viride we have a remedy powerful for good when properly used, but that of Norwood's tincture it is better not to inject more than five to ten minims for the initial dose, to be followed by doses of five minims at intervals as required to hold the pulse, and that it is well to combine it with morphine.

ACUTE AND CHRONIC CORYZA AND ITS SIGNIFICANCE IN CHILDREN.

By E. G. WOODRUFF, M.D.,

AUBURN, N. Y.

OF the many diseases and affections in children and infants, what is more common than coryza, acute and chronic? The question of what serious consequences may follow such a condition in children if left to itself, is one to which of late a great deal of attention has been given. It would seem that the best answer is to be found in a monograph recently published by Dr. Emanuel Finck, of Hamburg.¹

In the following lines it has been the endeavor to set forth the most salient points of the above-mentioned publication.

It is a well-known fact that the nose as a respiratory organ modifies the air passing through it in three ways: (a) It warms it; (b) it moistens it; (c) it filters from it dust and most of the other impurities.

Mackenzie demonstrates that air passing through the nose is warmed one degree more than air passing through the mouth.

Block has found that the inspired air on its way through the nose gains five-ninths of the difference between its temperature and that of the body; hence, that the lower the temperature of the inspired air prior to its entrance into the nose, the warmer it becomes by its passage through it.

For instance, if the air inspired has a temperature of -8°C. , by the normal breathing it will be increased to 25°C. , since the difference between its temperature and the body heat amounts to 45°C. In the nose the

¹ "Die Bedeutung des Schnupfens der Kinder," von Emanuel Finck. Halle-a-S.: Karl Marhold.

inspired air is moistened, owing to the presence of mucus on the surface of the normal respiratory tract. This thin layer of mucus suffices to retain at least the larger per cent. of dust and micro-organisms entering the nose during inspiration.

According to Jonathan Wright, eighty per cent. of the bacteria present in the air are arrested in the nose and, as Hajek has shown, a large number of them may be destroyed, as the normal nasal secretion possesses certain germicidal properties. It was found that the spores of anthrax are killed by it in three hours, and that nearly all germs that produce affections of the respiratory organs are destroyed in the same manner. It is readily understood, therefore, that any cause which alters the character of the normal nasal secretion facilitates the entrance into the body of the germs of infectious diseases—an important point, considering the fact of the greater susceptibility of children compared to that of adults to diseases of this kind. As is known, a child can acquire an acute coryza even so early as its birth, if the mother be suffering from a purulent vaginal discharge; also if in bathing the child unclean sponges are brought into contact with its face.

The inflammation of the nasal mucous membrane results in a partial or complete obstruction of the nasal passages, so that the child is compelled to resort to mouth breathing; and breathing of this character for children is surrounded with many dangers.

In the first place it interferes with the child's nutrition. If the baby is nursing at the breast it must continually release the nipple in order to breathe through the mouth; in consequence of this it grows impatient, and finally can no more be induced to take the breast and rapidly shows signs of emaciation. Further, this mouth breathing seriously disturbs the sleep.

Babies under normal conditions sleep with closed mouth; also when awake in the first months of life they are not able to breathe through the mouth. They learn this kind of respiration only gradually; consequently, when nasal breathing is made impossible through the coryza, the child cannot enjoy a sound and refreshing sleep. Dyspnoea sets in and the child awakes with a loud cry. This disturbance of sleep is an essential cause of the great debility observed in babies with acute coryza. Chronic coryza in children is followed by consequences not less serious than those of the acute form. These consequences consist chiefly, first, in a hypersecretion with a changed quality of the secretion; second, in hypertrophy or atrophy of the mucous membrane. The hypertrophy of the nasal mucous membrane is a hindrance to nasal breathing. This form of respiration only is adapted to the requirements of the organism and to its protection against injurious germs contained in the air inspired. If the lumen of the nasal cavities remain stenotic a long time, owing to a hypertrophic rhinitis, the result must be a rarefaction of air behind the stenosis proportionate to the latter and to the force of inspiration and aspiration of blood to the mucous membrane lining the pharyngeal space. This hyperæmia is not alone confined to the mucous membrane coating the pharyngeal space, but extends through the entire respiratory tract, even as far as the alveoli. Experience teaches that almost all children suffering from chronic coryza are affected with bronchitis, which is but the natural consequence not only of the narrowing of the nasal fossæ, but also of the changed character of the nasal secretion, which now allows the air to enter the respiratory tract in an unchanged condition. Under such circumstances it is obvious that a sufficient oxidation of the blood cannot take place. This lack of oxygen is indicated in children which have a marked stenosis of the nose even in their appearance—a pale, livid face and

bluish-tinged mucous membranes. If the child at the same time be of a neuropathic disposition attacks of pavor nocturnus may occur. The popular explanation assigning bad dreams as the cause does not seem satisfactory from a scientific point of view; for whence come these disturbing dreams? In sleep the child breathes only superficially and if the nose is in any way obstructed, after a few hours a light carbonic-acid poisoning must set in, followed by a sensation of oppression and heavy dreams. In a similar way can we explain the occurrence of enuresis nocturna, found so frequently in children affected with chronic coryza. A much more serious result of a long-existing nasal stenosis is deficient development of the thorax. Owing to the superficial breathing, the lung does not attain that degree of expansion on which depend, on the one hand, sufficient oxidation of the blood, and, on the other hand, a sound and normal development of the thorax. In most children of this kind we find that the thorax is flattened, but in many of them, especially in those of rachitic tendency, the deformities of the thorax are much more marked. The lower part is retracted on account of the increase of the endothoracic pressure, and remains so permanently; whereas the upper part is dilated, owing to the forced respiration.

It is easy to understand that under these circumstances the vertebral column is likely to be involved. Cases have been reported in which one nasal passage was obstructed, the consequence being a scoliotic deformity of the vertebral column. The correctness of this statement has been proved in two ways. Ziem obliterated by means of suturing one of the nasal orifices in kittens, and observed as a result a scoliosis. Further, the treatment of nasal obstruction improves very rapidly certain forms of kyphosis, scoliosis, and deformities of the thorax. If the nasal passages of a child are obstructed at the time when it learns to speak, this obstruction will form a great impediment, for the air which normally escapes through the nose during the act of speaking is here forced back against the larynx, and this throws increased work on the latter. Consequently we have a relaxation of the laryngeal muscles and an early fatigue of the voice. A symptom almost constantly present in children suffering from chronic coryza is impairment of hearing more or less pronounced. A hyperæmia and in most cases a hyperplasia of the naso-pharyngeal space necessarily obstructs the ostium pharyngeum tubæ, and interferes with the supply of air to the tympanic cavity. In children this occurs much more frequently than in adults, since the peculiar form of the pharyngeal opening of the tube favors such a condition.

In not a few eye affections of children can the causes be traced back to a chronic coryza. Ziem even asserts that two-thirds of all eye diseases are due to nasal affections. He has shown that purulent catarrhal inflammation of the lachrymal canals is produced by the entrance of pus during the act of blowing the nose. Von Hasner found that among fifty-nine cases of diseases of the lachrymal duct fifty-one showed a pathological condition of the nasal cavities. J. Michel and Seifert observed among thirty-eight cases of dacryoblenorrhœa thirty-seven with affections of the nose. Farravelli and Krüch found among cases of diseases of the lachrymal sac thirty showing nasal catarrh. It is an indisputable fact that the impeded nasal breathing gives rise to a disturbance of brain functions. Children which show evidence of chronic coryza are prone to forgetfulness and headache and make slow progress in school, although their mental abilities may be normal. In every chronic coryza, no matter whether it be of atrophic or hypertrophic form, the character of the secretion is changed, both in quality and quantity, and, as already mentioned, loses

its germicidal properties. This may account for the fact observed by many practitioners that tonsillitis and diphtheria occur relatively often in such children. One of the constant symptoms of scrofula, the swelling of the cervical and submaxillary glands, occurs by the invasion of micro-organisms into those peripheral endings of the lymph tracts which have a direct or indirect communication with the above-mentioned glands. Since these endings are situated in the nose and mouth, the fact is obvious that chronic coryza must play a not inconspicuous rôle in the etiology of scrofula. If the significance of the foregoing facts be fully appreciated, we will no longer treat these symptoms alone with iron, cod-liver oil, etc.; but above all endeavor to re-establish the normal condition of the mucous membrane of the nasal passages, the result of which will be a disappearance of all scrofulous symptoms.

Finck made an exhaustive investigation regarding the relations of chronic coryza to retro-pharyngeal abscesses in children, with the result that in all cases, except those dependent upon caries of the vertebra, chronic coryza was present. In conclusion, it may be said that Strümpell, Weichselbaum, and others have made the observation that there exists a connection between an abnormal condition of the nasal mucous membrane and cerebro-spinal meningitis.

VIENNA, March, 1896.

Progress of Medical Science.

Syphilitic Spinal Disease.—Dr. Sottas has published an elaborate study of syphilis as it affects the spinal cord. From the *International Medical Magazine* we learn that the author has formulated the following conclusions as resulting from his observations on this important subject: 1. Syphilis can act on the nervous system in two ways: First, directly; in attacking the parenchyma, it determines thus at the onset of the affection the first vague nervous troubles of the secondary period, and later, perhaps, certain systemic affections, as tabes. This mode of action is not clearly explained, for there are no anatomical characteristics which permit us to recognize the origin of the affections which are attributed to it. Second, indirectly, in producing an inflammation of the vascular, lymphatic, and connective-tissue elements. The alteration of the parenchyma is secondary to these lesions. The reality of this process cannot be disputed; it is affirmed by the aspect of the inflammatory lesions, which, although not special to syphilis, are nevertheless to a certain point characteristic of this affection. The process can strike all parts of the cerebro-spinal system, but is limited sometimes exclusively to the cord. 2. Syphilis of the cord appears at a period near that of infection, with a maximum between the end of the first year and the end of the sixth, and is much more frequent in men. 3. The inflammation begins with the vascular walls and perivascular regions and involves especially the small vessels of the periphery of the cord. In the large vessels it involves the internal and especially the external tunic, developing about the vasa vasorum. From this point it involves the perivascular lymph space, afterward the lymphatic system of the meninges, and finally the entire arachnoid cavity. The infection spreads by the circulatory system and rapidly in the lymphatic system, where it assumes an independent form. At this period the lesions are constituted by: An inflammation of the vascular walls, which attains its maximum in the veins and small vessels; a diffuse general infiltration of the connective tissue of the meninges; an irritation of all

the surfaces bathed by the cerebro-spinal fluid (surfaces of the meninges, ventricular walls). These inflammatory lesions are characterized by a tendency to nodular formations (miliary gummata of the meninges, of the vessels, of the cord). 4. The alterations of the nervous parenchyma, of the essential elements, and of the neuroglia are secondary; they may result from imperfect nutrition on account of the vascular lesions of the cord and of the nourishing membrane, or from an invasion of the medullary parenchyma by the specific infiltration. The first is the more important cause. 5. According to the intensity, the distribution, and the rapidity of evolution of the primary lesions, the anæmic necrosis of the nervous tissue appears abruptly as a transverse softening, which may be located at different points of the cord or predominate in one or the other vascular department; or else it appears slowly, and then the destruction is accompanied by a process of substitutive reaction of the neuroglia, which replaces the destroyed elements. This period of substitution is favored by the partial return of the circulation (collateral circulation, development of the vasa vasorum, formation of new capillaries in the obliterated vessels), and terminates in the neuroglia sclerosis. The connective tissue which enters the cord with the vessels is also thickened. 6. Although the necrobiotic lesions followed by sclerosis constitute the principal alteration, there are certain medullary and especially radicular changes, which result from the invasion of the nervous tissue by an infiltration extending from a point in the meninges or from a perivascular sheath. This process can in certain cases assume a considerable importance. 7. While the lesions preserve the same characters, they may vary in their distribution. They are generally diffuse, but they sometimes assume the aspect of a transverse lesion, more or less intense, more or less limited, and located at different heights of the cord. They can be distributed more irregularly in a considerable extent of the cord. In every case they are more marked in the marginal zone. The dorsal location is the most frequent. Be the lesions confluent or be they disseminated, the result is always the same, and they produce the effect of a transverse lesion, accompanied by a secondary degeneration ascending and descending. The lesions involve especially the territory of the postero-lateral spinal vascular system. They may predominate in certain regions of the cord—the lateral columns, the posterior columns, the gray substance of the anterior horns—and thus simulate certain systemic affections. 8. The ordinary clinical evolution is the following: At the period of formation of the primary vascular lesions and of those of the meninges, there are diffuse premonitory phenomena. At the period of softening and of degeneration of the nervous elements there is an attack of paraplegia, followed by paralytic phenomena and grave trophic troubles. At the period of sclerosis there is the chronic spastic paraplegia. The abrupt onset can be manifested without being preceded by a prodromic phase, or in other cases the spastic paraplegia comes slowly without passing through the acute stage. 9. Death may occur either in the first period of the affection from the localization or extent of the lesions, or more slowly from the progress of the affection or from a complication. The ordinary termination of the affection is a spastic paraplegia persisting in a chronic state after an amelioration more or less marked. The complete recovery is possible only in certain conditions, when the primary vascular and meningitic lesions have been arrested before the final destruction of the nervous parenchyma. The reorganization of the necrosed nervous tissue, if it is possible, is manifested only in a limited degree. 10. In certain conditions the primary inflammation is accentuated in the meninges, producing a meningitis or a pachymeningitis, or else it as-

sumes the form of a circumscribed gummatous neoplasm. 11. The iodo-mercurial treatment is demanded at the appearance of the first symptoms. It acts only on the primary inflammatory productions and is without influence on the necrobiotic lesions once established. 12. The medullary syphilis is always a serious affection. Death may intervene in spite of treatment, especially in the acute forms. Outside of certain rare fortunate cases in which complete recovery is obtained, the amelioration never goes beyond a certain limit, which is fixed, on account of an incurable sclerotic cicatrix of the cord.

Prolapse of the Umbilical Cord.—Dr. Brothers proposes the Trendelenburg posture for this complication (*American Journal of Obstetrics*). This can be improvised by placing an ordinary chair upside down at the foot of the bed, the back of the chair making an incline for the legs and hips to rest upon. Dr. Brothers has used this method successfully three times. Version can be performed much easier with the patient in this position.

The Maternal and the Fœtal Blood at Birth.—Drs. Elder and Hutchison have reported before the Edinburgh Obstetrical Society the result of a series of observations on the blood of mothers and healthy children immediately after birth. They obtained the blood from the umbilical cord when it was cut and from the lobe of the mother's ear during the latter part of the first or during the second stage of labor. They arrived at the following conclusions (*Edinburgh Medical Journal*): (1) The blood of the newly born child is relatively richer in red corpuscles than that of the adult by 350,000 to 500,000 per cubic millimetre. (2) For a short time after birth—up to about two days—the red corpuscles seem to increase in number. This is probably due to the fact that the total volume of blood is less, for the reason that the fluid lost from the body during this time is in excess of that absorbed. Thus, concentration of the blood is produced. After the second day or so the red corpuscles gradually decrease. (3) The number of red corpuscles varies much more than in adults, probably because of greater variations in the total volume of the blood. (4) At birth there is always present a considerable number of nucleated red corpuscles. They vary, however, in number in different cases. (5) About the sixth month of intrauterine life the number of nucleated red cells is very much greater than at birth. They probably rapidly decrease in number during the later months of pregnancy, and altogether disappear from the blood in a few days after birth. (6) The blood of the newly born child is relatively much richer in hæmoglobin than the blood of the adult. (7) The individual red corpuscles are richer in hæmoglobin than those of the adult. (8) The blood of the mother at parturition is anæmic. (9) In any individual case the blood of the mother is considerably poorer in red corpuscles per cubic millimetre than that of her child, and it is still more deficient in hæmoglobin. (10) Both the blood of the mother and that of the child contain a larger number of white corpuscles than normal adult blood. The blood of the mother may be quite as rich in white corpuscles as that of the child. (11) The blood of the child contains a distinctly larger proportion of lymphocytes and a distinctly larger proportion of neutrophile leucocytes than the blood of the adult; the number of eosinophile cells seems to be slightly deficient. (12) At the sixth month this excess of lymphocytes is probably even more marked than at birth; they probably decrease during the later months of pregnancy. (13) After parturition the number of white corpuscles in the blood of the mother (at least of those who suckle their children) decreases markedly in a few days. The great difference between the constitution of the blood

of the mother and that of her child would altogether dispose of the idea of any mixing of their bloods, even if histological investigation had not already proved that this did not occur. There can be no doubt that the excess of hæmoglobin and consequent preponderance in oxygen-carrying power on the part of the blood of the child must be one of the most important means by which its metabolism is carried on as it is, and yet, although this excess of hæmoglobin has been long known, its importance is not usually drawn attention to in this connection. When it is remembered that the child's blood can be oxidized only indirectly through the blood of the mother and is consequently in a possibly comparative state of cyanosis, it can be seen that a great quantity of red corpuscles is valuable for the child to compensate for this. This great excess in red corpuscles and hæmoglobin is also found in children with congenital malformations of the heart and cyanosis. The excess of hæmoglobin and of red corpuscles in the blood of the child in utero also shows that the life of the child is to a certain extent parasitic, *i.e.*, that it has a certain amount of independence. In cases of anæmia the blood of the child does not seem necessarily to suffer *pari passu* with that of the mother, but on the contrary the child seems to get more than its share.

Rectal Examination of Pregnant Women.—Dr. Beckman has tried this method with great success in one hundred parturient women, the details of pelvis and cervix being easily made out (*The Medical and Surgical Reporter*). The duration of the pregnancy and the state of the bladder could be determined in seven per cent. of the cases, and the fontanels and sutures could not be felt in twenty-eight per cent., but this was less important, since the position of the fœtus could easily be detected by external examination and especially by auscultation. It was always possible to distinguish the occipital from the frontal portion of the head. The advantage of rectal examination is that infection through the genitals is avoided, the only objection being that sometimes examination through the vagina may become necessary, and that infection may occur through the examining finger, though the latter is easily disinfected, since the rectum does not contain specific microbes. The author considers rectal examination of great value to midwives, enabling them to determine if the presence of an obstetrician will be necessary. Zweifel's experience in the Leipsic obstetrical clinic showed that students instructed in this method of examination could determine all the necessary details without recourse to vaginal examination. Ries believes that midwives should be forbidden to make examinations through the vagina, as their duty is only to assist at normal births. Kroenig is inclined to permit vaginal examinations only (1) when it is difficult to determine through the rectum what part of the fetus is presenting; (2) when the midwife is not able to bring about relaxation of the cervix; and (3) when the pains last more than two hours.

Menstruation.—Prof. A. F. A. King, of Washington, D. C., published a paper in the *American Journal of Obstetrics*, in which he attempted to prove that menstruation had not existed in the original woman, but had gradually developed as a result of deterioration in the race produced by physical and mental indulgence. The age of puberty varies in different countries, ranging from the tenth to the twelfth year in warm countries to fifteen and eighteen in northern regions. Raciborski demonstrated many years ago that the average duration of menstrual life is thirty-three years, and therefore a woman should cease menstruating from the forty-fifth to the forty-eighth year. It is never necessary to make a vaginal examination for painful menstruation on a girl at the ordinary age of puberty.—PAUL F. MUNDÉ (*Med. Brief*, April, 1896).

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, April 25, 1896.

SHALL NEW YORK HAVE A GREAT MEDICAL LIBRARY?

NEW YORK has now reached that stage of development as one of the imperial cities of the world when it is imperative that every thoughtful citizen should consider well the nature, present condition, and future prospects of those elements in its organization on which its true glory and greatness will depend in the coming century. Thus far our institutions, whether religious, charitable, political, or educational, have too often had a spontaneous origin and an unsymmetrical growth. The foundations on which they were constructed have proved inadequate and hence unstable, and in their development they have failed to meet the necessities of the next generation. But the time has come when it is evident that, if New York is to secure a commanding position among the capitals of the world as a great centre of moral, social, scientific, and intellectual influence, it must not only create new organizations adapted to meet the ever-increasing demands of a higher civilization, but it must also strengthen the foundations and enlarge the capacity of many existing institutions.

These facts apply with full force to the medical institutions of this city. Without any special effort, but in the natural course of events, New York is rapidly becoming the centre of medical learning on this continent. Its general and special hospitals, its schools for undergraduates and graduates, its laboratories and libraries embody those conditions and advantages which are essential to meet all the requirements of scholars devoted to the cultivation of every department of the medical sciences. And the question which now confronts our profession is: How shall these conditions be made most available for the demand which will be made upon them in the near future? There is but one feature of this subject which we shall discuss at this time, and we select that because it is most urgent.

The New York Academy of Medicine has made an appeal to the public for an endowment fund of \$100,000 for its library. The claims of the Academy upon the public for aid in its efforts to make the library worthy of the city are very modestly set forth. It is asserted "that the Academy has earnestly, persistently, and successfully exerted itself to promote the public health: 1, by affording information and aid on important sanitary subjects connected with the public streets

and water supply of the city; and 2, by combating the malign influences of infectious diseases in the city and country at large through co-operation with the health department of the city and the medical bodies in other States of the Union. In the recent cholera invasion a committee of the Academy labored long and untiringly, both in the city and at quarantine, under adverse circumstances and at a great personal loss, to prevent the entry into the city and country of this terrible destroyer of human life and prosperity. The medical profession is engaged in ceaseless and gratuitous labor in behalf of the stricken poor, and has never been niggard in its financial or physical contributions to their benefit."

We do not hesitate to add, in much more emphatic language, that New York owes to the Academy, as the chief incorporation of the medical profession, a debt which money can never discharge. To that profession she is indebted for the only condition on which her present and future greatness must depend, viz., a healthy residence for an enormous population. To-day the citizens of New York enjoy greater protection from contagious and infectious diseases, from foreign pestilences, and from local sources of sickness, than any metropolis of equal size in the world. And this immunity is daily increasing through the labors of the health department, the most perfectly organized branch of the city government. This department was created and has been administered by representatives of the Academy of Medicine.

And what does the Academy now ask of the citizens of New York? Not pecuniary rewards for its past services, but larger means of usefulness. It asks only that it may be assisted in its efforts to make New York a great centre of medical learning. Already its medical schools are filled to overflowing, and the time is not distant when, if all its vast opportunities for medical instruction are properly utilized, it will attract not only thousands of students from all parts of the country but medical writers and authors. But one of the important elements in the foundation of a great and attractive centre of medical education is a public library in which the student and ripe scholar alike find ready at hand every kind of information they may seek. To create such a library has been the aim and effort of the Academy for nearly half a century. And these efforts have been crowned with a remarkable degree of success, considering the limited means at its command. The library contains at present forty-five thousand volumes, and during the past year was consulted by upward of ten thousand readers.

But, well equipped as the library is, it comes far short of the demands which are made upon its collection by medical scholars. It must be remembered that in no department of human knowledge is scientific investigation making such rapid advances as in medicine. The collected literature of antiseptic surgery, of bacteriology, of medical electricity, and of hypnotism, for the last decade, would make a large and costly library. Worthless as much of this literature may be intrinsically, yet no reference library can afford to be without a single publication on these as on all medical subjects. It should be impossible for any person to seek

in vain for an original article on any medical or allied subject in the Academy's library. But to meet the demands of such a library for constant accessions to its collection, both of current serial literature and books and pamphlets, a large endowment fund is absolutely necessary. The desire to create such a medical library, which will meet every want of the student now and henceforth, is the aim of the Academy, and to accomplish this purpose it makes its appeal to every one who has the best interests not only of the city but of humanity at heart.

HOW SPECIAL SKILL IS ADVERTISED IN THE NEWSPAPERS.

THE true inwardness of the prevalent professional advertising in newspapers is so apparent to every ordinary student of human nature that none of the usual excuses are of any avail. The oft-repeated explanation that it is impossible to prevent it is very properly received with the smile that adjusts a strained courtesy with an obvious untruth. While it may appear to the offender as the only means of prying his conscience to a proper level of rectitude, it nevertheless leaves an ugly crack in his general character. The fact is that in estimating the evolutionary processes which from a newspaper point of view make certain men the most famous discoverers and the most successful operators of their class, we are necessarily forced to consider the controlling influences of the weaker rather than the modest incentives of the stronger sides of human nature. These conditions are so well understood that every man whose operation or whose method of treatment of disease is figured and described is very properly open to the suspicion of having met the reporter more than half way in an apparently laudable ambition of enlightening the public. With every disposition to be reasonably liberal in the interpretation of motives, with every willingness to admit that there are always exceptions to every rule, that there are not a few medical men whose opinions on general questions affecting public health are eagerly sought by the daily press, that there exists the usual amount of nonsense concerning the more absolute and more literal interpretation of ethical rules, we on the other hand fully believe that the burden of explanation of every newspaper report of a medical man's personal exploits rests entirely and solely with the party thus advertised and thus directly implicated. We speak advisedly on this point, and can, if need be, prove our position by very direct testimony. It is an insult to ordinary intelligence to suppose that a detailed account of a surgical operation can be made by any newspaper reporter who, by the merest chance, may have forced his unwelcome presence into a hospital *clinique*. The newspaper man, bright as he may be, is never sufficiently educated in his anatomy and is never able to give a scientifically accurate and detailed account of the surgical technique that necessarily belongs to the proper performance of the most ordinary operation. There is only one man who can do this satisfactorily, and he is the operator himself. More than this he, in the great

majority of cases, does give it, whether he is willing to admit doing so or not. Too much credit cannot be given to the enterprise of the daily press, but every sensible medical man knows its limit in regard to the possibility of accommodating the ordinary every-day knowledge of affairs with the carefully written technical accounts of the latest "most wonderful and most dangerous operation." The usual method of such reports is to describe the procedure in necessary detail, to illustrate the operation from actual photographs, and at the end make it appear that the operator was unwilling to be interviewed, was annoyed at the publicity of the report, and with transparent modesty was more than sorry that his "humble efforts to advance his glorious art" should in such an unseemly way be heralded by the press. This is done every day with the traditional stupidity of the ostrich which, although hiding its head, leaves the less desirable parts of the body better exposed to view and more open to attack.

The newspapers are governed by legitimate principles in obtaining news. There is always something with which to make a proper start. Very little missionary work is done in the way of hunting up obscure but deserving genius. Such game, as a rule, distributes its own scent, and is never better satisfied than when the pack is in full cry. Examples of this are frequent enough with every outsider who views the matter objectively. The laws of cause and effect are never violated. The fox in the chicken coop is seldom a mere coincidence. Only recently it has been found that a very worthy stickler for etiquette was guilty of actually paying for an account of his professional movements in the society column of a leading London court journal. It is the false pretense of the thing that carries its condemnation on its face. Fortunately for all concerned, the man who does it gets his labor for his pains. The casual amusement of the public is one thing, and the contempt of the silent majority in his profession is altogether another thing. The latter can never be reached nor measured, but like all other quiet forces sooner or later makes itself felt in the directions of professional ostracism and professional ruin.

The real motive for professional advertising is always self-interest. Backing all attempts in that line is the desire to make special bids for business. It is in imitation of the quack who aims to be the only one who may be skilled in the treatment of a given case. The ego is the pivotal point around which all other minor considerations turn. We in this way hear so frequently of the special operations that cannot be performed by any one but the subject of the report, and the cures for consumption, cancer, eye strain, and hydrophobia which are beyond possible imitation by others of the profession. There is every difference between the man who speaks for himself and the one who is content to voice the opinion of his profession as a body concerning matters of public health and public safety. In the latter instance he is a mere exponent of general and well-recognized professional opinions, his individuality is entirely lost in the cause he represents, and his only desire the laudable one to reflect due credit upon his fellow-workers. The mo-

ment this principle is lost sight of, his real motives have but one interpretation and his ostensible excuses have but one construction.

A NEW DANGER IN TALL BUILDINGS.

MR. CHARLES F. WINGATE, the well-known sanitary engineer of this city, in a letter to the *Sun* calls attention to a new source of danger in the so-called "sky scrapers" in what he describes as draughts of sewer gas from the escape pipes of overtopping buildings into the windows, chimneys, and light shafts of adjacent houses.

"In a recent notable case," he writes, "the entire family of the superintendent of a large office building, occupying spacious rooms on the roof, surrounded by loftier buildings, but with a magnificent outlook over the harbor, have suffered from severe forms of zymotic disease, including repeated attacks of malarial fever, so that the family have been nearly decimated and have been forced to abandon their apparently ideal quarters. Growing plants were destroyed by the virulent odors which penetrated their rooms, so that it was impossible to open windows, or to occupy the apartments for living-purposes."

This view of the subject is an entirely new one, and, being presented by a careful and competent observer, deserves to be considered in the light of a possibly ever-present and powerful factor for evil in all neighborhoods invaded by these unsanitary abominations. It is quite possible, now that attention has been drawn to the facts in question, that many well-founded complaints will be made which may claim the attention of the health department in the direction of some necessary legislation on the subject. The health department has it in its power not only to verify or disprove the existence of the conditions presented by Mr. Wingate, but to extend its observations upon the possibility of the existence of like conditions in every part of the city in which similarly deleterious down draughts are likely to be produced.

News of the Week.

A Medical Mayor.—Dr. Daniel A. Currie has been elected mayor of Englewood, N. J. Our congratulations are tendered accordingly.

Appendicitis from Chewing-Gum.—A young man in Peekskill was recently operated upon for appendicitis, and in the inflamed and ulcerated appendix was found a piece of chewing-gum which had been swallowed accidentally a few days before the disease became manifest.

The Late Dr. J. West Roosevelt.—The directors of the New York Physicians' Mutual Aid Association have heard with deep regret of the death of Dr. J. West Roosevelt, an honored member of the association. His learning, his probity, and his manliness were qualities which endeared him to all with whom he came into contact. They acknowledge with deep appreciation his generosity and kindness in be-

queathing to the association the amount of his claim, \$1,000, as an addition to the Permanent Fund of the association, and feel that in no surer way could a benefaction be made, for all time, a blessing to the needy members of his profession in this State. It was ordered that the name of Dr. J. West Roosevelt be placed on the list of benefactors of the association, and that notice of this action be sent to the medical journals.

Dr. Leszynsky Vindicated.—The charges of mismanagement made by Dr. William M. Leszynsky against the president and board of managers of the Hebrew Sheltering Guardian Society Orphan Asylum, situated at West 150th Street and the Boulevard, which resulted in the resignation of the entire medical board, have been sustained by the investigating committee of the State Board of Charities, which has recommended measures for the better government of the institution.

Reward for the Discovery of a Cure for Tuberculosis.—It is said that Mme. Audriffred has given to the Paris Academy of Medicine a sum equivalent to \$160,000, on condition that the same be securely invested and the income be paid yearly to the man who discovers a specific remedy for consumption, whether a Frenchman or a foreigner, when it can be definitely decided that such a remedy has been discovered.

Typhus Fever is reported by Miss Clara Barton, president of the American Red Cross Society, to be prevailing to a frightful extent in Marash, Syria. In Zeitoun also there are from forty to fifty deaths daily from this disease.

Tuberculosis in England.—According to Dr. Murrell, from 50,000 to 60,000 people in England and Wales die annually from pulmonary tuberculosis, and another 50,000 from other tuberculous diseases. From 1848 to 1880, 1,702,002 deaths were registered due to phthisis, the majority being young adults. No other disease claims an equal number of victims.

Dr. Francis J. Quinlan has been appointed laryngologist and rhinologist to St. Vincent's Hospital, New York City.

Depilatory Action of the "X" Rays.—Prof. John Daniel, of Vanderbilt University, writes in *Science* that, being asked to undertake the location of a bullet in the head of a child, he and Dr. W. L. Dudley decided to make a preliminary test of photographing through the head with their rather weak apparatus before undertaking the surgical case. Dr. Dudley lent himself to the experiment, and a plate holder containing the sensitive plate was tied to one side of his head, with a coin between the plate and his head, and the tube was set playing on the opposite side of his head. The tube was about one-half inch distant from his hair, and the exposure was one hour. The plate developed nothing; but twenty-one days after the experiment all the hair came out over the space under the "X" ray discharge. The bald spot was two inches in diameter, which was exactly the size of the "X" ray field close to this tube. The skin looked perfectly

healthy, and there had been no pain nor other indication of disorder. Professor Daniel thinks this incident may possibly be confirmatory of one theory which has been offered as to the nature of the "X" rays. The suggestion, beginning with Professor Roentgen himself, has more than once been made that they are longitudinal rather than transverse vibrations. It is difficult to distinguish a longitudinal displacement of the ether from an electric current, as far as it goes. A well-known method of depilation is that by electrolysis, or sending a current to the roots of the hair by a needle. If any such quasi-electric current has resulted from the "X" rays, the effect upon the hair might be thus accounted for. The intensity of the discharge in this case was not sufficient to heat the tube except very slightly; and the occasional small electrostatic spark from the surface of the tube to the hair, but which was hardly noticeable, would also, the writer thinks, not account for this effect.

The Extermination of Tuberculosis in Cattle.—The New York State Board of Health has decided that the only effectual way to eradicate tuberculosis in the herds of cattle is to kill the diseased animals, and it proposes to petition the legislature to appropriate enough money to enable the health authorities to pay the owners a fair price for all diseased cattle destroyed. It will ask next year for an appropriation of \$300,000 to carry on the work.

Hospital for Contagious Diseases on Staten Island.—The Richmond County Medical Society has issued an appeal asking for contributions to a fund sufficient to erect a hospital for the treatment of contagious diseases on the northwest portion of the Smith Infirmary grounds.

Typhoid Fever in Rahway.—There are upward of forty cases of typhoid fever in Rahway, N. J., and it is believed that the cause lies in the pollution of the Rahway River.

The Philadelphia County Medical Society and the American Medical Association.—At a business meeting of the Philadelphia County Medical Society, held on April 15, 1896, the following preamble and resolutions were adopted:

"Whereas, The American Medical Association completed its organization and commenced its actual existence in the city of Philadelphia during the first week of May, 1847;

"Resolved, That a committee of three be appointed by the chair to publicly urge that the association celebrate in 1897 its fiftieth annual meeting with ceremonies appropriate to its long and successful career.

"Resolved, That the delegates of the Philadelphia County Medical Society to the meeting of the American Medical Association at Atlanta be instructed to extend to the association a cordial invitation to hold its semi-centennial meeting in Philadelphia, the city of its birth."

Accordingly, the president of the society, Dr. J. C. Wilson, Dr. John B. Roberts, and Dr. W. M. Welch were constituted a committee to effect the purposes of the resolutions.

Dr. E. B. Landis, a graduate of the University of Pennsylvania, who went to Corea in 1890 to become physician of the port of Chemulpo, recently returned to Philadelphia on a visit, bringing with him a valuable and interesting collection of Corean ethnological objects for the Museum of Archaeology of the university. Dr. Landis has been made surgeon in charge of the mission at Chemulpo and has been elected a member of the Royal Asiatic Society. At the conclusion of the recent war with Japan he was decorated by the Emperor of China with the Order of the Double Dragon, third division, first class, for services rendered upon the battlefield.

The Election for President of the Royal College of Physicians, held on Monday, March 30th, resulted, as already announced, in the selection of Dr. Samuel Wilks. The votes on the first ballot were as follows: Dr. Wilks, 76; Sir W. H. Broadbent, 20; Drs. John Ogle and W. H. Dickinson, 9 each; Sir W. Roberts, 7; Drs. Pollock and Church, 6 each; Sir W. Priestley, 3; Sir Dyce Duckworth, Dr. Powell, and Dr. Allbutt 1 each, and one blank paper. As no fellow had obtained a two-thirds majority, a second ballot was taken between the two highest, with the result that Dr. Wilks received 114 votes, and Sir W. Broadbent 22 votes. Dr. Wilks received his M.D. degree from the University of London in 1850. The office of president of the Royal College of Physicians would seem to be an honor to be bestowed on the great men of the profession, yet curiously enough few of those in the past have had reputations that lived. "On examination of the list of past presidents," says the *British Medical Journal*, "it is undeniable that but few of them are known outside the walls of the college; indeed, with the exception of Linacre, Caius, and Glisson, and perhaps Sir Hans Sloane and Sir George Baker, down to the end of the seventeenth century, it is safe to say they have left no public mark. It will possibly be a surprise to some to learn that the immortal Harvey was never president; it is true that in 1654 he was elected to the office, but he was then advanced in years and in failing health, and declined the honor. Among other names which we do not find on the list, but which would have added lustre to it, may be mentioned Sydenham, who was not even a fellow, and Heberden, who have both left imperishable names in medical literature, while the names of those great popular physicians, Radcliffe and Mead, are far better known than those of most on the list."

The Plague in Hong-Kong.—There were seventy-five cases of plague reported in Hong-Kong during the week ending April 7th, as against forty-seven cases during the previous week.

Medico-Legal Women.—The Society of Medical Jurisprudence at its April meeting voted in favor of admitting women to membership in the society.

The Tsarevitch, Grand Duke George of Russia, who has pulmonary tuberculosis and has been living on the Riviera, where he was believed to be improving, is reported to be now much worse, and fears are felt that he can never return to Russia, even if he lives for a few years longer.

The Strangers' Hospital, Rio Janeiro.—We have just received the annual reports of the Strangers' Hospital, Rio Janeiro, for the years ending June 30th, 1894 and 1895, respectively. During the half year ending December 31, 1893, there were only 25 patients admitted, but from January to the end of June, 1894, the great amount of sickness prevailing in the port, aggravated as it was by the exigencies of the revolution, taxed the capacity both of the hospital and of its staff almost beyond due limit. In this period 172 patients were admitted, of whom 149 had yellow fever. There were 53 deaths, including 45 from yellow fever, 2 from pernicious malaria, 2 from tetanus, and 1 each from heart disease, enteric fever, disease of the kidney, and gangrene of the pharynx. From July 1, 1894, to June 30, 1895, there were 104 patients admitted, with 13 deaths, 9 of which were due to yellow fever. The matron and three of the nurses were attacked with yellow fever, which, unfortunately, proved fatal to one of the nurses (Miss Clayton). The hospital was founded with the object of providing prompt and skilled attendance for a limited group of English and American subscribers, their families and employees, in times of illness, especially during the recurring epidemics of yellow fever, but it has now acquired more of a public character than was originally intended.

The Metric System.—A bill was passed in the House of Representatives a few days ago providing that all the transactions of the government and of all departments thereof, involving weights and measures, except the surveys of the public lands, should hereafter be effected according to the metric system. The bill also provides that from and after the first day of January, 1901, the metric system should be the only legal system of weights and measures recognized in the United States. The measure is not to become a law, however, for after the bill had been passed the vote was reconsidered and the bill was sent back to the committee.

The Cholera has reappeared at Alexandria, Egypt, and several natives as well as a resident English merchant have died of the disease.

A Gift to Columbia.—The chemistry building for Columbia University is to be erected as a memorial to the late Frederick Christian Havemeyer. President Low has received a letter presenting the building, which is to bear the name of Havemeyer Hall. The gift is made by the sons and daughters and nephews of Mr. Havemeyer.

The Medical and Surgical History of the Rebellion.—Mr. Broderick, of Kansas, has introduced a resolution into the House of Representatives instructing the superintendent of documents to receive subscriptions for the Medical and Surgical History of the Rebellion and for the Index Catalogue of the Surgeon-General's Office at the estimated cost of reproducing these volumes from the stereotyped plates. Whenever the number of subscribers for either of the works is four hundred the public printer is to reprint and deliver them to the superintendent of documents for sale

to the subscribers. The bill has not yet passed the House and is unlikely to receive much attention during the present session, at least, of Congress.

The Prevention of Bovine Tuberculosis.—The French Government has decreed that all cattle imported into France from foreign countries must be tested with tuberculin at the frontier before being admitted. In those cases in which the characteristic reactions denoting the existence of a tuberculous process are revealed the animals are, after being marked, refused entrance into the country unless the owner gives his consent to immediate slaughter. The tuberculin test is not applied to cattle which are formally declared to be imported for slaughtering purposes. In these cases, however, proof must be forthcoming within fourteen days that the beasts have been killed.

Long Island Association of Alumni of College of Physicians and Surgeons.—There has recently been organized in the city of Brooklyn an alumni association of the College of Physicians and Surgeons, New York, which will be known as the Long Island Association of the Alumni of Columbia University (Medical Department). The following officers were elected to govern the affairs of the association for its first year: Charles Jewett, M.D., *President*; H. Beekman Delatour, M.D., *Vice-President*; E. S. Hodgskins, M.D., *Treasurer*; C. F. Barber, M.D., *Secretary*; George Wackerhagen, M.D., Ernest Palmer, M.D., H. A. Fairbairn, *Directors*. Its object is both scientific and social.

Barbarous versus Scientific Methods in the Disposition of Capital Criminals.—Under this title Dr. J. S. Pyle, of Canton, O., returns to his project of utilizing criminals condemned to death for the purpose of scientific experimentation. His argument is that "a human being whom justice has condemned to suffer death, has forfeited every naturally inherited right and indebted himself to society for the loss of one or, perhaps, more of its members and the expenses of a fair and impartial trial. This latter justice exacts to the same extent as it does the death penalty, and, if the purport of the law is followed, the right to experiment upon capital criminals cannot be denied. . . . Why a capital criminal should not be used in the interest of suffering humanity is hardly to be understood. Can intelligent people exhibit more sympathy to criminals of this class than to the patient sufferers dying daily from diseases that might be prevented by the knowledge gained from such experiments? Can a sentiment be respected which removes human sympathy from the suffering, law-abiding citizen to the capital criminal? Can the execution of a death sentence conducted in the same manner as a modern surgical operation be truthfully represented as more brutal and less sympathetic than hanging or electrocution? The facts are that in no way would it approach the frightfulness or brutality exhibited on the gallows or in the electric chair." We fail to find in Dr. Pyle's article any new arguments that lead us to modify a previously expressed opinion that the proposition is one that shocks human sentiment.

Jefferson Medical College.—The trustees of Jefferson Medical College have purchased properties at the northwest corner of Tenth and Walnut Streets adjacent to the present college and hospital buildings, with a frontage of 118 feet on Walnut Street and 107 feet on Tenth Street. It is proposed to erect upon the new site the most complete hospital building in the country and to alter the present college in correspondence.

The Homage Which Vice Pays to Virtue.—The question of medical advertising has recently been brought up in an English court, with the result of putting some discomfiture upon certain guardians of the British medical conscience. A physician in Blackpool was taken to task by the *British Medical Journal* for permitting his name to appear in the prospectus of a hotel as its physician, the editor expressing the opinion that "the medical man in question has not only disparaged the honorable traditions of the medical faculty, but contravened the well-understood rule of modern practice," and adding "that so reprehensible a departure from professional rule, in face, too, of the protesting dissent of the local practitioners, and in the absence, moreover, of our (self-)solicited opinion, is wholly incompatible with the honor and dignity of the profession, and justly subjects him to medical reprobation." This public reprimand was very naturally resented by the sufferer, and he sued the editor for libel. The case was tried at the Manchester assizes, and the defence called a number of medical witnesses to show that the reproof was justifiable. Among these was Sir Dyce Duckworth, treasurer of the Royal College of Physicians and a member of the Medical Council, a body whose function it is to determine the degree of respectability of medical practitioners in the United Kingdom, and whose members can see notes in other persons' eyes at very long range. This witness gave it as his expert opinion that "it was objectionable to advertise a medical man's name in connection with a hotel, and it was undesirable, even in the case of a hydropathic establishment." But he is a medical examiner for a life insurance company, and the counsel for the defence called attention to the fact that his own name, together with that of the hospital with which he is connected, and his private address appeared in the prospectus of this company, which was widely circulated and placed in large numbers on office counters, and even hung in picture frames upon the walls of hotels and other public places. When asked if this was not advertising, he said that it was not, adding that "his private address was given for the convenience of those who had to see him." The jury was too democratic and too free from hypocrisy to see a difference between the two forms of advertising, and promptly gave a verdict against the editor of the *British Medical Journal*. In some caustic comments on this case the *Medical Press* says that it "has done good in one sense, it has shown the public that whenever a practitioner holding the position of Sir Dyce Duckworth allows himself to be advertised in a shameless manner nothing is said of it by his compeers, but when a hapless medical man in a small country town adopts any species of self-advertisement

the hands of the powers that be are held up in horror at the iniquity of the offence, and he is condemned accordingly. The truth of these facts became so apparent at the trial during the cross-examination of Sir Dyce Duckworth that a lay contemporary waxed merry over the inconsistency which was displayed." The same editor and the same witness have also allowed their zeal for ethics to be smothered by their zeal for publicity in another direction. The witness honored us last summer by a flying visit to these shores, and the fact was announced in an item in one of the leading London journals. The editor recently went to the Riviera for the benefit of his health, and this interesting fact was announced in the *Times*. A confrère, thirsting for knowledge, made inquiries concerning these little items of news, and was informed by the publisher that such notices were always charged for at the rate of three lines for a guinea, and ten shillings and sixpence for every additional line. In the vocabulary of the unregenerate announcements of this kind which are paid for at the regular rates are usually called advertisements. Casuistry is truly a wonderful science, which seems to reduce itself, in the minds of certain of its professors, to the question of whose ox is gored.

The Society for Medical Progress of the West Side German Dispensary held a meeting April 11th. Specimens were presented by Dr. Augustin Goelet; also papers on the management of "Infant-Feeding" by Dr. Louis Fischer and on "Septic Endometritis" by Dr. S. Brothers. The subjects were discussed by Drs. Dessau, Agrimonte, Zwisohn, Gordon, Valentine, and others.

Antimikrobia is a new compound composed of cod-liver oil and ozone and advocated by Dr. Erich Langheld in a paper before the Congress of Internal Medicine at Wiesbaden as a promising remedy for tuberculosis. The remedy is administered subcutaneously.

College of Physicians of Philadelphia.—At a meeting of the surgical section of the College of Physicians of Philadelphia on April 10th Dr. Edward Martin exhibited a man in whose case he had two years before evacuated three pints of pus from an abscess of the liver consecutive to dysentery, with perfect recovery. He presented also an old man from whom he had removed both testicles some eighteen months previously for hypertrophy of the prostate, with admirable results. The man had suffered with prostatic symptoms for perhaps a dozen years and the cystitis and irritability of the bladder were most pronounced. He was partially uræmic when he came under observation, but immediate improvement followed the operation and has since been maintained. Dr. John B. Roberts showed two cases of fracture of the patella, one of which was treated by means of Levis' modification of Malgaigne's hooks and the other by a horizontal purse-string suture. Dr. W. H. Noble presented a man who four years ago had received a bullet wound of the left superior maxilla and in whom recently a tumor developed in the right

upper jaw which upon removal proved to be an osteosarcoma. By using an artificial plate for the roof of the mouth the man had no appreciable difficulty in speaking and presented but little deformity. Dr. Noble showed also two cases in which saddleback noses in syphilitic subjects were greatly improved in appearance by the insertion of a suitable silver plate through a median incision. He exhibited further a man from whom the left cornu of the hyoid bone had been removed. It seemed that the bone had been fractured by a fall upon the edge of a watertrough and the detached fragment had begun to cause irritation. Dr. T. S. K. Morton reported a case of osteomyelitis in which early operation was performed before the occurrence of suppuration, although bacteriological examination of the removed structures disclosed the presence of streptococci. Dr. W. J. Taylor exhibited a ruptured liver from the body of a boy who had been underpinned by a wagon overturned by a trolley car. The lower lobe of the right lung was also ruptured. Notwithstanding these serious injuries, the boy lived for nearly twenty-four hours after the accident.

Wills Eye Hospital.—Dr. James C. Bloomfield has been elected resident surgeon at Wills Eye Hospital and Dr. A. G. Thomson an assistant surgeon.

Club Practice in England.—The London correspondent of the *Sun* says that the agitation in medical circles in England against the growing evil of club practice has reached an acute stage. Clubs for obtaining medical attendance at contract rates are becoming very common. These clubs undertake to supply members with all necessary medical attendance for a fixed annual fee, which in many cases is as low as sixty-two cents. It will readily be seen that the service which a professional man can render for such a pittance is nominal rather than real. A doctor must have some thousands of patients on his list in order to make a bare living. It would, of course, be physically impossible for him to do much more than put in a very brief appearance at the actual deathbeds of his subscribers. His presence at any less pressing emergency would be quite out of the question, and so it has proved according to the testimony at various coroners' inquests. Medical men of all classes are taking up the question, and contract medical service at present rates is being severely discountenanced.

The Red Cross in Abyssinia.—A Red Cross expedition has been fitted out in Russia to give succor to the soldiers of King Menelek's army. The expedition, which consists of sixteen surgeons and some seventy attendants, nurses, interpreters, etc., is fully equipped with medicines, surgical instruments, comforts of the most approved modern kind, and provisions for the use of the members for a hundred days. It is now at Odessa waiting permission of the Italian government to proceed to Massowah and thence to Abyssinia.

Dogtail Sutures.—It is said that the tendons found in the tail of a dog make better sutures than either catgut or kangaroo tendon, when properly prepared in sublimate.

Winter Holidays.—Sir T. Spencer Wells writes in the *British Medical Journal* of a winter holiday which he passed in the island of Jamaica and in Florida. Jamaica, he says, is a beautiful island with a delightful climate, warm sunshiny days, and cool nights; not so warm as during the same season in Ceylon, rather warmer than the Canary Islands and Madeira, and much warmer than Algiers, Corsica, or the Riviera. He recommends a visit to Jamaica to tired-out London doctors who can spare the time and do not fear sea-sickness.

Not a Health Resort.—The death rate among the European residents of the island of Lagos, off the west coast of Africa, is one hundred and fifty-four per thousand according to statistics given in a colonial-office report recently issued.

Guy's Hospital is in a good way of having a large re-endowment fund. The response to the public appeal in connection with the festival dinner, at which the Prince of Wales is to preside, has been unexpectedly large.

The Plague at Hong-Kong.—A report dated March 2d, received by the Marine Hospital Bureau from Dr. W. F. Arnold, U. S. Navy, stationed at Hong-Kong, China, says that the plague has assumed epidemic proportions at that place. The isolation of suspected individuals has ceased to be practised, and all bills of health of the port state its prevalence, giving details of the precautions taken in cases where important mail steamers were concerned. It was also very prevalent in Canton and high up West River. Surgeon Arnold says that the disease is very fatal. With the exception of about a dozen mild cases that came about a month ago, at least ninety-five per cent. of observed sufferers have died, and that usually within the first four days of illness.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the U. S. Navy for the two weeks ending April 18, 1896. April 8th.—Passed Assistant Surgeon L. L. Young, detached from the Naval Hospital, Norfolk, and ordered to the *Albatross*. Passed Assistant Surgeon E. S. Bogert, detached from the *Albatross*, ordered home, and granted three months' leave. Assistant Surgeon J. M. Moore, detached from the *Vermont* and ordered to the Naval Hospital, Norfolk. April 17th.—Assistant Surgeon C. M. De Valin ordered to examination for promotion.

An A. M. A. Badge.—The craze for badges and buttons has seized upon some members of the American Medical Association, and it is proposed to get up a badge whereby the members of that body may be distinguished on sight from the outside world.

A Forecast.—The American Medical Association will hold its annual meeting, beginning May 5, at Atlanta. Considerable interest is felt in certain quarters as to the result of the meeting, and if straws tell which way the wind blows it will be a stormy session.—*Vermont Medical Monthly*.

Charity versus Feasting.—A Russian journal is quoted by *La Médecine Moderne* as publishing the following story: It was proposed to celebrate the twenty-fifth anniversary of the scientific career of Professor Korsch, of Odessa, by a banquet, which was to be given by his students and friends. When one hundred and fifty names had been subscribed, and the total subscriptions amounted to one thousand roubles, the professor proposed, instead of having the banquet, to devote the sum to the payment of the tuition fees of poor medical students. This proposition cooled the ardor of the subscribers to such an extent that all but seventeen of the hundred and fifty withdrew their subscriptions, and the total amount left was hardly ninety roubles. If these are the facts, Professor Korsch lost his birthday dinner, and the poor medical students gained but little by it.—*Boston Medical and Surgical Journal*.

Deadly Water.—A St. Louis doctor writes in the Sunday papers warning his fellow-citizens against the drinking of water in large quantities. As if there were any danger of that.

The Coming Meeting of the American Medical Association at Atlanta promises to have a larger proportion of working scientists than has been present at any meeting of the association for the past five years. The San Francisco and Baltimore meetings displayed decidedly retrogressive tendencies. The officers elected at these meetings were certainly not in many instances the best representatives of either the association or the profession. One of the trustees elected has frequently been a tool of the politicians in placing ward heelers in medical offices. His greatest feat since his connection with the association journal has been an unsuccessful attempt to suppress discussion of the dispensary abuse. Such an attempt evinces a contemptuous disregard of the best interests of the profession that should merit removal. The outrageous way in which various sections elected executive committees in defiance of the constitution indicates the loose way in which the business of the association has been run. The Atlanta meeting should adopt some method whereby the secretary is something more than a figurehead, since on him rests the responsibility for many of these blunders. The place of meeting of the association will undoubtedly aid any attempt at reform in the bad business methods which have of late obtained. It is not probable that the beneficent rule prohibiting speaking from the platform will be as blatantly violated as it was in Baltimore and San Francisco. The programme announced, while of a high character, has been far exceeded in previous years.—*Medical Standard*.

The American Climatological Association will hold its thirteenth annual meeting in Lakewood, N. J., on May 12th and 13th.

Dr. Grace, the Champion Cricketer.—The subscriptions received by the various committees for raising a testimonial to Dr. W. G. Grace, the English cricket champion, now amount to nearly \$50,000.

Water Supply of the Lake Cities.—The *Indiana Medical Journal* says that Buffalo, with an abundance of pure water within easy reach, is short of pure water, and, like Chicago, is in the condition of the ox that drinks and passes water in the same pool. Duluth is another lake city which has suffered severely from self-pollution of its water supply. There is no excuse for any lake city being short of water or drinking its own sewage.

The University of Maryland is to have a new hospital built after the most approved modern plans.

The Supply of Cod-Liver Oil is in danger of giving out, as it is said the catch of Norwegian fish is diminishing each year and also that the yield of oil is less in proportion to the number of fish caught.

The Tsetse-Fly Disease.—In 1894 Surgeon-Major Bruce—who had already done good work in Malta fever—showed that tsetse-fly disease, that scourge to the traveller and the farmer in Africa, is associated with the presence in the blood of affected animals of a protozoal organism resembling, if not identical with, trypanosoma Evansi, the cause of the surra disease in India. In a recent report he gives a description of the hæmatozoon of the tsetse-fly and of the disease with which these organisms are bound up, as it affects a variety of domesticated quadrupeds—the dog, the horse, the ox, and the ass. He has failed as yet to get an explanation for the fact that the tsetse fly and the disease depend on the presence of large game in the endemic districts; but he clearly proves that the fly itself is not pathogenic, and that it merely acts as a passive conveyer and implanter of the pathogenic protozoal germ. The ordinary and natural source of the germ he has not discovered. He points out the similarity, if not identity, of the symptoms of surra and fly disease; and, as it is known that the former is caused by a trypanosoma, he considers that the probabilities are that the diseases are the same—possibly slightly modified by local conditions. Lingard, however, hesitates to admit this; he points to the fact that, while in Africa the ox is liable to fly disease, in India bovines are immune from surra. Bruce suggests that some local peculiarity in Indian cattle may account for this—that their immunity from trypanosoma disease may be of the same nature as the immunity enjoyed by the Algerian sheep from anthrax, a view which receives some support from the circumstance that fly disease is a milder affection—at all events a less acute affection—in the ox than in some other domesticated animals. We trust that ere long we may hear more from Surgeon-Major Bruce on this subject; meanwhile, we congratulate him on what he has already done—an admirable piece of work which possesses not only great pathological interest but which may prove to be of no small economic importance.—*British Medical Journal*.

Congress of Hydrology and Climatology.—The fourth session of the International Hydrological, Climatological, and Geological Congress will be held at Clermont-Ferrand at the end of September, 1896.

A Correction.—In the report of the meeting of the Practitioners' Society held March 6th it was stated that Dr. C. S. Bull read a paper before the Ophthalmological Society in London; the body before which the paper was read was the American Ophthalmological Society and the place of meeting was New London.

The Association of American Medical Colleges will hold its annual meeting in Atlanta on May 4th. On invitation of the American Academy of Medicine, the association will meet with that body to discuss several papers on medical education at 9 A.M. The regular official session will be held at 4 P.M. The president of the association is Dr. William Osler, of Baltimore, and the secretary Dr. Bayard Holmes, of Chicago. Fifty-five colleges have paid their dues for the past year and are members in good standing of the association.

Chinese Decoration of Dr. Atterbury.—By a recent edict of the Emperor of China, Dr. Boudinot C. Atterbury, of Peking, has received the decoration of the Double Dragon for his services to the wounded during the late war with Japan. Dr. Atterbury is the first of American doctors to be thus honored.

Scarlet Fever Hospital.—The bill to enable Mrs. Minturn's scarlet fever and diphtheria hospital to receive a site from the city of New York at East Seventeenth Street and the East River was passed in the Assembly on Thursday last by a vote of 89 to 42. The bill now goes to Mayor Strong for his approval.

The Société de Médecine de Paris celebrated the centenary of its foundation on March 21st.

The Cleveland Medical Society is indeed flourishing. Of this no further proof is needed than the statement that at each of the meetings of February 28th and March 13th twenty new members were elected. That the society should be compelled, by the abundance of scientific material offered, to hold weekly meetings in March is also significant.—*Cleveland Journal of Medicine.*

The Bill Abolishing the Office of Coroner in New York has been killed in the Assembly. A substitute bill has been recommended by the judiciary committee, which retains the coroner but abolishes the coroner's jury.

Hospitals in Pittsburg.—It is announced that Henry C. Frick, chairman of the Carnegie Steel Company, will build a hospital for children on Squirrel Hill, Pittsburg, within the next year, at a cost of \$500,000. The building will be erected on a plot of forty acres which Mr. Frick owns. The hospital will be placed under the control of the Episcopal Church. The Pittsburg correspondent of the *Cleveland Journal of Medicine* says that there are at present six large hospitals (one of which is homœopathic) in the two cities of Pittsburg and Allegheny, besides several smaller ones. This number is to be increased by two new ones, St. John's in lower Allegheny, and St. Margaret's in Pittsburg. This last-named hospital was provided for by the late John Schoenberger, a wealthy ironmaster, who left \$800,000 for the pur-

pose, stipulating in his will that the hospital should be under the control of the Episcopal Church and modelled after St. Luke's Hospital of New York. He also bequeathed a large tract of land upon which to erect the hospital. Plans for an up-to-date hospital on the pavilion plan, costing \$300,000, have been approved, and it is expected that work will be begun in the spring. So, if the full bequest of \$800,000 is realized, \$500,000 will be available for an endowment fund. Pittsburg has no hospital for contagious diseases, however.

Charity Punishable in Cuba.—Dr. Alejandro Echemendia was arrested recently at his home, in Sancti Spiritus, Cuba, charged with treating a wounded patriot, who was also taken to prison by the police. Investigation the following day showed that the man was not a rebel, but a laborer who was hurt in an accident. The doctor was attending him through charity. Both were released.

Obituary.

MARIANI SEMMOLA, M.D.,

NAPLES.

PROF. MARIANI SEMMOLA, of Naples, whose illness we mentioned last week, died on April 5th. He was born in Naples, January 31, 1831, and studied in the university there. After obtaining his degree he studied in Paris under Roger, Trousseau, and Bernard. In 1865 he was called to the chair of pharmacology and therapeutics in the University of Naples. In 1850, when but twenty years old, he presented to the Academy of Medicine of Naples a memoir on Bright's disease, in which he demonstrated the effect of nitrogenous and non-nitrogenous food upon the excretion of albumin in those suffering from this disease. He was subsequently the author of many treatises and monographs upon albuminuria, diabetes, diseases of the liver, and general therapeutics. An essay published in 1877, upon "Old and New Medicine," was translated into nearly all the languages of Europe, including Portuguese and Greek. His works were always so speedily translated into German that many thought he was of that nationality. He was the founder of the *Archivio Medico Italiano*. His last work, completed only three weeks before his death, was a treatise on diseases of the liver, written for the "Twentieth Century Practice." Professor Semmola was associated with Charcot in treating the Emperor Dom Pedro, and was decorated by his grateful patient with the grand cordon of the Imperial Order of the Rose. The municipality of Rio Janeiro also sent him a congratulatory address and voted him a gold medal. Two years later he was called to Constantinople to see the ex-Khedive of Egypt, and while there received from the Sultan the grand cordon of the Imperial Order of the Osmanie. The Tzar of Russia also made him an officer of the Order of St. Stanislas, presenting him with the insignia accompanied by an autograph letter. He was a member of the Legion of Honor of France and an officer in an Italian order of merit. In 1886 he was made a life senator of the kingdom of Italy. He was known personally to most of the leaders of medical thought throughout the world, and his was a familiar figure at every international medical congress, from that at Brussels in 1875 to that at Rome in 1894.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, April 13, 1896.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Rupture of the Quadriceps Tendon; Suture; Recovery.—DR. ARTHUR L. FISK presented a man, sixty-four years of age, whom he had seen in January, 1895. While engaged in unloading a large block of marble, the man suddenly slipped and fell backward. It was found that he could not stand, and he was taken to the Manhattan Hospital. When seen by the speaker on the following day, there was a rupture of the quadriceps tendon with complete loss of motion, and a sulcus above the patella as large as the fist. The man would not consent to operation for a week, and then objected to general anæsthesia, so the operation of suturing had been done under cocaine anæsthesia. On incision the gap between the ruptured parts had been found filled with clotted blood. This was evacuated. The suture was effected by the use of six stitches of kangaroo tendon and a superficial suture of catgut for the fascia and skin. The limb was put up in plaster of Paris. The man now had perfect use of the limb and was able to carry on his work without any inconvenience. The speaker said that he had used a one-per-cent. solution of cocaine and had injected it freely, so that the anæsthesia was good; but the muscular sense had not appeared to be completely dulled, and he would recommend that these operations should not be done without a general anæsthetic.

An Analysis of Cases of Floating Cartilage of the Knee Treated by Operation between 1885 and 1895.—DR. PERCY R. BOLTON read a paper with this title. He said that this particular period had been selected, partly because previous cases had been pretty well reviewed and partly because this period represented a more nearly perfect surgical technique. The total number of cases which were considered to have been reported in sufficient detail to warrant attention was seventy-two. Of these twenty-three were pedunculated and forty-nine non-pedunculated. Besides bodies detached by slight injury, portions might be chipped off from the ends of the bones as a result of severe injuries. This was exemplified in the following case: A heavy blow on the end of the femur caused ecchymosis and effusion into the knee-joint. An incision revealed a foreign body, three-fourths by half an inch, composed of articular cartilage and attached by periosteum to the condyle, from which it had been chipped off by the severe traumatism. The majority of the cases were examples of bodies detached by a process the nature of which is as yet unknown. In 1860 the cases occurring up to that time had been collected. Of the one hundred and thirty-five that had been operated upon by direct incision, there were 74.8 per cent. of successes, 21.4 per cent. of deaths, and 3.8 per cent. of failures. Muller, in 1886, had collected one hundred cases with ninety-six recoveries and four deaths. Between 1885 and 1895, Dr. Bolton said, he had found no fatal results recorded. Sixty-seven cases had been tabulated with reference to the function of the joint after operation. It had been found that in twenty-two per cent. there had been some disability, in thirteen per cent. more or less limitation of motion, and in four per cent. ankylosis. The treatment of the pedunculated bodies, involving as it did greater manipulation of the joint and more chances of infection, should be placed in a separate class. Sixty-two out of the seventy-two cases analyzed in this paper made

a complete recovery; in sixteen per cent. more or less disability was acknowledged. Of the ten unfavorable results six occurred after the removal of pedunculated bodies, and four after operations for the removal of non-pedunculated bodies. Of the six unfavorable results three were unavoidable from the operative procedures required, and three were due to disease existing prior to operation and persisting after it. Of the four imperfect results after the removal of non-pedunculated bodies, in one there was slight stiffness; another recovered with very slight disability after the removal of a loose cartilage one inch in diameter; another had some stiffness after the removal of a large foreign body from a joint the seat of a chronic effusion; and the fourth case required amputation through the thigh as a consequence of suppurative arthritis. As there had been no effusion at the time of operation, no drainage had been employed. In three of these four imperfect cases the patients probably recovered the use of the joint ultimately; in the fourth case alone could one say that the result might have been avoided. From a study of these seventy-two cases it was evident that a loose body in the knee could not be looked upon as a trifling condition. In most cases the incision was made on the inner side of the patella. Small non-vascular pedicles were divided without ligature; small vascular pedicles were tied off; and the larger pedicles were tied in two, the bleeding stump cauterized, and the synovial membrane sutured over the stump. Irrigation and drainage appeared to be of service in those cases in which there was already a chronic synovitis, or in which much manipulation was required, or when there was free hemorrhage into the joint as a result of free dissection. In other cases drainage did not seem to be required.

DR. FISK said he had had the misfortune to see two cases in which the joint had been opened, one accidentally and the other for a gunshot wound of the knee. The first case was that of a young man in whom the knee had been injured by being caught in some moving cogwheels. He had opened and irrigated the joint thoroughly and inserted drainage. At first a bichloride solution, 1 to 20,000, had been used for irrigation, and the tubes had been removed on the fourth day. The wound had healed readily and the boy had left the hospital with an excellent knee. The other case was one in which a bullet had been accidentally discharged into the knee and had become embedded in the condyles. Dr. Roger, of Denver, had made a transverse incision across the joint and sawed through the patella, thus exposing the joint. The ball was removed and the joint irrigated, but the patella was not again sutured. He had not been able to ascertain the ultimate result of that case. Allingham, in his book on the treatment of affections of the knee, advised an incision on the inner side of the patella. He reported a number of cases of "football knee" in which the semilunar cartilages had been torn off. In these cases the portion of cartilage had been removed and the joint closed by suturing the synovial membrane, and the muscular and skin layers separately. This author claimed that the same care should be taken in closing the wound in the knee that would be exercised in closing the wound after an abdominal section. If effusion occurred after the operation, the wound should be opened with a probe at the lower portion and the fluid allowed to escape. By the application of a little pressure all further trouble would be averted.

DR. ACHILLES ROSE said that in Germany there was much litigation over accidents, and in a journal devoted to the special consideration of this subject there had been published a very interesting article on the etiology of floating bodies in the knee-joint. Dr. Schiller had collected all the cases that he had been

able to find between 1883 and 1893. Of these one hundred and forty-three cases thirty-nine were of pathological origin, eighty-five traumatic, and in nineteen the origin could not be determined.

DR. JAMES P. TUTTLE said that four or five years ago he had had occasion to look up the matter of traumatism in the production of these floating bodies, and he had found that the majority of writers seemed to believe that most of the cases resulted from the gouty or rheumatic diathesis. He had seen personally three cases, in none of which could he find a rheumatic condition. All gave a history of more or less severe traumatism to the knee at some antecedent period. In two of the cases the bodies had been pedunculated, and had been crushed off with forceps. In the fourth case, after a severe crushing injury to the knee, a soldier had been treated by Dr. Nathan S. Smith, who had broken up the ankylosis. Many years after this the patient began to notice small floating bodies near the condyles. On examination, the speaker said, he had found three small floating bodies. After consultation it had been first decided to try immobilization. This having failed after several months of trial, a small incision was made and one of the most troublesome of these bodies removed, with the result that the pain and disability had been completely relieved. He felt that the evidence was to the effect that where multiple foreign bodies had been treated by operation there had been more or less limitation of motion, whereas in the cases in which there was only one body the results had been excellent.

THE CHAIRMAN said that in two cases in which he had operated upon two pedunculated bodies in the upper sac, the results had been good. One was a tubercular fringe in a joint otherwise healthy. The patient had remained in good health since then. The other was a mere fibroid thickening of the capsule of the joint. He would like to emphasize the point that had been made about the importance of suturing the different layers separately in closing the wound. Welch had shown the danger of carrying sutures through the deeper layers of the skin, owing to the existence of bacilli which could not be destroyed.

The Treatment of Sero-Cystic Formations along the Funo-Testicular Tract.—DR. THOMAS H. MANLEY said that in many cases of hydrocele after simple tapping it was known that a cure would follow. In his own experience, however, fully one-third had relapsed. In cases not desirable for radical operation, the practice of making local applications of muriate of ammonia and vinegar might be tried. This method had received the sanction of high authority in the past. With proper sterilization of the scrotum, acupuncture should not do any harm if ordinary care were observed. Although some surgeons still persisted in employing the trocar, it was not a procedure to be recommended at the present time. It was slovenly and dangerous. The artificial establishment of acute adhesive inflammation by the introduction of various chemical agents was a most unsurgical procedure, which was often ineffectual and not altogether free from danger. The orchitis which sometimes followed such treatment had been known to cause very marked atrophy of the testicle. Volkmann's method of incision had the distinct advantage of allowing the surgeon to determine exactly the condition within the sac. Personally he preferred the method of resecting the entire tunica vaginalis except the basic attachment of the testis. In these operations one must guard especially against infection and undue hemorrhage. For drainage he used catgut. A light, comfortable dressing should be used. He had treated in the past few years thirty-one cases by the open method, all successfully.

DR. J. P. TUTTLE said that there were many patients

who would submit to the injection method, but would not give their consent to the open operation, or who could not remain in bed for two weeks. He felt convinced that failures with the injection method were largely the fault of the person making the injections. In the first place one often failed to adopt proper aseptic precautions prior to making the puncture, and often omitted to secure thorough emptying of the sac. The quantity of fluid injected was also important. He did not approve of the use of iodine. It was his plan to use pure carbolic acid, for when diluted it failed to produce a cure. After the second or third day the hydrocele so treated would swell up almost as large as before from inflammatory effusion. This secondary effusion should be removed, and then careful pressure should be applied. This would usually effect a cure. He had injected as much as seventy-five to eighty minims of pure carbolic acid without any unpleasant consequences, and had rarely had occasion to do it a second time. It was much better to empty these hydroceles by means of an aspirator than by a trocar. After this method of treatment there was no pain except that produced by distention, and this could be removed by the secondary tapping.

THE CHAIRMAN said he would also speak in favor of the injection of carbolic acid, for he felt that certainly three-fourths of the cases could be cured by this method. The failures occurred chiefly in those cases in which there was more than one cavity. The existence of this condition could be determined at the time of the operation, and then each cavity should be injected separately. Where the sac had a very thick wall, it was better to excise the sac. It should be remembered that recurrences were not uncommon after Volkmann's method, and that they had been reported even after von Bergmann's method had been employed.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 16, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Scleroderma.—DR. F. X. DERCUM, of Philadelphia, before proceeding to read his paper upon this subject gave place to DR. BAILEY, who presented a patient with a condition which he thought fell under the generic term scleroderma. She was a Swedish woman, twenty-eight years of age. Her mother had had a similar condition for a year, and then had recovered completely. During her illness there was general swelling all over the body, inability to help herself, confinement to bed. One brother had also been similarly affected in childhood, and was unable to walk until ten years of age, but finally completely recovered. The patient denied having had specific disease. Eight years ago she was admitted to the Presbyterial Hospital suffering from general œdema and hardness of the skin. The diagnosis was made of erysipelas of the face. Six years ago she entered the same hospital for a similar condition, induration and thickening of the skin. Five years ago she had a third attack, when the skin was hard and thick and motion in the knees and elbows impossible. In 1893 she was admitted to another hospital, unable to move the knees and several other joints. She had received various treatment—iodide, iron, strychnine, thyroid extract, massage, etc. She had improved during the last three years, and thought her improvement due chiefly to massage. Dr. Bailey had been unable to discover any gain from thyroid. There had been no pain except in damp weather. The sweat and sebaceous glands had not been impaired. When shown, the patient's condition was much improved, but the skin on the face, arms, and legs was drawn and tense; there was stiffness of the

joints, particularly at the wrists, elbows, and knees; and in places were hard tumor-like bodies in the skin. Near the eyes the surface was flushed. The skin over the body was normal, but there was some stiffness of the vertebral joints.

DR. DERCUM then proceeded to read his paper, which treated chiefly of the histories of three cases which had come under his personal observation. He did not venture a theory as to the nature of scleroderma, contenting himself with a statement of the clinical facts, which in his cases seemed to point to an impression upon the nervous system as the starting-point—in one instance through a trauma of the head, in another to repeated chilling on entering an icehouse. He did not, however, claim that it was a nervous disease.

Scleroderma might show itself in diffuse or local form, and in different cases the amount of thickening, induration, and discoloration, which were the main dermal phenomena, varied. Its possible relation to the class of cases of which myxedema was a type was mentioned.

Case I. was that of a German, forty-three years of age, a machinist, whose trouble began with a scalp wound of the occipital portion of the head, inflicted by a falling body. He was unconscious for a few seconds, was taken to a hospital, and remained there four or five days. The wound healed promptly, but he was afterward referred to the nervous department for headache. Dr. Dercum found that the patient complained of severe pain at the site of the injury, and he therefore was disposed to think a local pachymeningitis had been set up by the accident. The accident occurred in May, 1894, and the man reported at irregular intervals until the fall of the same year. Dr. Dercum, having been absent, now saw him again and noticed that his appearance had markedly changed. His face was much fuller and the neck was swollen; there was also swelling over the shoulders, less in the skin of the forearm and back. His first thought was of myxedema. On being questioned, the man stated that the pain in the head had persisted since the accident; he had noticed that the skin of the face and neck had become thick and hard, and that this thickening and hardening had extended to the shoulders and their neighborhood. Dr. Dercum related in detail the further course of the case. At this time the skin was not pigmented, but it became so later, and subsequently as improvement took place the pigmentation became lighter and finally disappeared together with the thickening and hardness of the skin. Among other symptoms were interference with motion in the joints, sweating, and coldness of feet; these symptoms were aggravated in a warm room. The morbid processes appeared to be limited to the skin and subcutaneous tissue. The urine contained an unusual proportion of solids, the phosphates being in excess. A careful examination of the blood was made. The leucocytes were markedly in excess.

Case II. was that of a female, aged thirty-one, mother of one child, family history negative. About three years ago she noticed that her hands were swollen and red, and that she was stouter than formerly. The swelling was particularly noticeable in the evening, for then she had to transfer her finger rings to the smaller fingers. This condition began in January, and in February the feet had become so swollen that it was difficult for her to put on her shoes. A yellowish-green hue existed around the nails, and the fingers became stiff, so that she could not close the hands. In May there was slight pain in the left wrist, and the finger tips were dry and scaly. During the summer slight puffiness of the face appeared, and extended down the neck and along the arms. The skin of the left face, arms, and hands became reddish and there was pain in the

joints. The change in the surface tissues antedated the pains by six months. The pain in the joints was described as a soreness. Sweating was noticed. The urine was negative. Pigmentation developed in different places—on the hands, buttocks, abdomen, etc. The gait became restricted, but in no sense spastic. Menstruation was suspended for months. Visceral examination was negative. There was sharp pain over right occipital region, where a raw surface formed. The total solids passed in the urine daily was less than five hundred grains, the phosphates being in excess. Microscopical examination showed no evidence of renal disease. The specific gravity of the urine was low. Under dietetic and hygienic treatment this became normal, and the urine increased both in quantity and in the proportion of its solids. The blood showed an increase of leucocytes. Thyroid treatment was also given, and to this the patient attributed a diminution in the thickening of the skin. At the present time the skin had almost its normal appearance and there was improvement in the other symptoms, including motion in the joints. Permanent stiffness, however, remained in certain of the finger-joints, and the cause of this was explained by Roentgen-ray pictures, which showed light in the movable joints while the shade of the bones was continuous across the joints which remained immovable. With the improvement menstruation was re-established.

Two points of interest in this case were: 1, almost universal disappearance of superficial fat as the case progressed; 2, evidence by Roentgen-ray pictures of involvement in joints of other structures in addition to skin and subcutaneous tissues. Pain was also a marked feature in the case, and was of different kinds: 1, pain in joints, not depending on movement; 2, pain depending on movement; 3, pain suggesting neuritis. Then there were the trophic changes, including an ulcer of the ear and occiput.

Case III. occurred in a Swiss woman, aged thirty-two, and began about four years ago in the fingers and then in the hands, which became swollen and indurated. She had been in the habit of going into an icehouse frequently, and this was supposed to be the exciting factor. First one hand, then the other, became affected, and three years ago telangiectatic spots appeared on the face. When seen by Dr. Dercum the patient's face was markedly altered, the skin was drawn, there was inability to open the mouth widely, the superficial fat had disappeared almost entirely from the body. This patient felt worst in cold weather. At one time the thyroid gland was swollen. The urine was similar to that in the second case, its specific gravity being diminished to 1.009 and the total solids being less than five hundred grains. The amount of urea was considerably less than two hundred grains. The only nervous symptom of consequence was recurring mental depression, twice resembling mild melancholia. The parts most involved were the face, arms, hands, and neck.

The author referred briefly to the features of scleroderma as seen in cases described by other authors, and said, with regard to the influence of thyroid, which was used freely in the second case, that it seemed to have had the effect of hastening the disappearance of fat. Whether, like myxedema, it was dependent upon some change in a ductless gland, we could not yet say. In the first case severe nervous shock seemed to have had some influence, but if shock were a cause scleroderma ought to be as frequent as traumatic neurasthenia. In reality it was known to be very rare.

DR. A. JACOB was requested to open the discussion. He thought the disease was a very rare and a very interesting one. It was so rare that even in the large monograph of Levine, which appeared last year, fewer than two hundred cases were recorded. Yet

most members had probably seen one or more cases. He had had three, and had seen as many as three others. One of his was that of a man in the last stage, seen fifteen years ago, and, differing from many cases, the pigmentation persisted. The subcutaneous tissue had all gone, and he was so much emaciated and so stiff that he had to be lifted from bed. Of the other two cases the one seen in 1874, in a girl of nine years, was the most typical. She had been puny from birth. In the first year of life she had had tonic convulsions, particularly of the lower extremities, slight talipes equinus, and could hardly walk. When he saw her she was much emaciated; along both brachial plexuses were streaks of brownish discoloration raised a little above the adjoining skin: no fat appeared to be left. Similar brown spots were present on the face, scapulae, thorax, gluteal regions, on the thighs, etc. The appearance of the face was characteristic. The skin on the nose and at places on the cheeks could not be raised. She died a year later of pneumonia. The third case was that of a man with various pains and nervous phenomena. He showed one spot of discoloration about two inches long, raised above the surrounding skin. Other symptoms had led Dr. Jacobi to suspect incipient tabes dorsalis. He put him on mercury and iodide of potassium alternately, and the scleroderma disappeared.

In some cases of scleroderma there were so many nervous phenomena that they appeared to point to the nervous system as the commencement of the disease in those particular instances.

Scleroderma and Facial Hemiatrophy. — Dr. CHARLES L. DANA said the only case of undoubted scleroderma among his patients was in a person sent by him a dermatologist for facial hemiatrophy. Until then the scleroderma had not been diagnosticated. He had seen two or three cases of the associated conditions subsequently, there being a probable diagnosis of scleroderma in the atrophic stage. The relationship between the facial hemiatrophy and the scleroderma seemed to be close, if they were not identical. Scleroderma seemed also to bear a close relationship to Raynaud's disease. He felt sorry that Dr. Dercum had not advanced some bold theory as to the etiology. One of three possible explanations which came to his mind had not even been mentioned, namely, microbic origin. The others predicated the possible origin in a ductless gland or in degeneration of some nerve centre.

Dr. BENJAMIN SACHS said his first case of scleroderma was in a widow, aged forty-five, who had been under his observation and that of one or two dermatologists a number of years, and all of them agreed in the diagnosis. Treatment for several years was absolutely useless until they became acquainted with the remedial properties of the thyroid gland. A week after beginning the use of this the skin became again elastic, and she was able to take the needle into the hand and sew, which she had not been able to do for seven years. This case led him to use thyroid gland as an antifat measure long before its effects in this direction had been recorded. Each time the thyroid-gland treatment was discontinued there would be a relapse. This patient had the appearance of double facial hemiatrophy. There was also the slowness of mental action noted in myxœdema. Another case was in a patient who came for treatment of locomotor ataxia.

Dr. N. E. BRILL did not think the disease of bacterial origin. The future alone could show what biochemical change could produce such effects on the nervous system as were seen in some cases of scleroderma.

Dr. JOSEPH E. COLLINS thought the careful examinations of the blood made in two of the cases would probably place this among the most pregnant contributions to the pathology of scleroderma. Those findings would seem to point to none of the sources of origin mentioned by Dr. Dana as possible—microbic,

ductless gland, nervous lesion. They pointed rather to a humoral origin.

Dr. COLLINS thought there was a closer resemblance to acromegaly than to myxœdema, which latter alone had been mentioned to-night. The author's statement that if scleroderma were dependent upon trauma or cold, it would be very common, was no argument against such relationship. If it were, one might say with equal force that if nephritis were dependent upon exposure how common must be nephritis. It was only when certain conditions existed in the economy, whether referable to the nervous system, to the organ in which the disease appeared, or to the general metabolic condition, that the existence of the facts postulated could bring forth the disease. Though these facts were as common as cold, and the disease as rare as scleroderma, yet they should be regarded as cause and effect. His opinion was that scleroderma was a tropho-neurosis dependent on some humoral condition of the blood, and that it might be favored by inherited or by acquired conditions and exist in association with locomotor ataxia, facial hemiatrophy, or Raynaud's disease, the facts productive of one tending to the production of the others.

Dr. ARTHUR BOOTH described a case of scleroderma in the practice of Dr. Jackson. The thyroid gland was somewhat enlarged and the pulse rapid, but there were no nervous phenomena.

Dr. SHERWELL said dermatologists were in the habit of looking upon scleroderma as of nervous origin to a certain degree. He had himself a case associated with double facial hemiatrophy, if one could use the word double in this connection.

Dr. DERCUM closed the discussion.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PLAYFAIR TRIAL—APPEAL GRANTED—COLLEGE-OF-PHYSICIANS PRESIDENCY—DR. WILKS ELECTED—SMALL-POX AT GLOUCESTER—MIDWIVES BILL—MEDICO-CHIRURGICAL—INFANTILE DIARRHŒA—FOREIGN BODIES IN BRONCHIAL TUBES.

LONDON, April 3, 1896.

ON Monday leave to appeal was granted to Dr. Playfair, so the case is not fully disposed of. Nevertheless, many papers have treated the trial as if further litigation was impossible, and both the public and the profession have displayed intense interest in the questions involved—most of all in that of the inviolability of professional secrecy, and this is the one question which makes this *cause célèbre* of vital interest to every medical man. Dr. Playfair was accused of violating a recognized rule of medical ethics by communicating to third parties things that came to his knowledge in the course of professional attendance on a married lady. That lady was, it is true, connected with his wife's family by marriage and on terms of social friendship with his family. It was, therefore, urged that the right to protect his own wife and daughters justified him in divulging a professional secret. This, however, was brushed aside by the verdict of the jury, which awarded the unprecedented damages of £12,000 for the slander. The medical point is that Dr. Playfair removed a substance which he held to be a portion of recent placenta, and, as the lady's husband had been abroad sixteen months, the inference was obvious. He was supported by several obstetricians, but Dr. Spencer, professor of midwifery at University College, pronounced the substance blighted ovum, and he declared it might have re-

mained in the uterus eighteen months. This raises a question which will no doubt stimulate further research by obstetricians. It will be seen that a number of legal issues as well as pathological questions are involved, for the elucidation of which we look to the courts on the one hand and research on the other. But the question of professional secrecy has overwhelmed all others in public interest, and it is almost surprising to see how widespread was the assurance of the public that no doctor would betray the confidence of a patient. The general feeling is strongly that under no circumstances should a doctor betray his patient's secret—at any rate, short of the order of a court of justice, and some seem to hold that even such an order should be disobeyed at the risk of imprisonment. Women seem more outspoken against Dr. Playfair than men. His professional brethren, too, seem to have little sympathy with him. On the question of damages it is thought that the appeal court will reduce the amount, which is more than double what was asked for. There are many other points of interest, but which can very well wait until the appeal is decided.

On Monday the fellows of the Royal College of Physicians elected Dr. Wilks to the presidency. They could not have a better representative of the best minds in their order. The name of Samuel Wilks is known wherever pathology is studied. Guy's is a great school, but has no greater man among its teachers than the learned, acute, industrious physician who succeeds Sir R. Reynolds. As I reported, the ex-president declined to be re-elected. He has suffered from recurrent influenza, but the meeting was glad to be assured that he is now so much better that he might have been able to be present had the date been a week or two later. He was very cordially thanked, as he well deserved to be. An address he had prepared was read by the registrar.

Small-pox continues to scourge Gloucester. Out of six hundred and ninety-three patients one hundred and eighteen have died (up to the 26th ult.). Of ninety persons dying in the hospital it was ascertained that seventy-four had not been vaccinated and the remaining sixteen had not been re-vaccinated since infancy. Only one re-vaccinated person had been admitted. She had been inoculated about fourteen years ago, and contracted the disease while nursing small-pox patients. There were one hundred and seventy-two fresh cases last week. And yet the anti-vaccinationists still attempt to influence the people of Gloucester against the protective. But the consequences of their previous folly are being brought home with such force by the epidemic that the faddists are not listened to so much as under less alarming circumstances.

The Local Government Board has sent Dr. Parsons to advise the city authorities and the vaccination commission has sent down Dr. Coupland to make an independent inquiry into the epidemic. Perhaps this commission, which has now been sitting some seven years, will now hasten its report, that Parliament may have time to consider the question this session. It is remarked that this is the centenary of Jenner, who at one time in his life resided in Gloucester.

The opposition to the midwives bills so successfully carried on by Dr. Kentoul cost him more than £300. Some subscriptions were raised, but he is still £130 out of pocket. It is for the general practitioners, on whose behalf he fought, to reimburse him, and they should do it without delay. The advocates of the midwives soon raised £1,000. Surely the practitioners, whose living was in jeopardy, can spare a few pence each. Another bill is coming on and must be fought.

At the last meeting of the Royal Medical and Chirurgical Society Dr. Hayward and Dr. Buttar, in a paper on "Infantile Diarrhœa," suggested that microbes might be arranged as (1) irritant, (2) toxic,

and (3) infective, the ultimate effect in each instance being brought about by the harmful products of their activity; and this classification was a help in deciding when antiseptics might be expected to be of service. The best success was obtained by employing them in some of the acute forms of summer diarrhœa, and in chronic diarrhœa when bacterial agency might be suspected. Experimental researches by Dr. Hayward and Dr. Buttar as to the influence of drugs on the growth in artificial cultivation of proteus, bacillus coli, and the bacillus isolated in the Portsmouth epidemic by Dr. Klein were brought forward. Some considerations in diagnosis, prognosis, and treatment in infantile diarrhœa concluded the paper. Dr. Dawson Williams said the question raised long ago by Pasteur, whether an animal could live upon an absolutely aseptic diet had curiously enough been solved only the other day. Discredit had fallen on intestinal antiseptics because those who had first used them had talked of intestinal antisepsis, which it was impossible to obtain. In acute summer diarrhœa he found antiseptics of no use, but in the more chronic forms of diarrhœa they were of great value. Naphthalin was useful. He had obtained good results from salol, but the effects of that drug, so far as the intestine was concerned, were the same as those of carbolic acid; and he thought that better results could be obtained by the use of carbolic acid itself. He differed from the writers who said that this drug was most useful in the upper intestinal canal, for, on the contrary, he had found carbolic acid most useful in cases which were presumably instances of colitis. Dr. Kingston Fowler said he was called to see a woman who suffered from severe diarrhœa and a peculiarly offensive odor, which not only impregnated the stools but apparently came off from every part of the surface of the patient's body. He suggested that salol should be given in cachets, but the salol was given in tabloids. In three days the patient was practically well and fetor had disappeared from the motions, but in the latter all the tabloids were discovered undissolved and unchanged. The President (Dr. Dickenson) had observed in the form of diarrhœa associated with very fetid motions that the greatest benefit follows the administration of creosote. Dr. Hayward in reply said that the insolubility of tabloids had driven him back to the administration of fluid drugs.

Mr. R. J. Godlee read a paper on the "Effects Produced by the Retention of Foreign Bodies for Lengthened Periods in the Bronchial Tubes," and gave outlines of half-a-dozen typical cases. Several fellows also mentioned cases, and it seemed to be generally agreed that so long as the body remained there was danger, and as symptoms sometimes came on gradually we should not be too sceptical when the history of a foreign body having entered was forthcoming. Careful inquiries should always be made as to the possibility of a foreign body having been inhaled in cases of unilateral bronchiectasis. Dr. Norman Moore mentioned that Richard Morton in his "Phthisilogia," published about 1690, referred to a case of a man who, when nailing some things on a wall, sucked in three small nails. It was a week before he showed any symptoms and he died in a month. From the description of the necropsy one could gather that the bronchi were considerably dilated and that there was extensive purulent pleural effusion. A man was admitted into St. Bartholomew's Hospital who had "lost down his throat" the end of a clay pipe. He was attacked by coughing and died from hemorrhage. At the post-mortem the end of the pipe was found sticking in the tissue behind the tonsil, and it had induced sloughing which opened into the tonsillar artery. Another man entered St. Bartholomew's Hospital and one side of his chest was found to be resonant, but no

breathing was heard. He died in three days, and the thick end of a pipe was found lodged in one of his bronchi. There was no history of how it got there. Gangrene of the lung proceeded very rapidly in that case. Mr. Warrington Howard spoke of the necessity of persistently endeavoring to remove the foreign body when once it had gained entrance, and remarked that the passage of a foreign body through the nose was one way in which it might reach the larynx. He had recently removed such objects as a screw and the leg of a small china doll from the nostril of a child. Mr. Godlee warned against the danger of inverting a patient unless tracheotomy had been done or everything was ready for the operation.

WORKINGS OF THE MEDICAL-PRACTICE LAW IN MARYLAND.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Last week, in passing a house a few blocks from my office, I noticed a new doctor's sign, and how astonished was I when I read on it the name of a barber who keeps a shop only a couple of squares farther on—my old barber, "*quo tondente gravis juveni mihi barba cadebat!*" I hastened on to the place where the man keeps his shop, led by a painful curiosity and by a superfluous load of hair, and there was the new doctor with his staff of assistants performing delicate operations on the scalps and faces of his customers. "Hair cut, doctor?" he asked. "Hair cut, doctor," I answered. In short, the fellow—an ignorant, illiterate Russian barber, whose functions in that country include putting on cups and leeches, making enemas and blood-letting among the peasants and lower classes—seeing that a barbershop at reduced rates did not pay well enough, bethought himself all of a sudden of supplementing his emoluments with those derived from the practice of medicine, and accordingly went and swore before the authorities that he practised medicine in this city before 1892, paid a dollar, and obtained a license to practise medicine. And this man is not the only "doctor" of this description in the city. I know at least four or five of them in the quarter where I live, who, having been barbers and "leeches" in Russia and having been employed, may be, by some physician as a sort of nurse, after they had picked up a few prescriptions came over here and swore that they were doctors, and were licensed to practise medicine. One of these, an absolutely illiterate man, whose skill in the art of writing is limited to the half-dozen prescriptions which he knows and which he scrawls in an abominable handwriting and with horrible spelling, recently got a city appointment as vaccinator. But it is only these infamous quacks who find it so easy to obtain a license to practise medicine in Baltimore. For while any unscrupulous charlatan is at once enrolled among the "regular" practitioners if he only perjures himself, if a graduate of one of the three or four best medical colleges of the country comes here, with a bachelor diploma besides his medical one and with a State board diploma from a State that maintains the highest standard of medical education of any State in the country, he is told that his credentials count for nothing, and that he has to pass an examination if he wants to practise here. And supposing that this unfortunate graduate is not just out of college, perhaps has passed a year in a hospital, and has forgotten the common and botanical names of drugs, or perhaps never took the trouble to memorize them; and has also forgotten whether the bromides, *e.g.*, are classified by some particular text-book under hypnotics or depresso-motors or antispasmodics, he is very likely to fail on a paper that gives only six questions on every

subject, some of which are of the kind just mentioned. In fact a professor of one of the colleges here assured me that their best man failed at the State-board examinations, while very indifferent men passed.

This is the way the regular medical profession is protected in Baltimore, a city that claims to be an important centre of medical education.

A SUBSCRIBER.

PHYTOLACCA VERSUS ANTITOXIN IN THE TREATMENT OF DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The article in your issue of March 28th, by Dr. E. Alexander, of Juarez, Paso del Norte, Mexico, entitled "The Successful Treatment of Diphtheria without Antitoxin," is one of the class of articles frequently met with in medical journals. I remember an argument between a reputed learned physician and myself twenty-five years ago upon the efficacy of vaccination as a preventative of small-pox, and with another upon the point as to typhus and typhoid fever being identical diseases.

Dr. Alexander informs the readers of your valuable journal that he has "treated hundreds of cases of malignant diphtheria during the past several years with from two to four drachms of fluid extract of phytolacca and one drop of tincture of aconite in a four-ounce mixture, with prompt and complete recovery in all cases." In addition to this general medication Dr. Alexander lays great stress upon the use of a gargle of peroxide of hydrogen or a solution of carbolic oil, eucalyptol, and iodine. At this distance from Dr. Alexander's field of practice I am not competent to judge as to the influence of climate, soil, hygienic surroundings, etc., upon the diphtheritic germ; but if the microbe he has to deal with is similar in character to the one we meet here in malignant diphtheria, there is something wrong. For instance, several years ago I had in my practice an epidemic of diphtheria, among the rest a family having a number of children, of whom two had died. One evening at 4 P.M. I was at the house. A bright little girl came to me, and taking her upon my knee I petted her while giving directions for the night's treatment of the sick. The next morning when making my call the father met me at the door and said another one was dead, and upon inquiry I learned that it was the child I had nursed the evening before. The child had retired in perfect health, and from the first apparent symptom in two hours was dead. In this locality we regard such cases as malignant. Just what effect phytolacca with one thirty-second of a drop of aconite would have had upon this child I am not prepared to say.

I have used nearly all the drugs that have been recommended for diphtheria, and believe that the only one from which any benefit was derived was mercury in some form; all others are accessory.

In 1878 I read a paper upon the subject of diphtheria before the Lancaster City and County Medical Society, taking the ground that diphtheria was a systemic disease produced by a specific virus which was inoculable, that the disease was protective, and advocated inoculation as a preventive measure. Some time after that date I find the following entry in my note-book of cases: "Mr. H. S—, five children; one, four years old, ill with diphtheria. January 28, 1879, removed membrane from throat, abraded the arm of three of the children, and introduced the poison the same as vaccine virus. The eldest boy was not at home. The arms in four days showed signs of inflation at the point of inoculation; upon the fifth day the arms were quite sore and the throat reddened and there was chilly feeling; but none of the children contracted the

disease. The eldest boy, who was not inoculated, contracted the disease and died at his grandfather's." He was exposed the same as the rest. This procedure I have carried out since when a favorable opportunity presented, and in all the cases I have inoculated four days before the outbreak of the disease the patients were rendered immune; but in all cases in which the disease appeared upon the first, second, or third day there was no effect from the inoculation.

We have had an epidemic of diphtheria during the last winter, and my practice has been as soon as the diagnosis was made to use antitoxin. I also do not fail to inoculate the well children. I do not pretend to say that this inoculation is the best thing to do, but it was the best means I had at hand. The ideal measure is to inoculate an animal and take the product to inoculate or vaccinate the patient. Antitoxin is practically the same thing. The virus is injected into an animal and the serum of the blood is the antitoxin. Why not employ the product of inoculation instead; for instance, inoculate an animal and use the product to vaccinate the human subject? This is much cheaper and more easily used.

M. L. DAVIS, M.D.

LANCASTER, PA.

ANTISEPSIS AND ASEPSIS IN LONDON.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The remarks of Mr. Gabriel W. S. Farmer upon asepsis as practised in London, quoted in your editorial of April 11th, indicate that England has not changed for the better since I was there in 1891. But your own comment that "in London surgeons are far from being careful, proving that Lister, their own townsman, is too near to affect them by his example," seems to me to err in two directions: in the assumption that Lister does set a shining example and that his confrères refuse to be influenced thereby. I had the honor of seeing Lister operate in his own amphitheatre, and it remains one of the most interesting and memorable experiences of my life; but so far as asepsis goes, I recall that the example then set by the apostle of surgical cleanliness was imperfect, judged from either an American or a German standpoint.

There were a number of us waiting at Kings College Hospital, a German and several American surgeons, so that when Sir Joseph arrived, quite a retinue accompanied him to the theatre. With a geniality and *bonhomie* which won, I think, all our hearts, the great teacher addressed us, giving the history of the case on which he was about to operate, one of supposed stone in the kidney. The patient was then brought in, and we all began to look about for the antiseptic technique. It consisted in this: Sir Joseph kept his walking coat on, the same in which he had driven to the hospital, rolled up his sleeves about half way to the elbow, washed his hands with soap and water, and swished them around in a basin of double cyanide solution. His assistants, the house staff (undergraduates, to judge them by their looks), followed this example closely; kept on their ordinary coats, rolled up their sleeves, sluiced their hands with the cyanide solution, and were ready. I could not help seeing that the fingernails of the operator and staff were not carefully cleaned, and also that some of them needed such cleansing.

No spray was used. The instruments, whether previously boiled or not I do not know, reposed in what I took to be a carbolic solution. The field of operation was sponged with the cyanide and the operation began.

With beautiful skill the kidney was rapidly exposed, and searched with a needle for stone. None

being found, the wound was washed with the cyanide and closed by tiers of catgut, whether with drainage or not I fail now to recall. Cyanide gauze dressings followed, and the operation was completed.

We were assured that the results obtained under this technique were excellent, which was a poser for the Americans present, and also, I fancy, for the German.

So that when you speak of "surgical misdemeanors in the very home of the prophet," it is only fair to admit that in this matter the master is not above his disciples, and that it may be precisely by force of his authoritative example that English surgery is open to such criticism as that of Mr. Farmer.

At any rate, the example was followed in London five years ago. Sterilization of dressings was unknown, apparently. Clean operating-gowns one saw nowhere. Isolation of the field of operation by sterilized towels or sheets must have been thought too finicky and *doctrinaire* to merit trial. Operations were done in dirty theatres or in wards. The Samaritan and Soho Square Hospitals for women had apparently no operating-theatre, in our sense of the word. The patient's own room, freely decorated with dusty hangings and in some cases with the framed portrait of the operator, were usually employed for this purpose. One of the most famous surgeons at the former hospital I have seen hand a needle to a spectator to hold, while he changed the grip of the holder, using it at once uncleansed in the abdomen; and his nurse would complacently blow her nose and go on wringing sponges, without repeating the tedious formality of washing. But results were said everywhere to be excellent. In a few cases admittedly sepsis crept in, but that would happen anywhere. Not disputing this matter, it did seem sometimes that in some cases at the Samaritan "crept in" was a weak description of the open and undisguised invasion, the march past with colors and drums, the triumphal entry of infection.

Altogether the impression left by London was deep, but unpleasant.

The world will never cease to bless the great man who inaugurated surgical cleanliness, and one hesitates to speak except in reverence of the historic ritual which stamped out sepsis and made scientific and successful surgery possible; but the truth is beginning to be perceived by the English themselves, that the sooner Listerism in all its forms gives place to modern asepsis, the better for English prestige.

WILLIAM S. CHEESMAN, M.D.

AUBURN, N. Y.

THE DRIFT OF MEDICAL CHARITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Much is being written and more said at the present time about the abuse of medical charities; but if any rational, radical, or consistent measures have been adopted by any institution for weeding out the well-to-do from among its beneficiaries in consequence of these indignant ebullitions, the fact has failed to reach us. Occasionally some tired clinician, who has not availed himself of the opportunity of relieving his irritation in print, and who is trespassing on his own office hours in order to accomplish the treatment of some fashionably attired hospital patient, will visit his wrath on the head of his surprised and aggrieved victim. But the next day he recollects that he is in danger of his colleague's clinic running ahead of his own, so the silks and velvets are greeted with gracious smiles.

The physician with an established practice can view the present condition of affairs with the equanimity of

a Calvinistic divine in the presence of original sin. It is to be thundered against, of course, but then it's the other fellow who is responsible for it. The young practitioner, who is the only sufferer, is bound hand and foot. Not only does his chief hold him responsible for any falling off in the attendance, but the greatest of all the hospital commandments is, "No clinical assistant shall refer patients to his own office;" and woe to the man who is caught in the act. It was better for that man if a Penrose investigating committee had its foot on his neck. The well-to-do patient has taken in the situation and, with his thumbs in his armpits, inquires, "Well, what are you going to do about it? If you don't choose to treat me there are plenty of hospitals that will."

If the present order of things is to be changed, it takes neither a prophet nor the son of a prophet to see that it is not the members of the medical profession who are going to bring the change about. Neither does it require any special gift of foresight to see that the ancient order of things will never be re-established. There are broader and profounder causes at work than professional and institutional rivalries and jealousies to account for the changed character of the hospital clientèle, ones with which the closest corporation of physicians and surgeons could fight only a losing battle. There are signs written large which show that the free hospital and dispensary is soon to stand side by side with the free school, the free library, free pleasure grounds, and our other socialistic institutions. Many of our hospitals are already supported by the State and others largely subsidized, and there is a growing class which demands free treatment as a political right without any sense whatever of pauperization. An interne in one of our hospitals which carries on a large outpractice was called out to see a patient for some very trifling cause, and the woman was told that the next time she sent there would be no response. "You are paid by the State and you have to come when I send for you," was the reply. How many times in a month is a doctor thanked for his services? Occasionally a grateful patient offers a small fee. "There, doctor," said a woman as she pressed a dime in her physician's hand, "that is for you. 'Tain't for the hospital; I want you to keep it yourself. You deserve it for all you've done for me." But these occasions are rare. The patient thinks you are well paid by the experience he affords you, and he walks off with his self-respect and self-complacency intact.

If you ask the bank clerk and travelling salesman and the would-be lady in furs and feathers why they come to the hospital instead of going to a doctor's office, they tell you it is because they want the best treatment. They know if their case is a serious one they will have a free consultation over it of the leading specialists. It seems to be only the class for whom dispensaries were originally intended who still have any prejudice against them. "There, honey," said an old colored aunty as she handed out a quarter, "that's all yo're goin' ter git. If I could affo'd to pay mo' I'd have a doctah." "Does yez thenk Oi'd come to tin-cint docthors ef Oi hed the money to pay betther ones?" asked an irate daughter of Erin. Ignorant foreigners, used to the summary methods of their native institutions, imagine that you look upon them merely as interesting subjects of scientific experiment, including vivisection, and will often suffer long before they will take advantage of the aid provided. It is the keen and thrifty native who appreciates the advantages of hospital treatment, or that other class who, in the struggle to keep up an "appearance," have to choose between the doctor's and the milliner's bill.

But while it is easy to see whither the public and the hospital are both tending, it is not so easy to say

what is to become of the thousands of physicians who are being turned out yearly from our colleges and universities. That salaries will have to be provided ultimately in every branch of the hospital service is a statement that admits of no denial. But co-operation and concentration in medical work, as elsewhere, means a reduction in the number of laborers, and the increasing army of the unemployed here have the same privilege as the twenty-five hundred starving physicians of Paris.

Medical charity is not a question that can be solved by itself. It is part and parcel of a larger problem at which the whole of civilized humanity is working just now. But one cannot help speculating how philanthropic old ladies and ambitious testators, with their traditional ideals of amelioration, will feel when they begin to realize what radical social tendencies are being fed by their self-denials and intended benefactions. Would it not be well to suggest to some of them that they divert a part of the funds into endowing a Home for Indigent and Indignant Physicians and Surgeons or into founding a Society for the Suppression of Medical Students?

HELEN MURPHY, M.D.

PHILADELPHIA, March 14, 1896.

NOTES ON THE LECTURES OF BENJAMIN RUSH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: An extract from the *Journal of the American Medical Association* in your issue of April 4th calls attention to "a volume of notes in the handwriting of a medical student who attended the lectures of Dr. Benjamin Rush in 1784," which has recently become the property of the Rush Medical College, Chicago.

There is in my possession a bound volume of three hundred and eighty-eight pages, in excellent preservation, written in a plain hand, entitled "A Course of Lectures on the Theory and Practice of Medicine, by Benjamin Rush, M.D., Professor on Theory and Practice of Medicine in the College of Philadelphia. Read in the College from November 1, 1790, to February 1, 1791."

The volume was copied for my grandfather, the late Dr. Thomas O'H. Crowel, of Catskill, N. Y., in 1791, and is inscribed as "a literal copy from a similar volume, belonging to Elihu H. Smith," a native of Litchfield, Conn., who contributed the following:

"Preface. The following Volume consists of Notes taken down at the reading of the different Lectures. In copying them, I have omitted many things which were imperfectly obtained; Some entire dissertations, which might be procured more at large in books; and the Histories of diseases, wherever they could be supplied by Dr. Cullen's First-lines of the Practice of Physic. The work now stands as a monument of the joint labours of my fellow-student, Mr. Robert Johnston, and myself. And it is not without some pride that I thus unite my name with his, whose Talents for Observation, and Abilities for Medical Researches, promise him a distinguished rank among the Great Physicians of the Nineteenth Century. E. H. Smith."

Dr. Smith entered upon the practice of his profession in New York City, displayed great ability, became associated in the editorship and publication of a medical journal, the title of which I cannot recall, and while still a young man, fell a victim to yellow fever, which prevailed in epidemic form with intense malignity.

An index, in red ink, in the writing of Dr. Crowel, includes one hundred and thirty-five subjects, among which are amnesia, anger, breeding-sickness, costiveness, dropsy, epilepsy, fear, grief, hydrophobia, in-

flammatory fever, love, lust, madness, and so on, to the end of the alphabet.

WM. C. WEV, M.D.

ELMHURST, N. Y., April 11, 1896.

Therapeutic Hints.

Chronic Diffuse Nephritis.—Chronic diffuse nephritis is more frequent in males than in females, and occurs chiefly in persons past middle life. Constitutional syphilis, intemperance, and privation are counted among the most prolific causes. My personal experience has led me to think that the disease is especially frequent among brain workers, among men whose nervous systems are continually on an overstrain, who have large business responsibilities, and who, as a rule, lead temperate lives.—DR. BIERWIRTH (*New York Medical Journal*, April 4, 1896).

Miliary Tuberculosis.—Reported cases of cures of general miliary tuberculosis involve an error of diagnosis. The prognosis is absolutely fatal, but the almost always present impossibility of unimpeachable diagnosis makes a positive prognosis out of the question. The treatment is entirely symptomatic. Palliative treatment is frequently indicated and all means and measures of treatment—hygienic, dietetic, and medicinal—are addressed directly or indirectly to the increase of the tolerance of the patient.—PITT (*Medical Review*, March, 1896).

Interstitial Keratitis from Syphilis.—Protect the eyes by means of smoked glasses. If iritis be present instil atropine; wash the eye with a four-grain solution of boric acid. Mercurial ointment, in inunctions of one drachm, should be rubbed into the abdomen twice daily. If the patient does not stand inunction, give one-forty-eighth of a grain of bichloride of mercury with eight drops of tincture of chloride of iron. If the disease progresses, hot-water compresses will be found to be of advantage. If great pain be present in the frontal or temporal region, leeching the temple may be resorted to and gives prompt subsidence of the symptoms.—NORRIS.

Coryza. —

R Ichthyol. 1
Ether, ...
Alcohol āā 1
Distilled water 97
M. S. To be sprayed into the nose.

—DR. VUENSCHÉ (*Le Progrès Médical*).

Threatened Abortion.—Suppositories of opium, one grain in each, one to be given at night and in the morning, together with the fluid extract of viburnum prunifolium in doses of one drachm four times a day.—HIRST.

Herpes Zoster. —

R Starch. 3 iv.
Zinc oxide 3 i. 3 iv.
Camphor gr. iv.—gr. xii
Opium gr. iv.
M.

For the accompanying neuralgic pain a pill of the following composition may be administered three or four times a day:

R Extract of stramonium,
Extract of hyoscyamus āā gr. 1.
Extract of belladonna gr. 1.
M.

—ROBIN.

Pediculi.—Oil of sassafras will destroy pediculi and their ova.

Antitoxin.—The dose of antitoxin used depends upon the time of making the injection, the body weight

of the individual, and the gravity of the disease; also whether it be used for the purpose of immunization or for cure. I should also add it is necessary to know the strength of the antitoxin to be used.—ROSENTHAL (*Atlantic Medical Weekly*, March, 1896).

Locomotor Ataxia.—Tabes began with lancinating pains in 67 per cent. of cases; bladder symptoms in 22 per cent.; disturbances of the sexual functions in 15 per cent. On the whole, the knee-jerk was absent in 92 per cent. of cases; lancinating pains present in 88 per cent.; pupil symptoms in 70 per cent.; impotence in 58 per cent.; "girdle" sensation in 31 per cent.; optic atrophy in 6.7 per cent.; and crises in only 5 per cent.—DR. LEIMBACH (*Deutsche Zeitschrift für Nervenheilkunde*, Band vii., Heft 5 und 6).

Acute Bronchitis. —

R Bromoform gr. exij.
Codeine phosphate gr. xv.
Compound syrup of squill 3 iiss.
Syrup of lactucarium ad 3 iv.
Powdered gum arabic q.s.
M. et fiat emuls. S. Two teaspoonfuls every two hours.

—DR. BABCOCK (*Medicine*, March, 1896).

Bronchitis and Asthma. —

R Potassii iodidi 3 ij.
Ammon. carb. 3 i.
Tinct. lobeliae 3 ij.
Spts. chloroformi 3 iv.
Vir. ipecac 3 i.
Inf. senegæ q.s. ad 3 vi.

M. S. A tablespoonful in a wineglass of water every four hours.

—*American Medical Review*.

Hemiplegia from Diphtheria.—Nevertheless, rare exceptional cases do occur which offer difficulties in diagnosis, such as those which arise after slight preceding symptoms, with hemiplegias and monoplegias, ushered in by apoplectic attacks. Such cases are, however, in contradistinction to the typical picture of diphtheritic paralysis, the greatest rarities, and will scarcely come to the observation of even very experienced physicians.—VON ZIEMSEN.

Pruritus Vulvæ.—Local applications of warm chloral solution (one per cent.) twice daily; ten-per-cent. solutions of chloral; corrosive sublimate, 1 to 500; and an ointment containing one part of olive oil, three of menthol, and six of lanolin. If these are not beneficial, the galvanic or faradic current may be applied. Excision of the affected parts is a last resort.—MARAIN (*Centralb. für Gynäkol.*, 1895, No. 49).

To Prevent Lacerations of Perineum.—1. Guide the head forward along the pubic bones. 2. Hold head back during several pains, thus allowing the muscles of the perineum time to relax. To overcome the powerful force of the abdominal muscles, tell the patient to breathe very quickly; this causes them to lose their power.—McKELWAY.

Suprarenal Capsules.—Recent experiments apparently prove that the suprarenal capsules are nervous ganglia. Their total extirpation invariably causes death within two, three, or four hours.—*Lancet-Clinic*.

Chronic Lead Poisoning.—1. Remove source of poison. 2. Relieve colicky pains by the administration of belladonna and opium. 3. Relieve constipation by giving one grain of calomel every hour for five hours, to be followed by a full dose of Epsom salts and by rectal injections. If this should fail give croton oil. 4. To eliminate the lead give potassium iodide in ten to twenty grain doses three or four times daily. 5. If patient is apoplectic, bleed. 6. If patient is anæmic, give iron. 7. Restore functions by the use of strychnine and electricity.—WOOD.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 18, 1896:

	Cases.	Deaths.
Tuberculosis.....	212	141
Typhoid fever.....	5	3
Scarlet fever.....	115	8
Cerebro-spinal meningitis.....	4	5
Measles.....	531	36
Diphtheria.....	239	38
Small-pox.....	0	0

Requirements for Medical Graduation and Medical License in the Different States.—Mr. James Russell Parsons, Jr., director of the examination department of the Board of Regents of the State of New York, has kindly furnished us with the following official report founded on the statutes at present in force in the different States:

1. Of the one hundred and forty medical schools in the United States, there were only fourteen in 1894-95 which absolutely required a four-year course of medical lectures, four of these schools being in New York State. Details with reference to the length of courses for graduation in this and in other countries were given in my 1894 report, a copy of which is sent herewith. Since that date other schools, such as the medical department of the University of Denver, the University Medical College of New York City, Eclectic Medical College of New York City, Syracuse University of Syracuse, and the medical department of the University of Buffalo have adopted four-year courses. Following is a list of the medical schools which have adopted four-year courses, with date of adoption, as given in the report of the examination department for 1894:

College of Physicians and Surgeons (New York), 1894-95.

New York Medical College and Hospital for Women, 1894-95.

New York Homœopathic Medical College and Hospital, 1894-95.

Woman's Medical College of New York Infirmary, 1894-95.

University of Pennsylvania, 1893-94.

Women's Medical College of Philadelphia, 1893-94.

Harvard University Medical School, 1892-93.

Boston University School of Medicine, 1890-91.

Department of Medicine and Surgery, University of Michigan, 1890.

Homœopathic Medical College, University of Michigan, October, 1891.

Northwestern University Medical School (Illinois), 1893-94.

Meharry Medical Department of Central Tennessee College, 1893-94.

Johns Hopkins Medical School, 1893-94.

Leonard Medical School (North Carolina), 1882-83.

2. The present New York medical law, as amended by laws of 1896, ch. 111, which took effect March 21, 1896, will require as a condition for admission to the licensing examination and as a condition for an M.D. degree, four years' study of medicine and four satisfactory courses of medical lectures for matriculants after January 1, 1898.

3. The constitution of the Association of American Medical Colleges, including sixty-three medical schools in the United States, will require of candi-

dates for an M.D. degree in 1899 or thereafter, four years' study of medicine and four courses of lectures of not less than six months each, with the following exemptions:¹

a. Graduates of recognized colleges and universities who have completed the prescribed course in chemistry and biology therein.

b. Graduates and matriculates of colleges of homœopathy.

c. Graduates and matriculates of colleges of eclectic medicine.

d. Graduates and matriculates of colleges of dentistry requiring two or more courses of lectures before conferring the degree of D.D.S. or M.D.

e. Graduates and matriculates of colleges of pharmacy.

f. Graduates and matriculates of colleges of veterinary medicine.

All students are required to comply with the provisions of the entrance examination and prove their fitness to advanced professional standing by an individual examination upon each branch below the class he or she may desire to enter.

4. In twenty-one States at present writing diplomas do not confer the right to practise medicine, an examination being required in all cases. Following are the States referred to:

Florida, Rev. Stat. 1892, § 806.

Delaware, Laws 1895, ch. 4.

Georgia, p. 85, 1894.

Louisiana, Laws 1894, ch. 49.

Maine, Laws 1895, ch. 170.

Maryland, Laws 1892, ch. 296; Laws 1894, ch. 217.

Minnesota, Statutes, § 671.

Mississippi, Code, § 3,243.

Montana, Pol. Code 1895, § 600.

New Jersey, Laws 1894, ch. 306.

New York, Laws 1893, ch. 661.

North Carolina, Code, § 3,121.

North Dakota, Rev. Pol. Code, § 275.

Oregon, Laws 1895, p. 61.

Pennsylvania, Laws 1893, ch. 52.

South Carolina, Laws 1893, ch. 25.

Texas, Civ. Stat., § 3,632.

Utah, Laws 1894, ch. 77.

Virginia, Laws 1894, ch. 7.

Washington, Laws 1889-90, p. 114.

West Virginia, Laws 1895, ch. 7.

Indian Territory (Cherokee Nation).

In some tables Alabama and Massachusetts are classed with the States in which diplomas confer no right to practise, but there are certain exceptions in the Alabama law (see Civil Code, § 1,296), while in Massachusetts (Laws 1894, ch. 458) graduates of Massachusetts medical colleges are exempt from examination.

5. The thirteen following States require either approval of medical diploma or examination by State or other duly qualified boards:

California, Code.

Colorado, Gen. Stat., vol. 4, p. 625, § 2,547 f.

Connecticut, Laws 1893, ch. 158.

Illinois, Laws 1885, p. 225.

Iowa, Code, § 2,546.

Kentucky, Laws 1893, ch. 179.

Missouri, Rev. Stat., § 6,871.

Nebraska, Laws 1891, ch. 35.

South Dakota, Laws 1893, ch. 133.

Tennessee, Laws 1889, ch. 178.

Vermont, Statutes 1894, § 4,633.

Rhode Island, Laws 1895, ch. 1,353.

Indian Territory (Choctaw Nation, Creek Nation).

Territory of New Mexico, Laws 1895, ch. 7.

Territory of Oklahoma, Statutes 1893, § 352.

¹ That is, admission to advanced standing.

6. Ten States require only presentation of diploma or other certificate of qualification to unqualified local officers:

Arkansas, Laws 1893, ch. 75.
Idaho, Code, § 1,298.
Indiana, Burns An. Stat., § 7,319.
Kansas, Gen. Stat. 1889, § 2,450.
Michigan, Howell An. Stat., § 2,287 f.
Nevada, Gen. Stat., § 4,974.
Ohio, Rev. Stat., § 6,992.
Wisconsin, S. and B. Stat., § 1,423, § 1,436.
Wyoming, Code, § 1,925.
Territory of Alaska.
Territory of Arizona, Laws 1893, ch. 66.
District of Columbia.

7. Though in all States except New Hampshire, in which no registration is required, certain attempts have been made to regulate the practice of medicine, yet these attempts are crude and imperfect in the ten States which require only the presentation of authority to practise to unqualified local officers. The New York plan, now adopted in twenty-one States, is the most effective.

New Hampshire has no legal requirement.

Twenty-one States require examination in all cases.¹ Alabama and Massachusetts also usually require it, but certain counties are excepted in Alabama (Civil Code, § 1,296, 1886), and in Massachusetts graduates of medical colleges in the State (Laws 1894, ch. 458). Neither requires diploma or special training before examination.

Florida, Rev. Stat. 1892, § 801 f, passed 1889. Board of three examiners in each judicial district. Diploma required. No further conditions.

Delaware, Laws 1895, ch. 40. Two State boards, regular and homœopathic. Diploma, study four years, including three regular courses of lectures in different years. Competent common-school education.

Georgia, Laws 1894, p. 85. Three State boards—regular, homœopathic, and eclectic. Diploma from college requiring three full courses of six months each.

Louisiana, Laws 1894, ch. 49. Two State boards, regular and homœopathic. Diploma of college in good standing, as determined by board. "A fair primary education."

Maine, Laws 1895, ch. 170. Diploma not required. Applicant to give proof of "possessing a reasonable amount of average knowledge in the branches of science he desires to practise in." General subjects of examination named.

Maryland equals New York (1890), Laws 1892, ch. 296. Two State boards, regular and homœopathic. Diploma (or license in foreign country), study of medicine three years, three courses of lectures in different years. Competent common-school education.

Minnesota, Kelly Rev. Stat., § 671 (passed 1887, ch. 9). Examination after three courses of lectures of six months each. Laws 1895, ch. 89, adds that after January 1, 1899, four courses are required. No diploma.

Mississippi, Code 1892, § 3,243 f (essentially the same as Laws 1882, ch. 19). State board of health grants license. Application to state details of preparation. No requirements in law.

Montana, Pol. Code 1895, § 600 f (passed 1895). Diploma after January 1, 1898, four courses of six months each.

New Jersey, Laws 1894, ch. 306 (equals Maryland and New York 1890). Diploma or foreign license, four years' study, three courses in different years. "Competent common-school education."

¹ Unless stated no further conditions required, and one State board of examiners only.

New York, Laws 1890, ch. 507. Three State boards—regular, homœopathic, and eclectic. Diploma or foreign license. Three years' study, three courses, competent common-school education. Amended, Laws 1895, ch. 636, requiring higher degree of previous training, gradually increasing till in 1900 a full high-school course is necessary.

North Carolina, Code, § 3,121 (passed 1858-59, ch. 258). Examination on specified branches. No details.

North Dakota, Code 1895, § 275 f (essentially the same as Laws 1890, ch. 93). Examination after three courses of six months each (equals Minnesota).

Oregon, Laws 1895, p. 61. Applicant to state details of training. No requirements in law (equals Washington).

Pennsylvania, Laws 1893, ch. 52. Three State boards—regular, homœopathic, and eclectic. Diploma or foreign license after four years' study and three courses in different years. "Competent common-school education" (equals New York, 1890).

South Carolina, Laws 1893, ch. 325. Diploma.

Texas, Civil Stat., § 3,632 (passed 1876, equals North Carolina).

Utah, Laws 1894, ch. 77. Diploma from chartered medical colleges in good standing.

Virginia, Laws 1894, ch. 70. Laws 1883, ch. 65, also require examination in all cases.

West Virginia, Laws 1895, ch. 7.

Amputation of the Leg at the Knee-Joint.—Dr. W. H. Buechner says (*Journal of the American Medical Association*, March 21, 1896) that the first mention of removal of the leg at the knee-joint dates back to 1581 and the operation was performed by Fabricius Hildanus. The method then seems to have been lost until 1764, when it was again brought to light by Hoin and indorsed by Petit and Brasdor. It was not, however, until Velpeau popularized it in 1830 that it began to approach the place which it now holds in the domain of surgery. The first American operation by this method was that of Dr. Nathan Smith in 1824.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

BOOKS RECEIVED.

THE HISTOPATHOLOGY OF THE DISEASES OF THE SKIN. By Dr. P. G. Unna. Translated by Dr. Norman Walker, Svo. 1,205 pp. Illustrated. Macmillan & Co., New York.

HAHNEMANN'S DEFENCE OF THE ORGANON OF RATIONAL MEDICINE. Translated by Dr. R. E. Dudgeon. 12mo, 130 pp. Boericke & Tafel. Philadelphia, Pa. Price \$1.00.

WATER SUPPLY. By William P. Mason. Svo, 504 pp. Illustrated. John Wiley and Sons, New York.

FEAR. By Angelo Mosso. Translated by E. Lough and F. Kiesow. 12mo, 278 pp. Longmans, Green & Co., New York.

THE NON-HEREDITY OF INEBRIETY. By Dr. Leslie E. Keeley. 12mo, 359 pp. S. C. Griggs & Co., Chicago, Ill.

A HAND-BOOK ON LEPROSY. By Dr. S. P. Impey. Svo, 116 pp. Illustrated. P. Blakiston, Son & Co., Philadelphia, Pa. Price \$3.50.

APPENDICITIS FROM THE MEDICAL STANDPOINT.

By W. N. McARTNEY, M.D.,

FORT COVINGTON, N. Y.

THE advances made in the diagnosis and surgical treatment of appendicitis in recent years have placed the treatment of this serious malady on a more scientific basis. That immense strides have been taken no one can deny, and yet current medical literature, as it appears in the journals, deals mainly with the surgical aspect of the disease, either almost entirely ignoring or utterly condemning its medical treatment. The practitioner who gives opium in appendicitis is severely criticised for using a drug which "masks the dangerous symptoms" of a malady that is almost certainly fatal if treated medically, and to temporize and treat the patient with hot applications and opium is frequently characterized as unscientific and cowardly. He is too conservative, or not conservative enough, out of date, too timid. He lacks the moral backbone to inform the patient of the necessity for operation, and in his abject cowardice, ignorance, or incompetence, calls the disease inflammation of the bowels, blunts the patient's sensibilities with opium, and the patient, after a fruitless struggle with the inevitable, dies a victim of the timid and temporizing policy of his medical attendant.

On the other hand the skilful, well-educated, scientific physician of to-day, when called to a case of appendicitis, familiar with the pathology, diagnosis, and manifold dangers of this dread disease summons at once a surgeon of ability to decide on the necessity and proper time for an operation, and the surgeon, with the dexterity born in him and perfected by so many hundreds of similar operations, opens the abdomen, removes the appendix, charges a round fee, and the patient makes a rapid and uneventful recovery. Look on this picture, then on that, the "before and after taking" the operative surgeon into counsel. This is at least the note we have heard most frequently of late.

Even some of our most eminent men in the profession, though more courteous in their language, trend the same way. Wyeth, in the *MEDICAL RECORD* of April 28, 1894, says that appendicitis should always be regarded as a surgical disease. Dr. Baruch tried medical treatment four years "and the patients died"; he advises against giving morphine, as it would obscure the symptoms. Duckworth says delay is little short of criminal. R. T. Morris makes it his rule to operate as soon as the diagnosis is made, no matter what stage of the disease (*MEDICAL RECORD*, February 15, 1895). G. R. Fowler states that the cases in which recovery ensues after the disease is well under way are exceedingly rare. Reclus asserts unqualifiedly that the diagnosis once having been made, surgical interference cannot be brought too early into the case. Murphy, in the *Philadelphia Medical News*, as quoted by the *MEDICAL RECORD* of August 31, 1895, says: "The rule

first, last, and always should be, operate on every case of appendicitis, promising or unpromising, at the earliest possible moment," while Roux, of Lausanne, advises us not to allow ourselves to be "intimidated."

These are certainly strong statements, and I may add from strong men. While every one has a right to his own honest convictions, yet some do not stop here, and to characterize the physician who does not immediately become an enthusiastic and out-and-out convert to these extreme views as incompetent, criminal, and cowardly savors of Tillmanism rather than logic, and is begging the question.

That the operation has done much for mankind, that it has come to stay, that it is frequently necessary and sometimes imperative, I fully and freely admit, and I believe that the men who have by earnest labor worked out the pathology and treatment and have improved the technique of the operation should receive all honor for the same, but I protest against the statement, either direct or by implication, that the physician who treats the average case of appendicitis on medical principles without resort to surgical measures is necessarily unskilful, ignorant, incompetent, unscientific, unsuccessful, or cowardly.

The physician fortunately situated near a well-equipped hospital who, when called to a case of appendicitis and recognizing the gravity of the case, sends his patient to the hospital or calls in a surgeon to operate, meets with approval as doing eminently the proper thing, and yet he may with equal fairness and justice be accused of cowardice in shifting the responsibility of a serious case to other shoulders. On the other hand, the practitioner less favorably located, a long distance, it may be, from an operative surgeon specially skilled in abdominal work, and still farther away from a hospital, may "mask the symptoms" with opium without being a coward. Perhaps

"He hath a wisdom that doth guide his valour
To act in safety,"

and perhaps experience or common sense, or a modicum of both, has taught him that his patient's chances of recovery were slender indeed were he to wait for an operator from some distant city, doing his surgical work under unfavorable sanitary conditions, at a date much too late, and with lack of proper care in the after-treatment. Suppose, for instance, that the patient lives ten miles away over frozen November roads, in the care of some old lady who does "family nursing." He may not be able to pay for the services of a skilled specialist. The doctor may find it impossible to get medical assistance, and may have no one to leave in charge of the case afterward. He might nurse the patient himself were it not for a dozen or two other serious cases depending solely on an already overworked man. Is the doctor necessarily a coward because his desire for operation is not keen in the face of all these disadvantages and many others I could enumerate?

And the patient, poor fellow, dies as the result. Not necessarily by any means. Perforation! gangrene! suppurative peritonitis! septicæmia! Don't all speak at once. I have heard of these things before. The doctor puts the patient on a light diet, gives opium

freely, applies a turpentine stupe possibly, if symptoms are not sufficiently "masked," gives more opium, and usually the patient recovers. Why? *Vix medicatrix natura*, assisted by the doctor.

During the past six years I have treated in all twenty-four cases of appendicitis. All recovered. Two have since died, one a year later from pulmonary phthisis, from which he was suffering at the time of his attack; the other from meningitis caused by an obscure head injury from being struck by a wagon some months after he recovered from the appendicitis. But all recovered from the appendicular disease. There were twenty males and four females, the ages ranging from fifteen to forty-four years. All of these cases were treated without operation.

But were these twenty-four cases all cases of appendicitis? That would be difficult to prove absolutely, as naturally no post-mortems were held. But I have seen appendicitis when it was a "new" disease. I have made a diagnosis of appendicitis in cases in New York and had the diagnosis confirmed by operation. I have seen operations for appendicitis, have assisted at these operations, have operated myself. I have made autopsies on those who died of appendicitis, and have made more on those who had had it in previous years, recovered, and died from other causes, and I feel competent at least to make a diagnosis of appendicitis in any ordinary case, and I say without hesitation that these twenty-four cases were cases of appendicitis.

These cases were all treated in private practice in villages or the surrounding country. I came here thoroughly imbued with the idea that I must operate for appendicitis, but found the difficulties practically insurmountable in most instances: therefore I treated the cases medicinally. Some of these cases were mild in type, but sixteen were severe. Several had recurrent attacks. Four developed abscess, two opening into the bowel, one into the bladder, and one externally. In a number of cases the temperature ranged 104° F. for days. In one case the bowels were locked for sixteen days, in another for twenty-one days.

Why should every case of appendicitis be operated on? If your patient refuses operation, are you not justified in treating him to the best of your ability without?

The symptoms of appendicitis are vague. Colicky pain, constipation or diarrhoea, nausea and vomiting; nothing diagnostic about these. Then severe pain in the abdomen, usually locating sooner or later in the region of the appendix, and made worse by movement. The patient lies very still, leg drawn up, bowels obstinately constipated—as a rule, not always; fever, rapid pulse, chill, tenderness over McBurney's point, rigidity, and distention of the bowels. Are these symptoms of appendicitis or of the peritonitis which accompanies it so commonly? Are these symptoms of the disease or of nature's defensive warfare against invasion of the peritoneal cavity? The truth lies just here: that the symptoms pertaining to appendicitis proper are largely negative, while the symptoms usually classed as such are merely the evidences of the conservative power of the human system. Nature's bulwark is being thrown up and the peritonitis is a conservative process. When the peritonitis is absent look out for a "fulminating" case, and a dangerous one.

You put your hand in the fire and it burns, pound your thumb with a hammer and it hurts, eat too many hard-boiled eggs and you have a frontal headache. Nature's way of saying "Take care." You get an appendicitis, and a consequent localized peritonitis, and nature puts you to bed, right leg drawn up to relax the abdominal wall and psoas muscle. You don't toss about with peritonitis. It hurts when you move. Nature's way of saying "Keep still." Bowels are con-

stipated. Why? To stop peristalsis. Tympanites comes on—paralysis of the muscular coat, to stop peristalsis and afford pressure.

The general practitioner gives an opiate in full dose. This doesn't quiet the pain. Why? Not enough to mask the symptoms? No, not enough to stop the peristalsis: stop the peristalsis and the pain is checked. And what happens now that the dangerous symptoms are "masked"—sudden death and general desolation? Not generally nor usually. The patient lies absolutely still, with coil after coil of intestine pressed closely against the cæcum and appendix—not round coils, but flattened, faceted coils fitting each other accurately without interspaces and pressed by rigid abdominal walls; later, from tympanitic distention. No peristalsis; absolute adjustment of their serous surfaces, and then a plastic exudate thrown out, gluing them all firmly together in a few hours.

"The great danger is peritonitis," says Wyeth. "The safety lies in the peritonitis" would be more proper. There is no peritonitis in the fulminant cases. Given a peritonitis localized about the appendix, and the adhesions grow firmer hour by hour and day by day. Then what happens? Catarrhal inflammation quietly subsides. Ulcer perforates. Where? Nowhere; up against the next coil of adherent intestine. Foreign body or fecal concretion ulcerates through. Where? Up against a glued-up coil of ileum. It can go back again where it came from: it can remain embedded and encysted in the exudate; it can go on ulcerating through into the coil of ileum, falling into the intestine, discharging when the bowels move, and leaving a small intestinal anastomosis between the appendix and the ileum to heal up shortly.

Suppuration may occur and an abscess in the appendix perforate, or an abscess form around the foreign body. What becomes of it? It may be absorbed, may perforate into and discharge by the bowel, may perforate into the rectum or into the bladder, may form a retroperitoneal abscess, or point externally. On the other hand it may rupture into the peritoneal cavity, but that is just what nature has been guarding against with her plastic peritonitis and you have been aiding her in her efforts to raise a bulwark in that direction.

The appendix may become gangrenous. It sloughs, softens, disintegrates, is discharged through its own stub, "hoist by its own petard." Perhaps it forms an abscess, which discharges offensive pus, perforating in the usual way. This is nature's way, nature assisted by the doctor, and she is often competent to handle a more serious matter than a diseased appendix two or three inches long and the size of a pipe-stem. Then the tympanites subsides. The pain doesn't subside, for the patient has had no pain under opiates. The tenderness disappears and with it the necessity for opiates; after a time the bowels move, unnecessary adhesions are absorbed, and the patient recovers. But in another case nature starts her plastic exudation, the doctor is called in, palpates forcibly perhaps to feel the appendix, makes a rectal examination. No morphine—salines. No improvement on the following day. Another examination, followed by sudden collapse. Then an operation. Gangrene, abscess, perforation, pus among adjacent coils of intestine. The appendix is amputated, the pus wiped out, the abdomen sewed up, and the patient recovers. Surgery has again triumphed. But might not an equally good result have been accomplished without operation? In the vast majority of cases, yes.

In performing autopsies I have been struck by the frequency of evidences of old adhesions about the appendix. In two instances I have found fecal concretions in the near vicinity of the appendix. In other cases I found the evidences of old inflammatory, ul-

cerative, or suppurative lesions. In one case the appendix was entirely obliterated. In one of the cases, in which a fecal concretion was found encysted, the patient, a physician himself, had given me prior to his death from surgical kidney a clear history of an attack of peritonitis beginning in the right iliac fossa twenty years previous.

The twenty-four cases referred to above were treated by opium, lots of it, given early, until pain was relieved, until peristalsis stopped; given without regard to the regulation dose, given until the effect was manifest. Sometimes morphine was used, sometimes opium. Sometimes ice was applied externally, but usually it was not well borne and moist heat was substituted. Turpentine stupes, intestinal antiseptics, liquid diet. When tympanites was not excessive it was let alone, being regarded as a conservative agent. When it was excessive and troublesome I found that turpentine usually failed to give relief, but that a rectal injection of quinine, six or eight grains, dissolved in aromatic sulphuric acid and mixed with acacia water, after the manner of Keith, was usually successful. In most of the cases a boggy tumor formed in the right iliac fossa. This was usually painted with iodine, and the iodides were given internally if it did not resolve. The bowels were allowed to move of their own accord, as a rule.

I speak from personal knowledge of these cases when I say that if every case "promising or unpromising" had been "operated on at the earliest possible moment" some of them would not have survived the operation. I am morally convinced of this, knowing the state of these patients and the surrounding conditions. One was, as stated, in an advanced stage of phthisis; another was a diabetic. In several cases the symptoms were for a time so alarming that I stood ready to operate on short notice, but the confidence born of previous success in treating these cases without operation and the difficulties in the way of operating with inadequate assistance led me to hold my hand.

Perhaps these twenty-four consecutive recoveries constitute an instance of "gambler's luck." If so I shall follow my streak until the luck turns. Possibly, however, nature may have had, under the plan of treatment followed, a fair chance to show what she could do. At least the treatment was a conservative one, following nature's method of cure and based on the principle that the peritonitis was not a dangerous but a reparative process. In recurrent appendicitis I have usually advised operation, but I have noticed that the recurrent cases have usually been mild. Where there was a severe and prolonged attack it has never in my experience been followed by a second attack.

In conclusion I would suggest that:

1st. The symptoms of appendicitis are vague, most of the symptoms so classed being those of a localized peritonitis subsequent to the appendicitis.

2d. That this peritonitis is not a dangerous but a conservative process.

3d. That the proper treatment in non-operative cases is to favor the formation of plastic exudate and to secure firm adhesions.

4th. That the dangerous cases are the fulminant cases, in which no warning peritonitis exists.

5th. That opiates do more than obscure the symptoms and that cases of recovery under this treatment are not "exceedingly rare," but that the medical treatment is rational and more successful than usually admitted.

6th. That it is too soon to lay down, as yet, a dogmatic and arbitrary rule that every case should be operated on, regardless of consequences.

7th. That the physician who treats cases of appen-

ditis with opium is not necessarily a coward physically or morally, and that his medical judgment may sometimes compare favorably with that of physicians who advocate the indiscriminate removal of every diseased vermiform appendix for a good consideration.

THE QUESTION OF POSITION IN THE TREATMENT OF FRACTURES OF THE LOWER END OF THE HUMERUS—THE TESTIMONY OF SIX HUNDRED AND FIFTY CASES UNDER THE CARE OF HARTLEY AND WOODBURY, CURTIS, VAN ARSDALE, AND THE AUTHOR.¹

By CHARLES A. POWERS, M.D.,

DENVER, COL.,

SURGEON TO THE ARAPAHOE COUNTY HOSPITAL, CONSULTING SURGEON TO ST. LUKE'S HOSPITAL.

UNTIL recent years there was but little difference of opinion regarding the position in which the elbow should be placed in fractures at the lower end of the humerus; the right angle was unanimously advised and employed, and this for the reason that the arm was in the most useful condition possible in case ankylosis ensued. The position was classic, and the injunction to begin passive motion at an early date in order to prevent ankylosis was faithfully followed. In 1880, however, Dr. Oscar H. Allis, of Philadelphia, in a most careful and scientific essay called attention to the change in the axes of the arm and forearm which may take place when the outer condyle slips down or the internal condyle is displaced upward, resulting in a deformity to which the term "gunstock"² is applied. For the avoidance of this Dr. Allis recommended that the forearm be placed in a position of extension. He also strongly emphasized the important principle that no passive motion be made at the elbow until union should be complete. This latter proposition, I believe, admits of no debate in the average case; passive motion before consolidation of the fragments leads to rather than avoids ankylosis. But to the contention that the position of complete or nearly complete extension should be employed in fractures entering the joint I shall ask your attention, and I shall endeavor to demonstrate to you that the position of safety is that of flexion and that this position is attended with sufficiently satisfactory results to warrant its being retained by the average practitioner of medicine.

In order to bring before you the arguments of those who favor complete or nearly complete extension I quote from a valuable paper read by Dr. John B. Roberts, of Philadelphia, before the American Surgical Association³ in 1892. Dr. Roberts said: "A surgeon who fully realizes the probability of impairment of the carrying-function in these fractures can without doubt treat them equally well in either the flexed or the extended position. Accurate readjustment of the fragments and provision for careful maintenance of the coaptation will usually produce good results. Practitioners who have comparatively few cases are, however, less liable than surgeons to appreciate the probability of a 'gunstock' deformity. In the flexed position of the elbow, moreover, the deviation of the axes of the arm and forearm does not exist; hence in this position a slight displacement of the plane of the articular surface of the humerus is easily overlooked.

¹ Read before the Denver and Arapahoe Medical Society, March 10, 1896.

² In a recent communication Dr. Allis writes that the success attained in treating these fractures with plastic dressings convinces him that manufactured splints held in place by roller bandages are largely responsible for this deformity.

³ Annals of Surgery, July, 1892.

For these reasons the extended position is the better for general adoption, since the angularity of the unbroken arm is then noticeable, and any interference with the normal deviation is very apparent." I fully agree with Dr. Roberts in thinking that the surgeon who sees many of these fractures will obtain satisfactory results under any form of treatment which his experience and judgment may lead him to adopt, but for the general practitioner, who sees these cases but seldom, to treat them in extension seems to me unwise, and I am led to this thought by the recollection of the following cases:

CASE I.—In July, 1893, a boy of nine years was admitted to my service at St. Luke's Hospital, New York, with the following history: Some six weeks previously he had fallen, injuring the left elbow. Immediately thereafter he was seen by a physician who told the parents that the elbow was broken. He put the limb up in complete extension, and applied splints which were changed from time to time and which were finally removed at the expiration of five weeks. At this time there was little or no motion at the elbow and despite vigorous measures the range did not increase. Six weeks after the injury, as I have said, the lad came under my care. Examination revealed the following condition: The elbow-joint was considerably thickened, especially in the region of the external condyle; the forearm was completely extended upon the arm, and could be flexed but 10° . Under an anæsthetic attempts to flex the elbow proved unsuccessful, whereupon a four-inch incision was made over the external condyle and the joint entered. The coronoid process of the ulna was found to be broken off and displaced upward and backward, lying posterior to the articular surface of the humerus, thus completely locking the joint. The fragment was removed. The external condyle was the seat of a fracture running downward and inward through the articular surface, the fragment being displaced anteriorly. The anterior surface of this fragment was chiselled away, whereupon the elbow could be completely flexed. The wound was sewn up without drainage, the elbow put up at a little more than a right angle, and an ordinary aseptic dressing applied. Complete primary union resulting, motion was begun at the end of four weeks. The arc rapidly increased and three months later the use of the elbow was very nearly normal.

CASE II.—One month after the foregoing case came under my observation I was asked to see a boy of twelve years whose physician told me that some four months previously the patient had sustained an injury to the lower end of the humerus, the exact nature of which he was unable to make out because of the swelling. He had applied splints in the extended position, removing them from time to time for the purpose of making gentle passive motion. The straight splints were not discarded until union was thought to be complete. At this time, however, the range of motion was very slight and could not be increased. When I saw the lad there was fibrous ankylosis, the forearm being extended upon the arm. Under ether the adhesions were broken up, the forearm brought up to 135° , and a plaster-of-Paris splint applied. Ten days later ether was again administered and the remaining adhesions were so far ruptured as to admit of nearly complete flexion. Plaster of Paris was applied with the elbow at a little less than a right angle, and two weeks later active motion begun. A useful limb resulted.

CASE III.—In March or April of 1891 a young man of twenty years was admitted to my service in the out-patient department of the New York Hospital. He said that he had broken his elbow four months or so before and that it had been treated in one of the metropolitan hospitals in the position of extension. Complete ankylosis resulted. When he came under

my observation there was no motion at the elbow, the forearm being completely extended upon the arm. Operation was advised but refused, and I did not see him again.

CASES IV. and V. are similar to Case III. Each came under my observation in the New York Hospital. In each there was complete ankylosis in the extended position. In both instances the elbow-joint was excised in narrow limits by the attending surgeon on duty—in one case by Dr. R. F. Weir, in the other by Dr. W. T. Bull. Both patients returned to the out-patient department for after-treatment. Each regained good use of the limb; the functions were excellent, considering that the joint had been excised.

These are cases which have been under my own observation, and I am sure that other surgeons can cite additional instances. I am far from saying that the ankylosis was due to the method of treatment; it might have occurred under other forms of management. In the first case the fractured coronoid would have prevented flexion and an operation at the time of injury was demanded; but if ankylosis were inevitable in either case extension was the worst possible position for it. We cannot say in any individual case of fracture entering the elbow-joint that a greater or less degree of ankylosis will not ensue, especially in people at or beyond midlife and in the gouty or rheumatic, and it is precisely for this reason that we should place the limb in the position best suited to its use in case of stiffening, provided that we do not hazard a deformity which will be of greater moment than can be compensated for by this position of election. I have myself long been convinced that the results are sufficiently good when the elbow is treated at or nearly at a right angle. In 1888 I read a paper¹ before the New York Academy of Medicine based on the analysis of fifty cases which had been under my own care. The position adopted was that of 90° or thereabouts. Each case was carefully followed to the end and the result is noted as satisfactory in forty-eight cases out of the fifty. Since the publication of this paper I have treated some seventy additional cases, and while the management has been varied in some details, its principle remains—that of immobilization at or near a right angle and the results are sufficiently good to warrant its continuance.

As I have said, the advocates of the position of extension argue that better coaptation of the fragments is thereby obtained, and experiments² on the cadaver seem to support their views. But it is interesting to note that a series of very careful experiments on the dead body recently conducted by Dr. H. L. Smith,³ of Boston, tends to prove the exact opposite, and that better coaptation is made by complete flexion. Obviously both of these views cannot be right, and, further, I do not think that this is a matter in which we can reason definitely from experiments made after death. These tests cannot take into account muscular action, which is a most important factor in the production of the deformity accompanying fracture, and we cannot transmit on the cadaver the exact violence which produces these fractures in the living. In view of these conflicting conclusions, and in the absence of any considerable number of cases supporting either, I have felt that it might be of interest to bring forward clinical evidence in substantiation of the claim that the position of safety, viz., at or nearly at a right angle, yields sufficiently good results to warrant its employment by the general practitioner.

In our largest cities the out-patient surgeons see the greatest number of these cases, and in order to supplement my own views I have communicated with

¹ MEDICAL RECORD, December 22, 1888.

² Berthomier: Thèse de Paris, 1875.

³ Boston Medical and Surgical Journal, October 18, 1894.

three of my former colleagues in the city of New York, Drs. Frank Hartley, B. Farquhar Curtis, and W. W. Van Arsdale, each of whom is in charge of large dispensary and hospital services, and the name of each of whom is a sufficient guarantee for the soundness and carefulness of his statements. Their cases added to my own make a total of six hundred and fifty, and are divided as follows:¹

Hartley and Woodbury, ² Roosevelt Hospital.....	250
Curtis, Chambers Street Hospital and the Vanderbilt Clinic.....	100
Van Arsdale, Good Samaritan Dispensary.....	180
The author, Chambers Street and New York Hospitals.....	120

650

The question which I asked each of the gentlemen was as follows: "What position do you consider best adapted to the treatment of fractures of either condyle of the humerus, or of the transverse fracture above the condyles, or of the so-called T-shaped fracture?" Their answers are as follows:

Hartley and Woodbury: (a) Internal condyle—gypsum splints from fingers to shoulder, forearm semi-prone, elbow at right angle. (b) External condyle—the same as the internal, except that the forearm is supinated. (c) Transverse or T-shaped—gypsum splint from fingers to shoulder or with shoulder spica, forearm supine, elbow at less than a right angle.

Curtis: Plaster-of-Paris bandage from fingers to axilla in most cases; occasionally when the superficial soft parts are impaired and need watching, a removable dressing with a wooden or tin splint. In the great majority of cases the limb is put up with the elbow inside of a right angle but not actually flexed, as the latter position would be less comfortable. The hand is in semipronation. When the "carrying-point" is lost and it is difficult to restore it owing to the slipping of the fragments, as usually occurs in fractures of the internal condyle, the limb is put up in full extension and supination with particular attention to the "carrying-point" for about two weeks, by which time the liability to lateral angular deformity has disappeared and yet union is not so solid as to render it impossible to correct any outer displacement which might interfere with flexion. Then ether is again given, the elbow flexed inside of 90°, and a plaster splint applied with careful attention to the position of the fragments. This splint is left in place until consolidation is complete.

Van Arsdale: In all cases flexion to 90° or to 80°; starch or pasteboard dressing until the swelling abates; then the same or plaster of Paris for three or four weeks, according to age (until union is complete).

In my own recent cases I have put the limb up in plaster of Paris at about 90° when first seen, except in those cases in which a tendency to "gunstock" deformity was apparent. In these latter instances I have made the angle 135° for ten days or two weeks, reduction being made under an anæsthetic with careful attention to the "carrying-point," and then changing the angle to 90° or to 80°. I am convinced that the extended position is not necessary to the obtaining of suitable coaptation of the fragments, and I am by no means sure that a moderate degree of cubitus varus is prejudicial to the usefulness of the limb; though I do not know that I am prepared to go quite so far as does Mr. Robert Jones, of Liverpool, who says that neither it nor cubitus valgus is of any consequence from either an æsthetic or a functional aspect.

Of my last seventy cases the result has been satisfactory in all but one. This was a young lady of twenty-four years who came to me one week after an

elbow-joint injury. Examination under ether revealed a V-shaped fracture, each condyle being separated and the lines running to a common point at the trochlear surface. Despite all care the arc of motion was limited to between 90° and 135°.

With forced flexion as advised by Smith,¹ of Boston, and Jones,² of Liverpool, I have had but little experience, not enough to warrant an expression as to its real value.

I have not presented in detail the cases of the men whose opinions I cite, nor my own. What I want to say is simply this: That after having actively managed this number of cases, six hundred and fifty, it is our opinion that the best results are obtained by treating the limb in the flexed position, and that the general practitioner will find the greatest degree of satisfaction in following this form of management.

PRACTICAL PHOTOMICROGRAPHY.

By W. C. BORDEN, M.D., F.R.M.S.,

CAPTAIN, MEDICAL DEPARTMENT, U. S. ARMY.

WITH the extensive use of the microscope in medicine and scientific research the need has been felt of obtaining exact pictorial record of many of the objects seen. Drawings, either free-hand or by aid of the camera lucida, are extensively used, but they are of necessity always more or less diagrammatic and often fail to give the necessary exactness, both from the impossibility of eliminating the personal equation of the draughtsman and from inability to reproduce the appearance of organic structure by line and stipple. Photographic processes, on the other hand, give pictures which in detail of form and structure are second only to the objects themselves; and the value of good photomicrographs as aids in teaching and for comparison, for future reference, and for publication, is generally accepted as unequalled, and their use is becoming more and more common.

But the extensive use of photomicrography has been prevented by several causes. These causes are complexity of apparatus, supposed difficulty of technique, difficulty of obtaining proper and always available light, and supposed large amount of time consumed. In view of these objections and of the value of the results obtained, all simplifications of technique and apparatus are of value and for the practical and more general application of photomicrography, while the results must be of the best, the time consumed must be small, the manipulations must be simple, and the apparatus must be one with which photographs can be taken at any time.

In the early days of photography, when the wet plate only was available, sunlight was necessary to photographic processes, and the traditions derived from its use cause many to still consider it essential to the production of high-class photomicrographs. With the introduction of the dry plate artificial light became available, and in spite of its small actinic power, relative to that of the sun, certain advantages connected with its use have given it many advocates. It is not necessary to enter into an extensive comparison of the relative optical, visual, and actinic value of sun and artificial light. Much has been written in favor of one and derogatory to the other. The fact remains that equally good work has been done with both. But for practical work artificial light has many advantages. Sunlight is uncertain; it varies in intensity from hour to hour of the day and with the time of year. It is apt to be obscured for days together or by passing clouds at critical moments, and, at most, is available

¹ In each instance the number represents the surgeon's approximate estimate of his own cases.

² Provincial Medical Journal, December, 1894.

but for a few hours of the twenty-four. Also the sun is constantly changing its position relative to the instrument, and when used for all except the highest power of the microscope, its image when focused on the plane of the object covers too small a field, and the heat and undesired colored rays have to be filtered out with light and heat filters. It is true that the latter disadvantages can be overcome by suitable but complicated apparatus, but the great objection of unavailability, except at uncertain times, still remains, and in consequence when sunlight is depended on many valuable records are lost from inability to photograph objects at once after their observation. For these reasons sunlight is not available for practical work. Practical work requires a steady, always available light, and these requirements can only be met by some form of artificial light.

Artificial light being necessary, the question of kind arises. So far as results are concerned almost any form may be used, provided it is properly used. Most of the objections made to artificial light have arisen from its improper employment. The main requirements in the light are simplicity and ease of manipulation. These combined with proper adjustment will give an effective light. The electric light, the oxyhydrogen light, the magnesium light, gas light, oil light, and, latest, acetylene light, have all been employed for photomicrographic purposes. The electric, oxyhydrogen, and magnesium lights all require rather complex apparatus, and they are all open to this objection, together with certain other objections pertaining to each. Of the magnesium light it may be said that no practical apparatus for its production has been devised. Electric light necessitates connection with an electric plant. It is expensive and the apparatus required is complicated. In the form of the arc light it gives a very satisfactory and powerful light, and it is probably the best form of artificial light for large institutions when used in the manner hereafter described for oil and acetylene light and with heat filter added. Aside from its power, second only to sunlight, it possesses no advantages over cheaper and more easily handled lights. The oxyhydrogen light is expensive and is troublesome to manage. It requires a complicated apparatus and does not give a light of sufficiently greater power over oil, gas, or acetylene to compensate for the trouble involved in its management.

For practical work there remain, therefore, oil, gas, and acetylene light. These are all easy to manage, they are best used in a similar manner, with similar apparatus, and for advantages of cheapness, steadiness, and controllability are unsurpassed. They differ in illuminating and actinic power, oil light being lowest, and acetylene light highest. Oil and gas light are of very nearly equal power, but they have not generally been considered powerful enough except for low and medium powers. This objection does not obtain when these lights are properly used or when used with orthochromatic plates. The ordinary commercial dry plates are mainly sensitive only to the more actinic rays of the violet end of the spectrum, and oil and gas light being deficient in these rays, photography with such plates and yellow-rayed light necessitates long exposure and generally gives imperfect results. As with sunlight, the difference between the visual and actinic focus enters as a disturbing factor, necessitating troublesome and uncertain adjustments or the employment of specially constructed objectives. Also the violet sensitive plate, owing to the like actinic coloring of many stained objects, often fails in development to give sufficient contrast for printing purposes. The orthochromatic plate does away with all these difficulties, arising as they do from complex conditions of differing visual and actinic focus, of working objectives not suitable for photography, and of plates

sensitive to the light rays of the wrong end of the spectrum. The orthochromatic plate is sensitive to yellow light. In artificial light, oil and gas light especially, yellow rays predominate, and when such light is used the projected image is mainly formed by yellow rays, and if the image is received on a plate sensitive to yellow, the visual and actinic focus will coincide with any objective, whether it is specially corrected for photomicrography or not. Also the yellow sensitive plate is so actinically sensitive to the yellow light that proper molecular change is produced in its silver compounds, causing in development sufficient contrast with almost if not quite all stained objects, and so greatly shortening the exposure that it compares favorably with those made by sunlight. For these reasons oil, gas, or acetylene light, properly used in combination with orthochromatic plates, gives the important necessity, an always available light, and one which is at the same time cheap, steady, easy to manage, and which can be used with ordinary working objectives with the certainty that if they give sharp visual definition they will give good definition photographically.

The remaining desideratum is an apparatus which shall be so simple and easy to manage that it can be connected with the microscope and the projected image photographed with little trouble and with a minimum expenditure of time.

The following is descriptive of an apparatus and method which have been adopted by the writer after much experience in photomicrography. The means and method are believed to be sufficiently simple and effective to warrant the assumption that by them photomicrography may be employed for practical work.

The apparatus consists of a camera hung in a vertical position, of a microscope with substage attachments, objectives and eyepieces, and a stereopticon, such as is used with oil light for projection purposes, in which is placed an oil lamp, or gas or acetylene burner. This apparatus is secured on a low strongly built table, and should either be in the laboratory or in a convenient adjoining room. This furthers its practical use, for when in working a field is found a photograph of which is desired, the microscope has only to be carried to the apparatus, placed in position, the light lighted, adjustments made, and the camera racked into position. With a conveniently placed dark room, the whole photographic operation will take but a few minutes. The working microscope should always be used for photography. By using the same microscope for both purposes the trouble and loss of time incident to changing the slide from one stand to another and refinding a given field is avoided. Every worker, especially in bacteriology, knows the difficulty and time spent in refinding a field once lost. The microscope stand may be of any well-constructed form. Any stand which can be depended upon for clinical or laboratory work can be used for photomicrography. For all-around photographic work it should have a substage ring and adapter for using objectives as substage condensers. A mechanical stage is convenient but not necessary. The microscope is used in the upright position. This position rather than the horizontal is to be preferred for several reasons. The upright position is necessary when movable objects, as colonies of bacteria floating on liquefied gelatin (Fig. 4), are to be photographed, or when, as in clinical photomicrography, photographs have to be made of urinary deposits. In bacteriological work, when bacteria are stained on the cover glass and examined or photographed before the balsam is dry, the cover is apt to slip if the microscope is used horizontally; but this does not occur with the microscope used vertically.

The horizontal position and long extension of camera is necessary for some classes of work, particularly

when large pictures have to be taken and when it is desired to obtain high amplification by extension of camera rather than by high eyepiecing, or when test diatoms have to be photographed with very high amplifications. For practical work, however, up to amplifications of one thousand diameters, and for photographs for illustration or reproduction, which are seldom re-

FIG. 1.—Photomicrographic apparatus arranged for use with oil light.

quired of over three and one-half or four inches in diameter, the upright position of microscope and camera is much to be preferred, on account of its ease of application and practical advantages.

The vertical position of the microscope necessitates a similar position for the camera. To allow easy working the camera is hung on a rackwork attached to a rigid upright, which is placed to the right of the microscope so that it will be out of the way while working. Both the upper and the lower ends of the camera are movable on the rackwork. The upper end which carries the screen and the plate holder is movable, in order that different amplifications within limits may be obtained with the same objectives. The lower end is movable that it may be racked up out of the way and allow the operator to manipulate the microscope before attaching the camera (Fig. 2). This is a great advantage, for the operator can seat himself at the instrument, adjust the object to the centre of the field, focus and adjust the substage, and arrange the illumination easily and effectively.

The camera bellows has an extension of two feet measured from the eyepiece of the microscope to the ground glass. This with a continental-model stand, a two-millimetre objective and projection, or working eyepiece No. 4, gives an amplification of one thousand diameters. With lower objectives and less extension of bellows amplifications ranging down to five diameters may be obtained. In focusing the operator can, by standing on a low box, observe the image on the ground glass and manipulate the fine adjustments of the microscope without using a focusing rod, though a suitable rod with cord passing around the milled head of the fine-adjustment screw can be easily attached to the upright if desired.

The Light.—A good and efficient light may be obtained by using an oil lamp, or gas or acetylene burner, properly adjusted in the body of a projection stereopticon with the projection ocular removed.

Of the three acetylene is much the best, and for illuminating and actinic power, combined with simplicity of apparatus and management, it is the best artificial light now obtainable for use in photomicrography. It can be easily and safely generated and stored ready for use, its making and use necessitating little if any more trouble than is connected with keeping an oil lamp in order. After experience with sunlight and various artificial lights I until recently settled down to the use of an oil lamp, believing it or gas to give when properly used the best light for practical purposes. Recently I have been using acetylene generated and burned in an apparatus furnished by Walmsley, Fuller & Co., of Chicago, Ill., and find it unequalled for practical work.

The gas is generated in a small generator and burned in a small burner placed in the lantern body (Fig. 2). If ordinary illuminating gas is used the burner is placed in the lantern in the same way, and when oil is employed a tri-wick lamp with only the middle wick lighted is used in the lantern. The large double condensers of the lantern serve to concentrate the light, while the double lantern body prevents the radiation of heat to the microscope and shuts off all radiating light. These are great advantages, for not only is the illumination improved by the concentration

FIG. 2.—Apparatus arranged for photomicrography with acetylene light. To show the acetylene burner it is placed outside the lantern. The camera is racked up so that the operator may arrange the object and substage.

of light but the microscope does not become heated, and if the room can be darkened, as it should be, by adjustable window shades, the absence of extraneous light greatly facilitates focusing on the camera screen. This method of using oil or gas light renders them sufficiently powerful for practical purposes and with acetylene gives great illuminating and actinic power. With oil light used without a light filter, bacteria can

be photographed with amplifications of one thousand diameters with exposures of from one and one-half to three minutes. Oil and gas lights are themselves so yellow that with them light filters are only required when photographing very difficult objects, such as methyl-blue stained gonococci or Klebs-Loeffer bacilli (Fig. 6). When a light filter is used a light yellow one of an aqueous solution of bichromate of potash placed in a glass trough gives excellent results. With it exposure is somewhat lengthened, being from three to five minutes for amplifications of one thousand diameters.

With acetylene light a light filter is more frequently required. This is due to the greater whiteness of the light and its consequent effect when transmitted through actinic-colored objects. With it most stained sections of tissue photograph well without a filter, the exposure required being very short, usually varying from five to thirty seconds. When a light filter is used the exposure is lengthened, but is short compared with that required with oil or gas light, being about two minutes for amplifications of one thousand diameters (Fig. 3). A good filter for acetylene light is made by dissolving ten grams of potassium bichromate in two

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 6.

FIG. 7.

FIG. 3.—Gonococci in urethral pus. $\times 1,200$ diameters. Exposed two minutes to acetylene light with yellow-light filter, using Zeiss' two-millimetre apochromatic objective, projection eyepiece No. 4, and with Abbe achromatic condenser in substage. The preparation was double stained with methyl blue and eosin. The gonococci and cell nuclei, being of a color complementary to that of the light filter, are distinct; the cell bodies, being of a similar color to the screen, are indistinctly photographed.

FIG. 4.—Colony of staphylococcus pyogenes aureus floating on liquefied gelatin. $\times 30$ diameters. Exposed twenty seconds to oil light, using Beck one-inch objective; no eyepiece or substage condenser.

FIG. 5.—Giant-cell sarcoma. $\times 275$ diameters. Section stained with borax carmine. Exposed twenty seconds to acetylene light, using Beck $\frac{1}{2}$ -inch objective, working eyepiece A, and Bausch and Lomb $\frac{3}{4}$ -inch objective in substage.

FIG. 6.—Klebs-Loeffer bacillus, grown on blood serum, stained with Loefler's methyl blue. $\times 1,000$ diameters. Exposed two minutes to oil light with yellow-light filter, using Zeiss' two-millimetre apochromatic objective, projection ocular No. 4, and Abbe condenser in substage.

FIG. 7.—Typhoid bacillus, grown on glycerin agar, stained with carb. fuchsin. $\times 1,000$ diameters. Exposed two minutes to oil light, using Bausch and Lomb $\frac{1}{2}$ -inch oil-immersion objective, amplifier in draw tube, and Bausch and Lomb $\frac{1}{2}$ -inch objective in substage.

hundred cubic centimetres of water and using at a thickness of three centimetres in a parallel-sided glass trough.

Adjustment of the Apparatus.—The camera being hung on the rackwork, the microscope is placed beneath it and the lantern is fixed about twelve inches in front of the microscope, with its central long axis in a plane which extends through the centre of the microscope mirror, the substage condenser, the objective, ocular, and centre of camera.

The light (oil, gas, or acetylene) being lighted and placed in the lantern, a stage micrometer is placed on the microscope stage and a medium-power objective and eyepiece are attached to the microscope. Light from the lantern is reflected on the micrometer by the mirror of the microscope, the observer accurately centres the micrometer rulings, then removes the eyepiece and projects the image of the micrometer rulings on the camera screen. The microscope is then moved to such position that the centre of the projected micrometer image is exactly in the centre of the screen. This position of the microscope is marked once for all, and whenever afterward the microscope is placed in the same position the centre of the object will be projected on the centre of the screen. The position of the lantern directly in front of the microscope should also be marked.

Adjustment of the Light.—Proper adjustment of the light is very important in working with artificial light, for upon this its efficiency depends. It must be properly placed relative to the lantern condensers and the light from them must be properly concentrated upon the object. In photographing with all but the lowest powers some form of substage condenser is necessary. This is due to the fact that the light must be focused on the object to give proper definition. In working with objectives of from eight millimetres up to but not including oil-immersion objectives, it will be found advantageous to use objectives of lower power as substage condensers, for if so used in ordinary observations they greatly improve the definition of objects. In fact, it may be laid down as a general rule that whatever gives the best microscopic definition will give the sharpest photographic image. Consequently in high-power work it will seldom be necessary to change the microscope attachments when a photograph is to be taken, for in bacteriological work the ordinary Abbe condenser which gives good definitions will, when properly adjusted, give good photographic definitions, statements to the contrary notwithstanding.

To adjust the light and substage condenser proceed as follows: With microscope and lantern in position and substage condenser centred, place the light to be used inside the lantern body, place an opal or ground glass between lamp and microscope, attach a low power objective, and, seated at the microscope, focus the objective accurately on the object. The opal glass is used to reduce the light which otherwise might injure the observer's eye. The ground glass is then removed, a fine wire screen placed close against the front of the lantern condenser, and by means of the substage condenser an image of the screen is projected on the object. The screen is then removed and a white card held above the eyepiece of the microscope with one hand, while with the other the light is moved about inside the lantern body until the image of the light projected on the card appears oval in form and equally brilliant in all parts. If the light is placed too near the condensers, there will be dark spaces on each side of the illuminated field; if too far away, the centre of the field only will be bright. If the light is a point or small disc the properly illuminated field will appear perfectly round; with the elongated oil or acetylene flame it will appear oval. The light

once properly placed should be fixed for future work.

With the light fixed and position of microscope determined, the operation of photographing is comparatively simple. When the observer finds a field which he desires to photograph, the microscope is carried from the working-table to that of the apparatus, placed in the marked position, and the light lighted. The operator then seats himself at the microscope, attaches the proper objective and substage attachments, focuses the former on the object and the latter on the wire screen placed against the lantern condenser, removes the screen, substitutes the opal glass, and, if using an Abbe condenser, opens or closes the condenser until the sharpest visual definition of the object is obtained. The opal glass is then removed and if required a light filter is placed between the lantern and microscope. The working eyepiece is then removed, a projection eyepiece inserted or an amplifier placed in the draw tube, or, if it is desired to use the objective alone, a tube of black paper, to prevent reflection, is placed in the tube of the microscope. The camera is then attached to the microscope and the projected image focused on the camera screen, preparatory to exposure.

In regard to the method of projection of the image much has been written regarding the relative value of using the objective alone, or with an amplifier in the draw tube, or with the ordinary working eyepieces or projection eyepieces of Zeiss. Practically, for all except the highest-power diatom work, equally good results can be obtained by either method, though where much work is to be done there are some advantages in the use of the projection eyepieces.

For photographing the projected image orthochromatic plates should be used. Of these I have used the Cramer rapid "isochromatic" exclusively, though probably other makes of orthochromatic plates might be found to work equally well. Certainly the "isochromatic" work so well that there is no necessity for going through the trouble of orthochromatizing plates one's self.

In developing I have obtained best results with formulas in which hydrochinone alone or with some other reducing agent is used. The following give clear negatives of sufficient contrast and gradation:

No. 1.

Water.....	300
Sodium sulphite.....	25
Potassium bromide.....	0.5
Hydrochinone.....	1.5
Metol.....	1.5

No. 2.

Water.....	15
Sodium carbonate.....	300

Use equal parts of No. 1 and No. 2.

Development should proceed slowly and should be continued until sufficient density is obtained. Rapid development and removal from the developer before sufficient density is obtained are to be particularly avoided in photomicrographic development.

A few reproduced photomicrographs are given in illustration of the methods outlined. They have been selected as representing ordinary practical work with different objectives and lights and with different means of projection and substage attachments.

Cancer of Cervix Uteri.—Dr. Charles Greene Cumston, instructor in gynecology at Tufts College, says obstruction of the ureters with consecutive anuria is one of the most frequent complications of cancer of the cervix uteri, and in a goodly number of cases is the direct cause of the patient's death.

THE TREATMENT OF PULMONARY TUBERCULOSIS.*

BY IRWIN H. HANCE, M.D.,

NEW YORK.

It is with a spirit of hesitancy that the writer undertakes to speak this evening upon a subject of such magnitude and importance, and his endeavors will be to place before his audience in a concise manner various recognized forms of treatment with a view to eliciting in the discussion the opinions of his hearers. His excuse for considering this subject is the widespread prevalence of the disease, as also the thoughts of the sufferings of the patients themselves and the sorrow and distress of the many dependent on them.

Unknown to the individual and unrecognized by the physician, nature frequently perfects a cure of this disease, as shown by the post-mortem records of many observers. Osler¹ states: "In my autopsies, excluding cases dead of pulmonary phthisis, 7.5 per cent. presented tuberculous lesions of the lungs." Since nature has thus clearly demonstrated her ability to overcome this disease we should employ only such remedial measures as will assist her, and all our efforts should be directed toward aiding and strengthening her in her battle against any further encroachment of the disease. These efforts may be embraced in three classifications: 1. Medicinal or therapeutic measures. 2. Specific treatment. 3. Climatic treatment.

Medicinal Treatment.—Many physicians have sought to treat pulmonary phthisis by means of antiseptics, aiming to act directly upon the tubercle bacilli by powerful agents introduced into the system either through the stomach, by inhalations, or by hypodermic injections; thus there has arisen a so-called antiseptic treatment of phthisis.

The fatal objection to this theory is that whatever drug is introduced in sufficient quantities to kill the tubercle bacilli would destroy the patient's life; this is undoubtedly true, yet many believe an amount may be introduced into the complex human economy sufficient to increase and strengthen the antiseptic action of the fluids, cells, and tissues of the body to such a degree as to turn the scale in favor of a more or less complete arrest of the disease.

By far the most important is the creosote treatment. Creosote was first discovered by Reichenbach in 1832, and recommended by Grandjean² in 1834 for use in tuberculosis. After a few years it fell into disrepute, until in 1877 it was again brought into use by Boucharde and Gimbert.³ The next year Sommerbrodt⁴ warmly recommended it in steadily increasing doses until tolerance was reached. Since that time it has been in constant use in nearly every country, and to-day is looked upon with greater favor than any other drug. There is a wide diversity of opinion as regards its action, one party believing that it has a greater or less specific action upon the tuberculous tissue, the other that its action is more local—upon the gastrointestinal tract—and that by improving nutrition it reacts beneficially upon the tuberculous process. Among the former are to be named Sommerbrodt,⁵ who states that "the creosote which is conveyed to the human organs, that is to say, the cells and the tissues and their fluids, changes the soil (Nährboden) for the tubercle bacilli to a degree that the existing colonies do not thrive in it and are destroyed." Conway⁶ believes "that creosote when used in large doses is a specific in tuberculosis."

Fraentzel,⁷ who used creosote as early as Sommerbrodt, advocates large doses, but is more conservative in his statements; if much fever is present, even 38.5 C., "no improvement is to be expected." "The number of successful results is proportionately small."

B. Robinson,⁸ who first applied creosote to the treatment of pulmonary tuberculosis in this city, and whose writings concerning its action and effect are the most complete in America, states: "As regards the general symptoms, they are nearly all benefited by the use of creosote—some, however, not immediately, or always in the same manner." He is a firm believer in the value of creosote inhalations, saying that "frequent and long-continued inhalations of creosote are extremely useful." For this purpose he gives three formulas. Modification of Brunton's formula:

R Iodoform gr. xxiv.
Creosote ℥ iv.
Oil of eucalyptus ℥ viij.
Chloroform ℥ xlvij.
Alcohol,
Ether āā q.s. ad 3 ss.

M.

Dr. Coghill's formula:

R Tinct. iodi ætherealis,
Ac. carbolicæ āā 3 ij.
Creosote 3 i.
Spts. vin. rect. ad 3 i.

M.

His own:

R Creosote 3 i.
Alcohol ad 3 ss.

M.

At first he uses this from five to fifteen minutes three times a day, and then lengthens the time of inhalations.

"The daily amount of creosote prescribed by me for adults, in private practice, has varied from three to six minims, and continued many months without increase or interruption or any evidence of intolerance." It is given in whiskey and glycerin.

William H. Flint,¹⁰ in 1890, states that the best results for each individual attend the administration of the maximum quantity of creosote which the patient will bear; and that the average patient will not tolerate more than ten to fifteen minims three times a day for any length of time.

The late Dr. A. L. Loomis,¹¹ in a discussion on the use of phenolic substances in phthisis pulmonum, stated: "I do not believe that these drugs have any effect upon pulmonary disease, except so far as they improve the nutrition of the patient by facilitating his digestion. I am quite sure they have no specific action."

The writer has had abundant opportunity to observe the action of creosote during his residence at Saranac Lake, where it was pretty constantly used, and on several occasions was pushed to the degree of tolerance by administering it by mouth and also by rectum. Under its use in afebrile cases the cough and expectoration are diminished, the patients' nutrition improves, and they gain in weight; in febrile cases it had no influence on the fever, and where there was an active tuberculous process, tending to spread, it certainly showed no specific action in checking the extension of the disease. In private practice he has seen in many patients, when they took very large doses, such severe gastric and intestinal derangements as to keep them confined to their bed, and the resulting physical depression has caused patients who were improving to be seriously injured by reason of the damage done to their assimilative organs. From watching some patients who were taking moderate doses of creosote and others as much as they could tolerate, he concluded that there was not enough difference in the results to warrant one in running the risk of upsetting the stomach by large doses.

Administration.—Only pure beechwood creosote should be used, for on its purity depends success. It must always be given on a full stomach; milk is an excellent vehicle for solutions of creosote; it should be given in pills or capsules and swallowed with half

* Read before the Section on Practice, New York Academy of Medicine, April 21, 1896.

a glass of water or milk. Sommerbrodt uses it in capsules with balsam of tolu; Fraentzel mixes it with tincture of gentian, alcohol, and sherry wine; M. Gutman with acetic ether, aromatic tincture, and simple syrup. It can also be given with whiskey or rum; an economical way is to buy empty capsules, No. 2, and subcarbonate of bismuth; pack the capsules slightly and drop in creosote, then cap them; do not put more than three drops in a capsule and make them up fresh every four or five days.

Commence with one minim after meals, increasing one minim every third day; if creosote is tasted for an hour or more after taking, digestion is disturbed, appetite fails, or diarrhœa sets in; or if the urine shows any changes, diminish the dose or stop the drug altogether.

It must be used persistently for a great length of time. The dose will vary according to the opinion held by the prescriber. The extremes will be reached, on the one hand by those who follow Sommerbrodt, who says "the more creosote tolerated per day, so much the better the action;" and on the other by those who, like the writer, use it with regard for its action upon the organs of nutrition, and therefore give only six or eight minims three times a day.

The writer has used the carbonate and creosote in soft capsules and has been well pleased with their action. The creosote is much more agreeable to take, better tolerated by the stomach, and can be used in doses of from twenty to thirty minims three times a day.

Guaiacol has been used as a substitute for creosote. Sahli¹² considers it as efficacious as creosote, and it has the advantage that the taste and smell are pleasanter.

Given hypodermically, Coghill¹³ reports very satisfactory results from its use in doses ranging from five to ten minims. Judging from the charts exhibited in his article, its effect upon the temperature was pronounced. Epidermically it has a powerful action upon the temperature; at the same time great depression may result, the temperature falling from 102° F. or over to 97° F., and occasionally as low as 96° F. Profuse perspiration occurs, and, if a very large amount has been rubbed on the skin, dangerous collapse.

The writer has used it hypodermically and seen fairly good results as regards its action on the temperature. Epidermically he has used it considerably, and when used in small doses (ten minims), repeated if temperature is not affected, twice at intervals of two hours, it is very useful for its antipyretic action.

Solis-Cohen,¹⁴ after watching its effect in thirty cases, concludes: "I think results here given justify extended use of the remedy, which by its influence on skin nerves reduces temperature and, when properly watched, without any deleterious injury, and in so much it promotes the patient's comfort."

Guaiacol will never take the place of creosote. When the latter cannot be taken internally it will serve as a substitute by hypodermic injections, the pain from which is not sufficient to annoy the great majority of patients. It is best given in sterilized sweet-almond oil in a thirty-three-per-cent. solution.

Epidermically it is in some cases a very serviceable antipyretic. It must be watched carefully, for severe collapse may result from too liberal applications.

The use of the chloride of gold and sodium and iodide of manganese has been brought before the profession by Dr. J. Blake White,¹⁵ of this city. He states that "the salts of gold not only dissipate the plastic exudation, but exert a profound effect upon the functions of organic life, arousing the organs to healthy action and necessarily improving the nutrition. There is good reason to believe that they exert a remarkable influence upon the general nutrition."

This improved nutrition or increased power of

resistance is the chief object sought in treating phthisis, and in so far this treatment has at times produced beneficial effects in the writer's experience. It improves the appetite, and the patients express themselves as feeling the tonic effect of the drugs. Dr. White begins with one twenty-fifth of a grain of the combined salts of gold and manganese in a one-per-cent. solution of carbolic acid. "Very pronounced reactions may follow injections, but should be avoided by small dosage to start with."

Gibbes and Shirley,¹⁶ acting on the theory of finding "something to combine with and neutralize the toxalbumoses, or whatever they may be, and arrest the disease," advocate the use of chloride of gold and iodine. Iodine inoculations are very painful and cannot be used for any great length of time, and many patients have refused to continue their use, owing to the pain produced. In large doses they occasion vertigo and nausea. The dose varies from one-twelfth to one-half of a grain. The chloride of gold is given in doses of one-twentieth to one-third of a grain.

Carasso, in 1894,¹⁷ gave in detail a form of treatment by peppermint inhalations and the internal administration of peppermint and creosote in combination with chloroform and whiskey. He reported forty-six cases, and stated that the bacilli in many cases disappeared from the sputa in from fourteen to sixty days. His results were so good that Dr. Trudeau placed twenty patients in his sanitarium upon this treatment. These were all patients who were doing well under ordinary climatic treatment, and they faithfully persisted in Carasso's treatment for four months. Result—not one lost the bacilli in that time. The mixture was so distressing to patients that it could be given only in small doses, or had to be discontinued because appetite was destroyed. The only favorable action was on the cough, which was diminished in severity by the inhalations; the secretion became less viscid and was more easily raised.

Baldwin¹⁸ has shown experimentally that the vapor of peppermint has no influence on tuberculosis in rabbits.

Edson's¹⁹ preparation, which consists of phenol and pilocarpine in combination, has been before the public such a short time that one cannot form any definite conclusions concerning its efficiency. At least a year or two must elapse before one can draw deductions about any new treatment of phthisis.

In the two most noted sanatoria in Europe, Dr. Dettweiler's at Falkenstein, and Dr. Brehmer's at Goerbersdorf, hydrotherapy is constantly used for its stimulating effect upon the peripheral nerves and its reflex action on the great nerve centres, as a result of which deeper respiration occurs and an improved stronger heart action is noted. By them, as also by Baruch,²⁰ of this city, from whose article is quoted the technique of its application, the bath, followed by friction and massage, is used as an adjuvant of the treatment, simply as a means of increasing the tissue changes and improving the patient's general condition.

Brehmer²¹ states that "in using it the patient must at once after the bath experience the feeling of comfort and warmth. His skin must become red. The douche seems to act upon the resorption of the pleuritic exudate." It is a dangerous method and must be used only by physicians.

Baruch says: "But, aside from this important consideration [its tonic effect], the predisposition to repeated colds and consequent probable aggravation of the local processes and general symptoms may be diminished by the neuro-vascular discipline to which the skin is daily subjected by applications of cold water in some appropriate form. This hardening process has long been recommended for those predisposed to phthisis," especially by Ziemssen, who says

"it is a remedy of extraordinary value." The technique varies with each case. Brief applications of low temperature, as by the douche or rain bath, the wet pack, or rapid ablutions, are followed by rapid reactions, and if well borne are exceedingly useful, as tonics. Among those unused to water at any temperature and who are much debilitated, higher temperatures are required, and only a portion of the body is exposed and bathed at a time. "The most useful hydropathic procedure in phthisis is the rain bath. The patient stands within a frame constructed of six semi-circles of inch tubing, the upper one on a line with the clavicles. Each tube has three lines of fine perforations, the upper line directed upward, the middle straight forward, and the lower downward. The water should have a fall of not less than forty feet. The temperature adapted to the average case of phthisis is 65° F. Here the pressure with which the water strikes the body affords a kind of massage which assists in producing reaction even in feeble individuals. The skin should become pink while under it. Decided chilliness continuing after thorough drying and friction is an evidence of improper selection of the temperature, duration, or method of the bath." Baruch then quotes in detail the histories of cases treated by him, showing some excellent results, but it should be noted that he did not fail to have his patients live in the air and sunshine, exercise very carefully, and improve their general nutrition by every possible means.

Specific Treatment.—Although the tuberculin treatment has passed into "innocuous desuetude" among the great body of physicians, it is still used by a few earnest conscientious workers for two purposes. First, as a test for tuberculosis in its earliest stages. In the writer's own experience it has been of service in this capacity, and in obscure cases of any form of tuberculosis he believes it can be safely used for diagnostic purposes without resulting in any injury to the patient. Second, commencing with very small doses, which are never sufficient to produce any reaction, it is slowly and guardedly increased until a point of tolerance on the part of the patient is reached, and then continued for a number of weeks until physical examination shows a thorough arrest of the disease. Should small doses produce any reaction, as shown by an elevation of temperature of one or two degrees, as also by physical examination, the treatment can be stopped before any injury has been done the patient. The writer recalls at least four patients who could not continue the use of tuberculin, but subsequently arrested their disease processes under proper climatic treatment. After the continuous use of tuberculin or its modifications, extending over a period of nearly five years, he is of the opinion that patients who are "relatively cured" by the use of tuberculin and climatic treatment have stronger resisting powers against subsequent infection than those who have secured the same result by climatic treatment alone. In other words, their "cure" (if one may use such a term) is much more firm and lasting than in other cases.

Climatic Treatment.—Under this form of treatment the best, and one may say the only satisfactory, results are obtained in pulmonary tuberculosis. Not many years ago it was thought that all consumptives must go to some warm climate or to Colorado to arrest their disease. Now it is known that the disease may be arrested in many localities which were not thought favorably of in the past, but the patient must be under proper medical supervision and lead a continuous out-of-door life. Unquestionably some localities have a far more favorable influence on the disease than others, and those which have been tried and proven to act beneficially on tuberculous lesions are the ones from which one should choose. The locality should

be one with an altitude of about two thousand feet or over, situated on the side of a hill which affords the greatest amount of daily sunshine, and sufficiently removed from any large village, that the air may be practically germ free. The variations in temperature should be as slight as possible, the soil such that the amount of moisture from rains, etc., is at a minimum. The extreme cold of the northern winters do not militate against certain localities in the North, for in the Adirondacks not only have the physicians observed that the patients do better in the winter time, but nearly all the patients express themselves as feeling better during the cold than during the warm weather.

Bowditch,²² of Boston, has been the pioneer in the United States in his efforts to establish a sanatorium near a large eastern city. His object was to treat those poor patients who could not afford to go away, and would otherwise be sent to some ward in a city hospital or remain in their own rooms under bad hygienic surroundings. The patients were under strict medical supervision, obliged to lead an out-of-door life, and in every particular were treated just as they are when sent to some suitable climate. He has met with a well-merited degree of success, and all of us here present would, without doubt, unhesitatingly endorse such a plan for New York City, whereby phthisical patients might be treated in a properly constructed sanatorium out in the country, instead of being crowded together in the wards of the city hospitals.

To sum up in as few words as possible, how shall a physician advise his patients who are afflicted with pulmonary tuberculosis? These may be grouped into two classes—the febrile and afebrile—and the treatment applies alike to both, only febrile cases require absolute rest out-of-doors for weeks until their temperature range registers 99° F. for a period of at least three weeks. Send your patients to some suitable locality. Have them lead a continuous out-of-door life. Let their exercise be controlled by its effect upon their system, a good rule being never to produce fatigue from exercise of whatever kind it may be. Give them the best quality of food and that which is most easily assimilable. Regulate their bowels. Improve the circulation of the skin by baths and friction. Use such medicaments as their symptoms call for, and give creosote and cod-liver oil unless the stomach rebels. In a word, give them pure air, improve their nutrition, and strengthen their resisting powers both physically and mentally.

Each physician present knows how simple it is to advise but how difficult to put in practice. Difficulties arise from the moment the physician makes his diagnosis, some of which we will mention:

First, the shock and mental depression, the result of telling your patient he has consumption. Deception always bears bitter fruit, and it is far better to say at once what is the trouble than to have the patient find it out later, when the disease has progressed to such a degree as to leave little hope of any successful issue. Then, too, the earlier the patient discovers his disease the greater the chances of his arresting it, and consequently he will recover much more rapidly from the mental depression due to his knowing what is the trouble. If he is but little incapacitated by reason of it, he very frequently can begin work at once in a proper climate, whereas later on he is obliged to remain absolutely idle for many months and with smaller prospect of a favorable result. If your patient has had hemorrhages, then there is the added danger of recurrent fatal hemorrhages, the direct result of overstrain, examples of which have been observed by some if not many of us here present.

Second, this may be good advice for the rich but not for the poor or those in moderate circumstances. Fortunately our humanitarians and philanthropists

have recognized the great need for charitable or semi-charitable institutions to help this deserving class and to-day there are several such sanatoria, viz., the Adirondack Cottage Sanitarium at Saranac Lake, the sanatorium at Liberty, N. Y., Dr. Bowditch's sanatorium at Sharon, Mass., one at Aiken, S. C., under the charge of Dr. McGahan, and the New Church Home at Denver, Col., with Dr. Fisk at its head. The charges at these are nominal and do not cover the expenses, most of them charging five dollars a week. Such places do much to re-establish the health of the consumptive and enable them to again become self-supporting members of the community, although in other climates.

Third, many patients remark that even if a given place benefits them they cannot return to live in New York or their former homes. Life is sweet to everyone, and the vast majority will decide quickly when the alternative lies between death in their former home or life in some other section of the United States.

Lastly, there are some who fear that by coming in contact with other consumptives they are further endangering themselves, and also they dread the association with and sight of other sick ones. To the former one may justly say that the tubercle bacilli within themselves are far more dangerous than the contact with others. With the latter the dread soon passes away, and they are very apt to consider themselves more fortunate cases than the majority and thereby become possessed of a happier mental condition.

Pyogenic Organisms.—Dr. Etheridge (*Amer. Jour. Med. Sciences*, April, 1896) speaks of the following as being the chief ones: The staphylococcus aureus, the streptococcus pyogenes, the bacillus pyocyaneus, the bacillus pyogenes fetidus, the bacillus coli communis, the bacillus tuberculosis, the bacillus proteus, the staphylococcus epidermidis albus, the micrococcus lanceolatus, and the diplococcus pneumoniae. The most characteristic purulent inflammations are produced by the staphylococcus and the streptococcus. The staphylococcus is much more likely to produce circumscribed purulent inflammations or abscesses.

Clinical Department.

VAGINAL HYSTERECTOMY FOR PUERPERAL SEPSIS DUE TO RETAINED DECIDUA—RECOVERY.

By ALFRED C. CARPENTER, M.D.,

NEW YORK.

A PATIENT of Dr. Joseph Moorhead, Mrs. McC—, aged twenty-two, mother of three children, was between two and three months pregnant, when she slipped and fell on the sidewalk and miscarried. The doctor was called, but did not arrive until "everything" had come away, as he was told, and had been disposed of, so he did not have an opportunity to examine it.

On the third day after the miscarriage she had a chill and the temperature rose to 103° F., pulse 110. The doctor, suspecting that possibly something had been retained within the uterus which was causing sepsis, ordered the nurse to give an intra-uterine douche of 1-3,000 bichloride every three hours, and quinine as an antipyretic. The evening of the fourth day she had another chill. The temperature rose to 105° F., pulse 120.

I saw her first on the morning of the fifth day. The temperature was then 104.6° F., pulse 130. The uterus was large, soft, and flabby. The cervix was widely dilated, readily admitting two fingers. The patient was placed in Sims' position and a quantity of partially decomposed, vile-smelling decidua was removed with the curette, and the uterus was irrigated with a hot 1-2,000 bichloride solution and packed with iodoform gauze. The packing was removed three hours later and intra-uterine douches of 1-2,000 bichloride solution were given hourly. I also ordered saline purgatives to be given freely. The temperature in the evening had dropped to 102.8° F., pulse 120. The following morning temperature was 102.4° F., pulse 120. In the evening she had another chill, and the temperature rose to 105.2° F., pulse 140.

I saw her again with Dr. Moorhead the following morning. The temperature was 105.2° F., pulse 140. There was a profuse purulent discharge from the uterus. There was no tympanites or abdominal tenderness except on deep pressure over the fundus uteri. I advised that hysterectomy be performed at once, believing it to be the only possible chance to save the woman's life.

She was brought to my sanatorium in the afternoon in an ambulance, and vaginal hysterectomy was performed as soon as the operating-room could be got in readiness.

Before she was put on the table a stimulating enema was given.

Chloroform was the anæsthetic used. It was necessary to give a hypodermic injection of strychnine during the operation, which only required about twenty minutes. The opening through the vaginal vault was not closed at all, but left open to give thorough drainage and packed full of iodoform gauze. A thirtieth of a grain of strychnine was given every three or four hours for the first twelve hours after the operation. The temperature the next morning had dropped to 101.8° F., pulse 120. The following day it rose to 104° F., but dropped to 101.4° F. as soon as the bowels were moved and clean packing was introduced. From this time on recovery was uninterrupted, the opening through the cul-de-sac had closed in twelve days, and the patient returned to her home in three weeks.

Until of late I have contented myself with curettage and intra-uterine douching in these cases of puerperal

sepsis, although not satisfied with it, for I have seen two patients die after it, and I am convinced that if hysterectomy had been performed both lives would have been saved.

Some operators advocate the use of the finger for removing clots and retained membranes, claiming the curette to be dangerous, that it is liable to puncture the fundus, and that it cuts away too much uterine tissue and opens the uterine sinuses, allowing new sources for infection. To be sure, a great deal of injury can be done with the curette. Indeed, I would never advise the introduction of any instrument into such a uterus by an unskilled hand, but in the hands of those of experience it can be used with just as much safety as the finger and to better advantage.

The attack is ushered in by a violent chill, followed by a high fever, and ending with profuse perspiration. Then, perhaps, the patient will go on for twelve, twenty-four, or possibly thirty-six hours and feel perfectly comfortable, then another chill follows, and then we know that our patient is doomed. With care and careful watching life may be prolonged, but the chills recur, and as the multiple abscesses and infarcts result from the distribution of emboli, a typhoid condition follows and death ensues.

When the second chill occurs and there is no longer doubt about the diagnosis, there is no other alternative. Is it not advisable to perform hysterectomy and thus prevent the spread of the pyæmic processes?

219 EAST NINETEENTH STREET.

THE TREATMENT OF ACUTE LOBAR PNEUMONIA AND ITS SIMILARITY TO THAT OF TYPHOID FEVER.

By S. A. VISANSKA, M.D.,

ATLANTA, GA.

My object is to bring before the profession the treatment of pneumonia and to show in many respects its similarity to that of typhoid fever. While they are entirely different diseases, the lesion of one in the lung, and of the other in the intestinal tract; one runs a course of a few days and terminates, as a rule, abruptly and the other has a period of slow invasion and slow termination; still the treatment is almost identical. It has been established beyond a doubt that pneumonia is an infectious disease and that the diplococcus pneumoniae of Fraenkel is the prime factor of this infection. Cold, low vitality, age, etc., were at one time considered the chief etiological factors, but I consider it a great mistake to lay so much stress on the word "cold," though it does "cover a multitude of sins." While I do believe that cold is an essential factor in the spread of the disease, and that age and low vitality offer a good bed for its development, we have conclusive proof that the disease is more prevalent in the South than in a colder climate. If a person is exposed to cold and dampness, as a rule he contracts a severe bronchitis with cough, expectoration, and perhaps slight fever, but lacks the grave symptoms of pneumonia. Typhoid fever is an infectious disease produced by the bacillus typhosus. Both diseases are self-limited, run a certain course uninfluenced in any way by medicine. They can neither be aborted nor cut short by any known means at our command, although a few in the profession claim to do this.

Now as to treatment. It has been clearly demonstrated that there are two essential points in the treatment of both diseases namely, to keep up the heart's action and to reduce the temperature.

The patient should be placed in a well-ventilated room with windows that open from above, free ventilation being obtained by drawing down the win-

dows from above, never through an open door. "Doors were made to close, windows to open." The room should be moderately warm, bed comfortable, mattress not too hard, cover light. The sputum should be caught in a bowl containing strong solution of phenol, for I believe this the source of infection as the stools are in typhoid.

The diet should be liquid and nourishing—milk, egg-nog, chicken soup, beef tea, cocoa, and occasionally a soft-boiled egg. To keep up the heart's action we have alcohol as our sheet anchor, and it must be used judiciously; in conjunction with this we have the sulphate or nitrate of strychnine, which I consider the very best tonic, nerve and muscular. In treating adults I prefer it given hypodermatically; for children, by the mouth.

To reduce the temperature old writers would advise filling the patient with quinine, veratrum viride, aconite, etc.—adding fuel to the fire. While these reduce the temperature, it is at the expense of a heart already overtaxed. Lately phenacetin, antifebrin, antipyrin, and other antis have been used with the same disadvantage.

Experience has taught us another plan, as in the treatment of typhoid fever, and this is the application of cold. It reduces the pyrexia, tones up the heart, relieves the pain (which is generally the accompaniment of pneumonia, owing to the pleura being involved), alleviates difficulty in breathing, promotes pulmonary circulation, hastens resolution, and disperses the products of exudation. It reduces pyrexia without weakening the heart's action and relieves the nervous symptoms; as a rule from the pyrexia we have delirium—and what is more comforting to our patient than an ice cap applied to the head? I prefer ice caps: the chest, arms, and back can be frequently sponged with ice water and alcohol until the nervous symptoms (if any) disappear and the temperature is reduced one or two degrees. Warmth should be applied to the lower extremities if required; and should there be great pain in the side after the application of cold, I would advise the use of morphine sulphate hypodermatically.

March 28, 1896.

FOREIGN BODY IN THE MALE URETHRA; REMOVAL BY INTERNAL URETHROTOMY.

By SINCLAIR TOUSEY, A.M., M.D.,

SURGEON-IN-CHIEF, ST. BARTHOLOMEW'S CLINIC; LECTURER ON CLINICAL SURGERY, NEW YORK POST-GRADUATE MEDICAL COLLEGE; ASSISTANT SURGEON, ROOSEVELT HOSPITAL, O. P. D.

ON December 24, 1895, a man presented himself at my surgical clinic, stating that he had had a foreign body in the penile portion of his urethra for the last twenty-four hours. He showed me the mate to it, a wooden ovoid of the size and shape of the head of a No. 37 French bulbous bougie. He said it was part of a puzzle, but his object in introducing it into the urethra did not transpire. The fact that he was thirty years old and had been married five years would indicate that maturity and matrimony are not always absolute prophylactics against such experiments.

There had been absolute retention of urine for twenty-four hours, and his efforts to express the foreign body manually had produced very considerable congestion and edema of the penis. The foreign body could be discovered by palpation at a distance of about two inches from the meatus, and it was quite firmly fixed in position.

After cocaineizing the anterior portion of the urethra, the meatus was somewhat enlarged and a narrow silver band bent into a loop was readily passed around the foreign body. Efforts at traction, how-

ever, proved useless, as the wood had swollen to nearly twice its original diameter and was held firmly in place by a fold of swollen mucous membrane. The silver loop having been removed, a narrow-bladed bistoury was passed into the urethra through the meatus. The mucous membrane was divided along the dorsum for a distance of half an inch over the foreign body. I was then able to express it with entire ease. The rather profuse hemorrhage was controlled by bandaging the penis firmly against the symphysis pubis, and on the patient's promise not to repeat the offence he was discharged.

29 WEST THIRTY-EIGHTH STREET.

DISLOCATION OF THE FOURTH CERVICAL VERTEBRA WITH FRACTURES.

By R. C. PAINE, M.D.,

BETHEL, N. Y.

My aim in presenting this case is to add one more fact in favor of early reductions of the fractures and dislocations in these cases.

April 7, 1891, I was called to see J. S—, aged fifty, who had fallen out of a wagon, striking on his head and right shoulder. Those who saw him fall said he rebounded in the air about a foot. When they lifted him he was apparently dead, his head being drawn back. When I saw him less than an hour afterward the head was drawn backward, the limbs were paralyzed, respiration was abdominal and difficult, while deglutition was impossible for anything but liquids; the patient was suffering extreme pain.

On examining the neck I found that I could not trace the cervical spines, as the head was drawn so far backward that only a mass of skin and muscles could be felt; where I failed to trace the spinal process the front part of the neck was very prominent, the larynx and trachea standing out, while the line of the transverse process of the upper cervical vertebra could be easily seen through the skin. The chin was so elevated that upon opening the mouth to its full extent it could not be brought within nine inches of the sternum. The patient was in great pain. I gave two hypodermic injections of one-third grain of morphine, which failed to relieve him.

Two hours after the accident I put the patient under chloroform. I then found that the spinal processes made a sharp angle at the fifth cervical vertebra. Upon opening the mouth and following the bodies down with my fingers, I found that the fifth stood forward sharply a little more than the length of my finger nail or about three-fourths of an inch in front of the fourth. I could also feel a movable fragment of bone on the right side and back of the body of the fifth. This was the transverse process of the fourth which was not found in its place, and I came to the conclusion that I had a dislocation backward of the fourth on the fifth with a fracture of the right transverse process of the fourth.

Having made up my mind to reduce the dislocation and being eight miles from another physician, I proceeded at once with the help of three or four laymen. After working an hour with traction and counter-extension without any result, I inserted a gag in the mouth, having an assistant make traction on the mastoid process. I then inserted my finger in the mouth, pressing backward on the body of the fifth vertebra and making counter-pressure with the other hand back of the neck, when the bone slipped into place with a snap. The chin dropped forward on the sternum, respiration stopped, and the pupils dilated. I gave a hypodermic injection of ammonia into the external jugular vein and commenced artificial respiration.

In two and one-half minutes I felt the pulse and it was just perceptible; in fifteen minutes the patient could carry on his own respiration, and in twenty minutes the pupils contracted. I then felt in the mouth and replaced the transverse process as well as I could. A few minutes afterward the patient regained consciousness. I then gave him a teaspoonful of fluid extract of ergot and five drops of croton oil. In a short time he could move all his extremities except the right arm. On examination I found that the neck of the scapula was broken, a condition which had been overlooked. I laid the arm in a comfortable position and told the patient not to move. As soon as I could procure the material for a plaster jacket I put one on, extending from the lower part of the thorax to the top of the head, leaving out the face but including the neck, using also a swallowing pad. This rendered the head and neck immovable. After the cast had hardened I set the shoulder.

The patient was kept in bed three weeks, the bowels were kept open, and ergot was given. In five weeks I took off the cast. The patient was then able to walk around, but a jar caused more or less pain. The pain in the neck continued for several months.

The neck was quite rigid, but the stiffness has gradually become less until now, four and a half years afterward, it can scarcely be noticed. The patient is now earning his living by hard work and is free from pain.

In these cases death usually results within seventy-two hours. This case is of interest, therefore, in that reduction was accomplished in such a short time after the accident, and from the fact that, although traction and extension were unable to reduce the dislocation, it was easily reduced by counter-pressure with extension. It is also of interest as showing that, even if the patient is apparently dead after the reduction, stimulants and artificial respiration should be persevered in. It also shows, by the paralysis and respiration, that the cord was compressed, yet if this pressure is removed in a short time there may be no permanent damage done to it.

SEVERAL CASES OF PSORIASIS SHOWING PROBABILITY OF CONTAGION.

By J. ABBOTT CANTRELL, M.D.,

PROFESSOR OF DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE; DERMATOLOGIST TO THE PHILADELPHIA HOSPITAL, THE FREDERICK DOUGLASS MEMORIAL HOSPITAL AND THE SOUTHERN DISPENSARY, PHILADELPHIA.

WITHOUT expressing my belief either in the heredity or in the parasite theory of psoriasis, I wish to record several cases in which the probability of contagion was a marked feature.

Ludwig Nielsen¹ says: "If it is really a question of infection, and not heredity, we ought then to meet with cases where the parents have been attacked after the children, a possibility which has hitherto never received any consideration. In one of our patients the mother had psoriasis for the first time long after the daughter. But as psoriasis manifests itself more frequently in early age, such cases must always be few and far between."

As such cases have come under my care within the later years of my clinical work, I felt that their report would at least be interesting to my readers.

CASE I.—A boy, aged twelve years, presented himself at the Philadelphia Polyclinic in April, 1886, with a well-marked psoriasis. He stated that no one of his family had ever presented such a disease and

¹ Selected Monographs on Dermatology, New Sydenham Society Reports, 1893, page 600 (abstract of his larger work).

this remark was borne out by the mother's statement at the next visit, as she then accompanied him. During the years in which he remained under observation, from the above date to the latter part of 1893, he had several attacks of the eruption and each time under the use of appropriate remedies the manifestation disappeared. In the early part of 1890 he brought his sister to my office, and upon examination I found that she had a mild attack of psoriasis. Under appropriate measures she also was cured. During the next three years she presented herself three or four times with fresh outbreaks and each time a cure was effected. In the latter part of 1890 the boy appeared at my private offices with his mother, who this time was the victim of the disease, which according to her statement was of three months' duration. She being rather garrulous, I studied from her statements the family history from the great-grandparents to the present generation, but could find no trace of a similar eruption in any but those mentioned. I also made inquiry of the father as to his antecedents, but found no history of such a condition being present upon his side. The cure in the case of the mother was effected in a short time, but she presented the disease several times during the course of the next three years.

CASE II.—A man, aged eighteen years, presented himself at the Jefferson Medical College Hospital while I was acting as instructor in diseases of the skin at that institution. He had had a psoriasis for several years and had been under treatment without avail. Under appropriate measures he became entirely free of his attack, but during the next four years he had several outbreaks. These were possibly worse than the original attack and in each the cure was made in a very short time. In about one year after his first appearance he again presented himself at the clinic, not for himself but on account of his mother, who accompanied him. She was a woman of about fifty years of age, and upon examination it was developed that she also had a psoriatic eruption, which had existed for several months before her visit. In studying the family history in this case I was unable to trace any antecedent similar eruption upon either the paternal or the maternal sides.

As I stated in the first portion of this paper, I do not express any opinion on the heredity or on the contagion of the disease under consideration, but if later such should be proven, these in conjunction with other cases hereafter recorded will assist to the belief of one side of the argument.

It has often been asserted that psoriasis was of parasitic origin. This belief was first spoken of by Lang¹ who made an attempt to classify scaly diseases according to the manifestations presented, and in later remarks² he gave the impression that a fungus had been found (epidermidophyton), but this was afterward proven by Reis to be an artificial product. A number of cases have from time to time been recorded in which this disease has sprung up after contact with persons so affected, and among these may be mentioned the cases of Unna, which were communicated at the Copenhagen congress in 1884. The disease was supposed to have been contracted by three children, in whose family no such disease had ever been present, from a nurse who was suffering from the complaint. Porr³ met with this circumstance in six cases in a total of sixty-six, while Neilsen found the disease to occur in a mother some time after it

had shown itself in her daughter. McCall Anderson¹ referred to a man showing the disease after his wife had had it for years. Aubert² spoke of a case in which psoriasis was developed in a husband and later in his wife. Hammer³ speaks of an instance in which father and daughter were treated at the same time. Thus I may refer to several others which are upon record, but I feel that a collection may be of more value after the discovery of a fungus, if such be made.

FATAL CHOREA.

By E. T. MILLIGAN, M.D.,

LECTURER ON VENEREAL DISEASES, MICHIGAN COLLEGE OF MEDICINE AND SURGERY, DETROIT, MICH.

MRS. —, aged twenty-six, primipara, developed chorea of the right side when two months pregnant, which continued until her death, six days after her confinement. Her mother was of a nervous, restless disposition and her two sisters were chronic rheumatics. At the beginning of labor a vaginal examination showed an os dilated to about the size of a dollar. The right side of the cervix was thick and elastic. The left side was corrugated, rigid, and very thin. After eight hours of severe pain the child was born. The placenta was expelled and the uterus contracted well. For four days the patient improved. On the morning of the fifth day every sign pointed to complete recovery. On the morning of the sixth day my patient's mother visited her. Some words passed between them, causing my patient to become very much excited, so much so that she left her bed and ran around the room. When she returned to bed her chorea returned with increased violence and was accompanied by great pain involving the right side of the body. After four hours of intense suffering paralysis of the right side set in, followed by coma and death six hours later.

Four hours after death I made an autopsy. The uterus was well contracted. The peritoneum was healthy. The edges of the mitral valves were studded with tiny vegetations, a true endocarditis being present. The middle cerebral artery on the left side, beyond where the anterior choroid is giving off, was plugged with an embolism of the same structure as that of the vegetations on the mitral valves. There was also a rupture of one of the smaller branches of the middle cerebral which supplies the corpus striatum. The hemorrhage from this branch was very extensive. I could not discover any pathological lesion of the spinal cord or of its membranes. If all cases of chorea showed a disposition to convulsions on but one side of the body, we might possibly be able to establish a supposition as to the causes of chorea. But unfortunately such is not the case. The scanty knowledge which we possess of the anatomy and physiology of the brain compels us to assume (in many of the diseases affecting the nervous system) a theory to be a fact, so that we endeavor to interpret through the manifestations of symptoms a cause for a disease. The autopsy on my patient left no doubt as to the cause of death. I am of the opinion that the chorea was due primarily to an endocarditis. We can readily understand that a small vegetation can be snatched from the mitral valves and carried along by the blood current, deposited in one of the small arteries of the brain, and there cause a loss of nervous equilibrium manifested by the name chorea.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 2, 1896.

THE PROPER DISPOSAL OF THE DEAD.

It is quite remarkable in view of the repeated discussion of the subject of cremation and the well-known and widely appreciated advantages of the method that comparatively little progress has been made in the direction of its more extended adoption. Every little while its advocates come to the front with their missionary endeavors to argue against the deeply rooted sentiment attached to earth burial and are brought up helplessly against the barrier of settled prejudice as the only answer to the most reasonable of expedients. The scientific aspect of the question challenges dispute. The fact that the sooner a decaying body is disposed of the better is as incontrovertible as that of death itself. Decomposition indicates this in its own imperative way. The dead body is no longer scientifically, sentimentally, or religiously a part of the individual, any more than is his cast-off shoe or worn-out garment. The attempt to preserve its identity in any form is a libel on natural laws. Its progressive change from the human form divine to a bloated loathsome mass of oozing corruption proves with the force of a physical fact that material and individual dissolution is absolutely inevitable. The result must always be dust to dust, ashes to ashes. Fortunately for the purely sentimental aspect of this question the slowly decomposing body, with its attendant changes of form, substance, and lovable associations, is hidden from sight and its true object lesson is entirely lost upon the mourning survivors. Thus we cheat ourselves into the belief that the body, as such, is not entirely gone from us and that there is some more substantial medium than mere primitive elements, dust and ashes, between us and the one that is literally no more. It is the association of the tomb with the earthly home of the departed one and the last look of a loved face. A day or two of additional time would result in the more becoming resignation of a cherished memory to the very tangible evidence of a distressing fact. The realization of advanced decomposition would bring about the proper vindication of the scientific objection to burial as now practised and the demonstration of the dangers to the living by the more or less extensive soil contamination that necessarily follows.

In the last number of the *Journal of the American Public Health Association* there are two articles bear-

ing upon the subject of dead-body disposal that contain many interesting data for profitable study. One of these is by Dr. C. O. Probst, the other by Dr. Edward A. Guilbert. Both gentlemen are advocates of cremation and present the usual forcible arguments for their side. The former writer, while willing to lean conservatively toward the prevailing prejudice of earth burial by the admission that under certain conditions it is safe and satisfactory, is nevertheless strongly committed to cremation as a better and more cleanly method of disposing of the dead. Admitting, however, that under favorable circumstances of sandy soil, isolated situations, distance from water supplies of towns, and possible destruction of many varieties of pathogenic germs, earth burial fulfils certain requirements, how much greater certainty of complete security for the living is proven by the rapid and absolute destruction by incineration of all probable cause of disease propagation! There is but one answer to the question and all argument ends with it. Dr. Guilbert not only discusses the sanitary but also the religious and sentimental aspects of cremation. In view of the fact that the opposers of incineration have been unable to combat the widely acknowledged sanitary advantages of the measure, they have taken refuge in an appeal to the prejudices that attach themselves to old customs, tender associations, and religious rites. The writer in question has clearly shown that, so far from cremation interfering with Christian rites, it has been openly advocated by leading members of every religious faith. Hardly a better answer can be offered to such as have endeavored to make earth burial a test of Christianity than is contained in the following paragraph:

"The bishop of Lincoln, England, 1874, during the dawn of the reform, evolved from his inner consciousness the surprising ex-cathedra statement 'that a revival of cremation would destroy belief in a final resurrection'! He forgot, in his affirmation of faith, be it said, to answer Earl Shaftsbury's pertinent question: 'What has become of the blessed martyrs?' I might add, Where are the innumerable, they, the Christian men, women, and little children, who have suffered death in conflagrations on land and sea? Is that inscrutable essence within man, the myself, the very life, which thinks and impels, loves and hates, and which we call the soul—is that really 'of the earth, earthy' and is it positively annihilated when the cremated body gently fades away, 'like the fabric of a vision, leaving no wrack behind'? If the soul of the martyr died when his body burned at the stake, what meaning is there in the liturgical averment: 'The noble army of martyrs praise thee.' That which has been annihilated can neither 'praise' nor blame."

THE LUNACY BILL—"A MOST OUTRAGEOUS GRAB."

A LEADING paper, itself a creature of the ruling political party and a constant apologist of the lunacy commission in the latter's efforts to subordinate the entire management of the State hospitals for the insane to

its own arbitrary will, has at length discovered in the new "insanity law" the consummation of the scheme by which, this paper alleges, the vast patronage of these institutions is to be brought under the control of the "bosses." The feature of this bill which the paper calls "a most outrageous grab" is harmless as compared with many other sections. It is designed simply to remove all the managers of these hospitals on a given date and have an entirely new class appointed. As the commission has already been able, by successive acts of the legislature, to reduce the managers to merely nominal officials by having all their powers transferred to itself, the proposed law is of little importance. The commission has for some time had in its grasp every power essential to the entire control of the finances and patronage of these institutions, and whenever the "bosses" choose that power will be employed to its fullest extent for political advantages.

It has been a matter of surprise for several years that the leading papers of this city have encouraged the process of despoliation of these great charities so persistently carried forward by the lunacy commission. It has long been known that the scheme of centralizing the control of State institutions at the Capitol, where they could readily be utilized for political purposes, has been the fixed policy of political leaders. However honorable and disinterested were the motives of those who originally created the lunacy commission, it was organized with a view to the final centralization of the management of these institutions in the hands of the party in power. This opinion we have always maintained, and our position has been sustained by the course which the commission has steadily pursued from the day of its organization to the present moment. It is too late now for any paper to raise the danger signal. The complete subjugation of the State hospitals to the political "bosses" has already been practically effected, and this bill is simply designed to give the sanction of law to the perfected scheme of centralized control. The boards of managers, heretofore free from political control, have been the main hindrances to the corruption thus directly invited, and when they are disposed of all will be lost.

THE DRIFT OF MEDICAL CHARITY.

CHARITY, as the term was understood by St. Paul, covers a multitude of sins. It is quite as true that charity, as we commonly use the word, is the root of an equally great multitude of sins. Indiscriminate almsgiving, which attains at times the proportions of a fad, often proves harmful to the recipient both financially and morally. Unfortunately, the undesirable effects do not stop with the recipient, but react upon other members of society. It is our purpose to call attention once more to the too numerous free dispensaries and hospitals, since it rests to a large extent with members of the medical profession to correct these abuses and bring this branch of charity into accordance with reason and justice. The poor we have

always with us, but when their number increases out of all reasonable proportion it is well to look carefully into the matter, as there is some serious malady affecting the social body.

In searching for causes for so many hospitals and dispensaries, we find among others that a desire on the part of society in general to be rid of sick and aged relatives, servants, and other dependents has made it the duty of philanthropists to provide for this class. A too easy means of disposing of dependents fosters improvidence among poorer classes, whose members see no occasion for laying up a small reserve fund against times of sickness or old age. This improvidence, in turn, begets a lack of moral responsibility the effect of which on the character of the individual and on society cannot be reckoned. If only the deserving poor were treated free of charge, the evil of the free dispensary would not be so alarming; but there are hundreds treated in this city every month who are abundantly able to pay. They choose this method of getting the advice of an expert, either because they do not know to whom to go or because they wish to escape the fee. This class of persons is thieving as much as though they supplied their larders by pilfering from the grocer. The benevolence that makes this possible is to be commended for its interest in the physical welfare of humanity, but it should also invent a method for inculcating a little more honesty in the race. One remedy suggests itself, if this disease of hospitalism has not already progressed too far, and this is that the city own and control all such institutions, as it already does a few. The supply can then be limited to about the actual need, and free dispensaries will cease to spring up like mushrooms. A more decent public sentiment might be engendered which would make persons who would scorn to beg food and clothing ashamed to accept medical attendance at the hand of charity. Again, if these institutions were under municipal control, the physicians and druggists being chosen in accordance with civil-service rules, the work would be more thoroughly performed. Dr. Bayard Holmes, in a paper on "Scientific Charity," read before the Physicians' Club of Chicago, says: "Charity, almsgiving, is an opiate now much used in treating humanity for that fell disease of which it suffers. This disease is known as competitive production. When it reaches its height it is manifested by a blush of idleness, poverty, and misery, which is soon followed by an eruption of benevolent societies, asylums, hospitals, dispensaries, jails, and penitentiaries. In the treatment of this disease narcotics are dangerous. Almsgiving and suppression of facts have proved fatal. The parasite should be attacked with the sharp edge of rational justice." If the privileged classes would exercise a little more real charity—the milk of human kindness—and if they were actuated by genuine Christian brotherhood rather than by a desire to outstrip each other in the scramble for the dollar, their deficiencies would not need to be covered by that mantle of mock charity, almsgiving.

This phase of the question belongs properly to the political economist. Let the physician consider his responsibility for present conditions.

The medical man is fostering this pest to his own detriment. He is sacrificing his time, his experience, himself, and often those dependent on him. He is bearing more than his share of the burden. When an institution is founded money is provided to pay nurses, attendants, servants, druggists, every one but the physician, and yet he is the mainspring; without him the institution could not exist. No one would think of asking a drug firm to stock a dispensary free of charge, of sending a missionary out without seeing that his material wants were provided for, of asking a clergyman or a lawyer to give his services without recompense. No one ever questions the right of these men to a reasonable compensation. Why, in the name of common sense and justice, should more be required of the medical profession than of others? Every physician in a hospital or dispensary should receive a salary commensurate with the service he renders. This would not detract from the quality of the work. A well-paid man is apt to do better work than one who receives no remuneration. The profession should adopt an amendment to its code of ethics making it unprofessional to render gratuitous services to benevolent institutions. A suitable scale of fees might be agreed upon. It is a violation of the ethics of medicine to steal a patient from a fellow-practitioner, yet the dispensary is an invention with all modern improvements for undermining the private practice of the physician. Numerous physicians will testify to the fact that after a dispensary has been opened in their neighborhood private practice has decreased from one-third to one-half. Whether the doctor engages in this work from motives of charity or simply for purpose of fattening up a clinic for his personal gratification, the results to the profession are the same. The duty of the physician to himself, to his family, and to society requires that he should correct this abuse. The following is quoted from one of our medical journals: "In France a physician won his *entrée* into the Legion of Honor by devoted services during a cholera epidemic, and his beloved wife recently elected suicide as a prophylactic against starvation. The moral in this case is macroscopic."

There are some good points made in Dr. Helen Murphy's letter on "The Drift of Medical Charity" which we published last week. There is no question that if physicians would do their duty by themselves and by their fellows, the time would not be far distant when the position of the hospital and dispensary doctor would be all that it should be.

An Aged Physician in Want.—The Charity Organization Society appeals for \$500 to secure admittance into a home for a worthy couple. The case is a hard one. An aged physician and his wife find themselves without means and without relatives or friends able to help them. Their reputation is excellent, and their need is believed to be due to circumstances beyond their control. Money for this object should be sent to the Charity Organization Society, United Charities Building, 105 East Twenty-Second Street, and will be duly and publicly acknowledged.

News of the Week.

The "X" Ray before the County Medical Society.

—At the meeting of the Medical Society of the County of New York, April 27th, Dr. W. J. Morton demonstrated apparatus and method of viewing and skiagraphing the interior structures of the human body by the "X" ray. The large hall was crowded to overflowing, and everybody present awaited patiently his turn to look into the darkened box and view the interior of his hand, placed between it and the screen separating it from the vacuum bulb or Crookes tube. Very distinct skiagraphs were shown of the bones of the hand congenitally deformed, of a fractured radius, of all the bones and even organs of an infant. By use of a screen of tungstate of calcium about seventeen inches in diameter, lent him by Edison, he was able with the room darkened to demonstrate to the entire audience the bones of his hand. A skiagraph was taken of a patient's hand supposed to contain a needle. It proved highly satisfactory, showing the needle and bones very distinctly. A Ruhmkorff coil with a spark of four and a half inches was employed. Dr. Morton said he would prefer a spark of twenty-four inches. The lantern-slide exhibition proved conclusively that the "X" ray was capable of more than simply showing a shadowgraph of the bones, as was at first supposed. It was capable of revealing the outlines of the various soft tissues as well, and even the interior of the bones, while by the aid of the fluoroscope we could see the beating of the heart. The society adopted a resolution opposing the adoption of a bill before Congress against vivisection.

The American Pediatric Society and the Collective Investigation of Diphtheria Antitoxin.

—Owing to the number of physicians who have signified their desire to co-operate in the collective investigation of diphtheria antitoxin by the American Pediatric Society, and have not yet had time to send in their reports, the committee wishes to announce that the time of receiving the reports has been extended to May 9th.

Antimicrobin is the latest remedy for tuberculosis. It was described by Dr. Langheld at the recent German Congress for Internal Medicine held at Wiesbaden during the second week in April.

The Newark City Hospital.—The plans for a new city hospital in Newark, N. J., have been accepted, and work upon the building will begin soon. The plans, which were drawn by Mr. Wilson C. Ely, call for a central or administration building, with four wings, three for patients and one for the nurses' quarters and school. The main building and wings are to be four stories high. There will be an electric plant for all power purposes, a finely equipped laboratory, and reception rooms and offices for the governing staff. The wards will be provided with two hundred and sixteen beds, and in the isolation section there will be twenty beds. The cost of the building is to be \$200,000.

Yellow Fever promises to be exceptionally malignant this year in Cuba, and the Cuban patriots rely upon its ravages among the Spanish troops to aid them in their war for independence. Reports to the United States Marine Service indicate a death rate of forty for the week ending April 11th at Santiago de Cuba. Even negroes as well as native Cubans have died at Santa Clara, it is said, and this is creating considerable alarm, since the negroes are usually expected to escape. Small-pox is also reported to be quite prevalent at several points and, as vaccination is not generally practised, an increase is looked for.

Dr. John Aulde has retired from the editorship of the *American Therapist*.

The Transactions of the Pan-American Medical Congress have just been published. There have been many inquiries concerning the delay in publication of these transactions. Dr. Charles A. L. Reed, secretary-general of the congress, transmitted the manuscript of the proceedings to the secretary of state, Washington, in November, 1893, but a little over sixty days after the adjournment of the meeting. With this act the proceedings passed beyond his custody and became the property of the United States government, by which they were printed. The delay was therefore not the fault of the officers of the congress.

Influenza is reported to be raging in Matabeleland, South Africa, and nearly half of the British troops engaged in suppressing the rising of the natives are suffering from the disease.

The Spitting Nuisance.—The health commissioner of Brooklyn has sent a communication to the presidents of the railroad companies asking them to post the following order in each car:

"Spitting on the floors of public conveyances is a public nuisance and a source of danger to the public health. It is hereby prohibited.

"COMMISSIONER OF HEALTH.

"Employees of this company are hereby required to enforce the above order of the health commissioner.

"SUPERINTENDENT."

We trust a compliance with this request will be more general than has been the case in this city, where a similar notice is conspicuous by its absence.

Diphtheria Antitoxin in Newark.—At a recent meeting of the Newark, N. J., Board of Health, the bacteriologist, Dr. Richard M. Connelly, reported that since the making of antitoxin was begun 1,200 vials of the serum had been produced. The serum was used in 660 cases out of a total of 939 cases of diphtheria reported since July, 1895. In the 660 cases treated with antitoxin there were 85 deaths. Of the 333 patients treated in the old way 138 died. Dr. Herold, in his annual report, said that antitoxin had proved a great life saver in the hands of physicians.

A Study of the Roentgen Rays in St. Petersburg.—A sum of 5,000 roubles (\$2,500) has been granted to the St. Petersburg Medical Academy for

the purposes of experiments with the "X" rays. A committee has also been appointed to consider the question of the application of Roentgen's discovery to practical medicine.

The First Heatstrokes.—What are probably the earliest sunstrokes on record in this latitude occurred on April 16th. An Italian laborer, thirty-seven years old, was overcome by the heat about midday and was removed to the Harlem Hospital, where he died shortly afterward. The other sufferer was a woman, twenty-five years old, who received a sunstroke while on an East River ferryboat, and was removed to Bellevue Hospital.

Typhoid Fever in Newark.—In the annual report of the health officer to the Newark, N. J., Board of Health it is stated that there was a marked increase in the number of cases of typhoid fever during the past year. The increase occurred when the street paving was in progress and in neighborhoods where the paving was being done. It was thought that the disease was traceable to the sand taken by the contractors out of the sand banks of the Passaic River. The river sand was covered at high tide, and the typhoid germs were deposited in it and carted to the city in the sand wagons. The bacilli were scattered by the wind, and in this way infection was spread.

Greater than the "X" Rays.—Professor v. Bergmann, in a recent address, disclaimed any desire of refusing to recognize the importance of Roentgen's discovery to surgery, as well as to other arts and sciences. It is, he said, a welcome addition to the surgeon's means of diagnosis, but he still thinks that the Esmarch bandage and antiseptics are achievements of far greater worth.

Dr. Ernest B. Sangree, of Philadelphia, has been called to the chair of pathology and bacteriology in Vanderbilt University, Nashville, Tenn.

English at the Moscow Congress.—Dr. J. W. Gleitsmann, of this city, writes: "As a number of your readers are undoubtedly interested in the preliminary arrangements of the International Congress at Moscow, 1897, I beg to state that I received information from Russia last week that the English language has been adopted as one of the languages of the congress in all its transactions and that laryngology and otology will form independent sections."

The Health of the State of New York.—The fifteenth annual report of the State Board of Health just published gives some very interesting statistics concerning the prevalent diseases and their relative mortality. Thus the death rate of typhoid fever in cities is 20.70 per thousand and in rural districts 23. Grippe is evidently dying out. There were 3,000 deaths last year, 6,000 the previous year, and 8,000 the year before. Only 414 deaths occurred from malaria. The actual number of deaths from all causes was less than during the last three years; 5,818 persons died of old age, 12,804 died of tuberculous diseases. The total number of deaths from diphtheria reached 6,616.

A Western Society of Ophthalmologists, Otologists, and Laryngologists was organized at a meeting held in Kansas City, Mo., on April 9 and 10, 1896. The following officers were elected: Dr. Adolf Alt, St. Louis, *President*; Dr. B. E. Fryer, Kansas City, *First Vice-President*; Dr. William C. Pipino, Des Moines, Ia., *Second Vice-President*; Dr. J. M. Martindale, Minneapolis, Minn., *Third Vice-President*; Dr. Hal Foster, Kansas City, *Secretary*; Dr. W. L. Dayton, Lincoln, Neb., *Treasurer*. Seventy-five members were in attendance. The next meeting will be held on the second Thursday of April, 1897, in St. Louis, Mo.

Long Island College Hospital.—The regents of the Long Island College Hospital, Brooklyn, have appointed Dr. H. Beeckman Delatour surgeon to that hospital. Dr. Delatour has for eight years been one of the surgeons to the Methodist Episcopal Hospital, for five years attendant at the Norwegian Hospital, and for three years secretary of the Brooklyn Surgical Society.

Progress in Skiascopy.—Tesla and Edison are hard at work endeavoring to turn Roentgen's discovery to practical use. Mr. Tesla has already succeeded in his experiments so far as to be able to look completely through a human body and distinguish moving substances on the other side. He says that he has now obtained all the power desired, and is devoting himself to differentiation of the rays. He hopes within a short time to be able to control the rays so as to see the different organs in the human body clearly and distinctly. This is the object of his present experiments. In addition to seeing through a body, Mr. Tesla has photographed the skeleton of his assistant at a distance of six feet from the tube. The screen used by him is the platino-bario-cyanide screen, instead of the fluorescent screen adopted by Edison, and he is confident that it is better for the purpose.

A Fanciful Explanation of Second Sight.—Dr. Ottolenghi suggests in the *Riforma Medica* that the supposed power of seeing through opaque media, which is claimed by certain trance subjects, may find an explanation in the light of the recent discoveries of Roentgen. The author supposes that in the abnormal conditions of the nervous system obtaining in this class of patients, the retina may be sensitive to the "X" rays, which, under ordinary conditions, fail to produce any impression.

The Cape May County (N. J.) Medical Society held its annual meeting at Cape May on April 16th. The president, Dr. Way, read a paper on "Fish-Slime Disease." The following officers were elected for the ensuing year: Dr. Eugene Way, *President*; Dr. W. A. Lake, *Secretary*; Dr. Randolph Marshall, *Treasurer*; Dr. A. L. Leach, *Essayist*.

A Portuguese Medical Meeting.—A national medical congress is to be held in Lisbon in July, 1897, on the occasion of the quadricentenary of the discovery of India. Professor José Antonio Arantes Pedroso, director of the Eschola Medico-Cirurgica of Lisbon, will preside.

American Orthopædic Association.—The tenth annual meeting of this association will be held at Buffalo on May 19, 20, and 21, 1896. The president of the association is Dr. Royal Whitman, of New York; secretary, Dr. John Ridlon, of Chicago.

A Medical Plunger.—A Russian army surgeon tried his luck at Monte Carlo last winter and won \$425,000.

Congratulations for Dr. Kingsbury.—The Fylde Medical Society, of which Dr. Kingsbury is secretary, held a special meeting in Blackpool on March 20th, to hear an explanation from him of the charges against him in the *British Medical Journal* of advertising in connection with a hotel, deeming it more satisfactory that his conduct should either be vindicated or condemned by members of his own profession than that the verdict of a lay jury, already given in his favor at the Manchester assizes, should be accepted as final. After discussing the question from all sides, it was voted unanimously "that, having heard the explanation given by Dr. Kingsbury, the Fylde Medical Society hereby unreservedly accepts the same as satisfactory." At the conclusion of the meeting Dr. Kingsbury received the warmest congratulations of his medical brethren.

The District Medical Society of Cumberland County (N. J.) held its annual meeting at Bridgeton on April 14th and elected the following officers: Dr. D. H. Oliver, *President*; Dr. S. M. Snyder, *Vice-President*; Dr. H. Mailly, *Secretary*; Dr. Joseph Tomlinson, *Treasurer*. Delegates were elected to the American Medical Association and to the Medical Society of the State of New Jersey.

The Middlesex Hospital in London will celebrate its one-hundred and fiftieth anniversary on July 1st.

The Language Question at Moscow.—The St. Petersburg correspondent of *The Lancet* writes that he has received a letter from Professor Crisman, the general secretary of the next International Congress, in which it is stated that the question of languages is to be reconsidered by the executive committee, and that in all probability the English language will be admitted to equal rights with German, Russian, and French. The letter continues: "This will be done because it has become clear that the exclusion of the English language would not be well received by our English colleagues, and the committee do not consider themselves justified in insisting on their first decision if the general opinion of our English colleagues is clearly against it. You may rest assured that the committee, in discussing this question and coming to their first decision, were guided solely by considerations of what would be of advantage to the congress, and were far from having in view the national aspect of the matter."

The Plainfield (N. J.) Medical Association at a recent meeting elected the following officers: Dr. O. L. Jenkins, *President*; Dr. F. C. Ard, *Vice-President*; Dr. Marc L. Clauson, *Secretary* and *Treasurer*.

The Edward Jenner Centenary at Gloucester.—It is extraordinary to note how at Gloucester, a town in which Edward Jenner resided for years, this centenary year of the discovery of vaccination is being kept. First, we find a board of guardians in fair weather when there was no small-pox about declaring themselves boastfully to be opposed to vaccination; then, frightened at their own mischievous default, first recommending vaccination to the public by means of circulars, and later, when still more frightened, actually turning right about face on all their former boasts and resolves, and deciding to enforce the compulsory clauses of the vaccination acts. Secondly, we find that their experience—just one hundred years too late—has been most bitterly bought, for, according to last week's papers, out of ninety deaths from small-pox in the hospital (there have been one hundred and eighteen in all in the city) seventy-four were of unvaccinated persons. Thirdly, we find that among this community which has been so long misled by the guardians there have within a few weeks been some seven hundred cases of small-pox, and that in the absence of any controlling vaccination the disease has seized that part of the town where the sanitary conditions are by no means worst, but where there was an undue proportion of unfortunate children who were unvaccinated. Fourthly, we find some thousands of pounds being spent in an attempt to check small-pox by hospitals, quarantining, and disinfection, but all in vain, for the disease goes on multiplying just the same: indeed, there were no less than one hundred and seventy-two fresh cases last week. And, fifthly, we find that even some of those most responsible for the terrible loss of life among the unvaccinated are hurrying to get protection by vaccination for themselves. We leave those who have been so grievously injured by disease, maiming, and death, to apportion the blame. Here we only note with regret and shame that any British city, and above all Gloucester, should be in the state in which that city finds itself in the centenary year of Edward Jenner.—*The Lancet*.

Alcoholism in Sweden.—The deaths from alcoholism are stated to amount in Stockholm to ninety per thousand. This is the highest rate in the world.

Obituary Notes.—DR. JOHN J. DALY, mayor of Rahway, N. J., died at his home there on April 14th. He was born in Rahway May 26, 1852, and was graduated from the medical department of the University of the City of New York in the class of '73. He practised medicine and surgery in Rahway, and succeeded to the practice of Dr. Abernethy, his preceptor, upon the death of the latter in 1874. He was first elected mayor of Rahway in 1885, and was four times re-elected and once defeated. He was also city physician of Rahway for several years.—DR. THOMAS T. MARTIN died at Allentown, Pa., on March 15th, at the age of forty-five years. At the time of his death he was prison physician and a member of the pension examining board. He had been coroner, and was a member of the health board.—DR. JAMES W. KING, of Milford, Conn., died April 16th, of tuberculosis of the bladder. He practised in Bridgeport from 1875

until a year ago, when he was compelled to retire. He was fifty-six years old, and a widow survives him.—DR. AMOS L. WILLIAMS, of Brookfield, Conn., was struck by a railroad train and instantly killed on April 16th. Dr. Williams was eighty-five years old, and was the oldest practising physician in Connecticut. He was graduated from the Yale Medical School in 1832, and from the Jefferson Medical College in 1841.—DR. W. K. MATTERN, of Philadelphia, coroner's physician and member of the board of education, died suddenly at Philadelphia on April 16th at the age of forty-nine years. He had accidentally infected himself some three years previously in the course of his professional work, and it is believed that death was due directly or indirectly to this cause. Dr. Mattern was a graduate of the Philadelphia College of Pharmacy and of Jefferson Medical College. He was for many years connected with the board of education, was for a time a police surgeon, and was physician to the coroner's office from 1892.—DR. WILLIAM HUNT, a well-known surgeon, died at Philadelphia on April 17th at the age of seventy-one years. He was a pupil of the late Dr. George B. Wood, and was graduated from the University of Pennsylvania in 1849. In 1850 he became a resident physician in the Pennsylvania Hospital, and in 1854 demonstrator of anatomy in the medical department of the university. In 1856 he was elected surgeon to the Episcopal Hospital, and in 1863 surgeon to the Pennsylvania Hospital. The last position he held for thirty years. He was at different times surgeon to Wills Eye Hospital and to the Orthopædic Hospital. During the civil war Dr. Hunt was an acting assistant surgeon, serving principally in the military hospitals in and about Philadelphia. He was a trustee of the University of Pennsylvania and a member of numerous scientific bodies. He was joint author of a work entitled "Surgery in the Pennsylvania Hospital, Being an Epitome of the Hospital since 1756."—DR. WILLIAM SHARP, of Rugsby, died at Llandudno, Wales, at the age of ninety-one years. He was practically the founder of the system of local museums, which is now followed by nearly every large town in England, and received the fellowship of the Royal Society in recognition of this work in 1840. Upon his suggestion, the teaching of physical science was introduced in England in the public schools. He had peculiar views concerning what he believed to be the laws of nature, or, as he called them, law facts, the adoption of which, he claimed, would establish the art of healing upon a firm scientific basis. The details of these inquiries were given in a series of "Essays on Medicine," published at irregular intervals since 1851.—DR. ISAIAH F. PRAY, fifty years old, died at his home, No. 254 West Fifty-Second Street, on April 23d. He was born in Maine in 1846, was graduated from Dartmouth College in 1870, and from the Medical School of the University of New York four years later. He was a member of the County Medical Society and of the Pathological Society.—DR. OLIVER GOSS, of Lakeport, N. H., died April 12th, after an illness of several months, caused by a strain received while endeavoring to hold a runaway horse. He was graduated in 1845 from the

Dartmouth Medical College. He was a member of the New Hampshire Medical Society.—**DR. R. H. WILSON**, a well-known dentist of Louisville, Ky., died at his home in that city after an illness of several weeks' duration. He was seventy-two years of age, and had practised in Louisville for over forty years.—**DR. WILLIAM W. L. PHILLIPS**, chief surgeon of the National Surgeons' Home, died of erysipelas at Hampton, Va., on April 18th, at the age of sixty-seven years. Dr. Phillips was born near Princeton, N. J., and was graduated from Princeton College in 1848, and from Jefferson Medical College in 1851. He entered the United States Army in 1861 as surgeon of the First New Jersey Cavalry Volunteers, and continued in the service until September 20, 1864, for the last two years of this time being surgeon-in-chief of the Second Cavalry Division of the Army of the Potomac. After leaving the army he was made post-surgeon and surgeon-in-charge of the draft rendezvous at Trenton. He served as physician to the city of Trenton for four years and also as physician to the New Jersey State Prison. He was a member of Trenton common council for several terms and also its president, and a member of the board of trade and its president for a time.

Pure Lager.—A bill has recently been introduced into the New York legislature providing for the brewing of pure lager in this State. The bill is drawn on the lines of the measure passed some years ago by the German government. The proposer of the bill says that most of the beer now turned out in this State is made drinkable only by the use of adulterants. It is understood that the bill will compel all brewers to keep their beer in storage at least six months before putting it on sale.

Report on Diphtheria Antitoxin.—The Metropolitan Asylums Board of London has just issued a report of the results following the use of antitoxin in the treatment of diphtheria at the hospitals under the authority of the board. The results were obtained during the year 1895 in six hospitals in which cases of diphtheria were treated. The total number of cases treated with antitoxin was 2,182, in 615 of which the patients died, representing a mortality of 28.1 per cent. The drug was not used in all the cases which came under treatment, but, generally speaking, only in the severer instances. The death rate from diphtheria in 1894 was 29.6, while in 1895 it was 22.5, a reduction of 7.1 per cent. In the laryngeal cases during 1894 the mortality was 62.0, while in 1895 it was reduced to 41.8. In the tracheotomy cases it was 70.4 during 1894, but in 1895 the death rate fell to 49.3. Thus, the improvement in the mortality rate was as much as 20.2 per cent. in the laryngeal cases and 21.2 per cent. in the tracheotomy cases. The clinical results of treatment by antitoxin, noted in the report, were: Diminution of faucial swelling and of the consequent distress; lessening or entire cessation of the irritating and offensive discharge from the nose; limitation of the extension of membrane; earlier separation of the exudation; limitation and earlier separation of membrane in laryngeal cases; improvement in general condition

and aspect of patients; prolongation of life, in cases which terminate fatally, to an extent not obtained with former methods of treatment. The report concludes with the following summary of the improved results in the diphtheria cases treated during the year 1895: A great reduction in the mortality of cases brought under treatment on the first and second day of illness; the lowering of the combined general mortality to a point below that of any former year; the still more remarkable reduction in the mortality of the laryngeal cases; the uniform improvement in the results of tracheotomy at each separate hospital; the beneficial effect produced on the clinical course of the disease.

The National Consumption Hospital for Ireland was formally opened in Newcastle, County Wicklow, on March 26th. The hospital is established on a plan similar to the one at Ventnor in the Isle of Wight. The hospital will at present accommodate only twenty-six patients, but provision has been made for further extension whenever funds may permit. Each patient will have a bedroom entirely separate from the others, and the establishment is heated throughout by a hot-air furnace.

A Newspaper Picture of Dr. Playfair.—The London *Star* thus describes the defendant in the suit which has recently caused so much excitement in London: "Dr. Playfair, the defendant in the case which is now exciting so much attention, is one of the most distinguished of living gynecologists. The public rush to his consulting-room, and his house in George Street, Hanover Square, is the resort of much talent, some rank, and a certain amount of fashion. Dr. Playfair is below the middle height, not especially attractive in appearance, and wearing thick, disfiguring glasses. In manner he is urbane, and he has a habit of rubbing his hands softly together in a way that suggests that his treatment would be gentle."

University of Pennsylvania.—The prolongation of the period of medical study is already making its salutary influence felt. The number of graduates from the medical department of the University of Pennsylvania at its coming commencement will be one hundred and nineteen, the smallest number in many years and as against two hundred and fifty last year.

Philadelphia Hospital.—Dr. Charles W. Burr has been elected neurologist to the Philadelphia Hospital in succession to Dr. Wharton Sinkler, who resigned recently after a long term of active and useful service. Dr. H. B. Allyn was elected medical registrar, Dr. B. F. Stahl neurological registrar, and Dr. John H. Gibbon surgical registrar.

Quarantine Against Tuberculosis.—The government of New Zealand has proposed a law forbidding the landing of any persons of debased physical and moral qualities, the object of the law being to establish a quarantine against tuberculosis. It is hoped that, if fresh importation is stopped, the disease at present existing in the island may be arrested or may die out of itself.

The Medical Association of Alabama will hold its annual meeting in Montgomery on April 21st and the three succeeding days.

Medical Patriots in Spain.—Spanish physicians are in no whit behind their lay countrymen in a readiness to fight the United States and in ignorance of the cause of their anger. Some have written to *El Siglo Médico* proposing, in case Spain declares war against the United States, that all civil practitioners in Spain should engage to do without pay the work of the army medical officers ordered on active service in garrisons and depots; that all practitioners should pay twice the amount they have to pay for their annual license; that all medical men should decline to act on behalf of American insurance offices in Spain, and that the doctors should undertake never to prescribe patent medicines of American origin.

Free Diphtheria Patients.—Dr. R. W. Bemis has been selected by the Philadelphia Board of Health to treat indigent patients suffering with diphtheria with the antitoxin when requested so to do by attending physicians, in accordance with the recent resolution of the board to thus utilize the surplus antitoxin not required for the purposes of the Municipal Hospital.

The War Against Cigarettes.—Greenwood, Ind., is another place which has legislated against the cigarette. Smoking them in the streets is forbidden. In Ohio the legislature has passed a law prohibiting the sale of cigarettes or tobacco in any form to minors, and has provided a severe penalty for offences against this law.

Medical Graduates in France.—The total number of candidates on whom the degree of doctor of medicine was conferred in France in the academic year 1894-95 was 969. They were distributed among the several medical faculties as follows: Paris, 537; Lyons, 12; Bordeaux, 110; Montpellier, 64; Toulouse, 57; Lille, 44; and Nancy, 15.

The Monmouth County Hospital in Long Branch, N. J., is being repaired and enlarged. Additional private rooms are being fitted up and a maternity ward has been added. The hospital is also being repainted, and the front facing the Central Station is to be rebuilt.

Treatment of Infantile Bronchitis.—Dr. Renaut, of Lyons, employs warm baths in the treatment of bronchitis in infants, and claims that by these means the capillary form of the affection can be almost surely averted. Whenever the rectal temperature rises to 102° F. the child is placed for five minutes in a bath of 100° F., the head being covered with a folded handkerchief. If there are any symptoms of cerebral congestion, a stream of water of the temperature of the room is poured on the head. A little champagne, or brandy and water, may be given while the child is in the bath. When taken out, he is quickly dried with warm towels and put back to bed. Frequently, after the third or fourth bath, the fever falls, the râles diminish, and the affection loses its threatening character.

The Futility of Trying to Bolster up a Weak Case.—In commenting upon the case of Kitson vs. Playfair, the *Medical Press* says that the attitude of the judge and the verdict of the jury prove how dangerous it may be to multiply weak medical evidence in a court of law, evidence that, no matter how distinguished the source from which it is derived, serves only to prove to the court and the public that medical men, even when the position is clearly a weak one, will, as is popularly said, "hang together." Never was this made more manifest than in the trial of Kitson vs. Playfair. Since the verdict in this case Dr. Playfair has received hundreds of letters of sympathy from persons of all professions and trades and of note, among them being a long letter from Mr. Gladstone.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the U. S. Navy for the week ending April 25, 1896. April 20th.—Assistant Surgeon H. La Motte detached from the *Franklin* and granted four months' sick leave. April 22d.—Assistant Surgeon M. K. Johnson detached from the Naval Laboratory and Department of Instruction and ordered to the *Franklin*.

To Pay the Costs of Dr. Playfair's Misdeed.—It is stated in an English society journal that Sir James Kitson has expressed his determination to defray out of his own pocket the whole of the damages and costs which may ultimately be imposed upon Dr. Playfair after appeal. Sir James, who is a very rich man, was one of the persons to whom Dr. Playfair betrayed his professional secret.

The Perils of Medical Practice in Cuba.—Dr. Pina and his wife were arrested a few days ago at Santa Fé, Province of Pinar del Rio. They were brought to Havana and thrown into the dungeons of Morro Castle. The charge against them is that they aided and abetted the patriots by attending to sick and wounded insurgents, Dr. Pina as a physician and his wife as a nurse.

Cherchez la Femme.—Dr. Adams, of the University of Pennsylvania, says that in his veterinary practice the wire hairpin is a frequent cause of disease in cattle, and especially in pastures in the vicinity of seminaries for young ladies. He suggests that the lives of many cows might be saved if the hairpin could be manufactured of a material that would be soluble in some one of the animal's stomachs.

Dr. Pio Rengifo, who died recently at Panama, aged seventy, was for many years one of the medical notabilities of the Republic of Colombia. Born at Cali in 1835, he received his professional education in London; in due course he became a member of the Royal College of Surgeons, after taking the degree of M.D. at St. Andrews. After a further period of study in Paris under Velpeau, Trousseau, Malgaigne, and other celebrities of the day, he graduated in the Faculté de Médecine in 1863. Colombia being then in the throes of civil war, Rengifo betook himself to Peru, and practised with success at Lima for some years. He afterward settled at Bogota, and he was

the first lecturer on pathological anatomy in the university of that city. He was also one of the founders of the *Sociedad de Medicina de Bogota*, and he was for some years editor of the *Revista Medica*, which is the organ of that society. Domestic affliction after a time made Bogota unbearable to him, and he went to New York. At the International Medical Congress held at Washington in 1887, Rengifo was a delegate from the Republic of Colombia. In 1891 he went to Panama, where he practised till his death. He was a man of singular integrity of character, with a high sense of the dignity of his profession. He contributed to medical literature papers on diseases of the liver, waxy degeneration, leprosy, etc.—*British Medical Journal*.

Medical Histrionics.—A medical play by a doctor called "Hypnotic Suggestion; or, a Woman's Vengeance," was recently performed at an Odessa theatre, the actors and the orchestra being all doctors, and the audience convalescent patients let out of the hospitals for the occasion.

An Epidemic among Horses of an unfamiliar disease, which kills four out of five of the animals attacked, has broken out in the Borna region near Leipsic.

Measles in New York.—The epidemic of measles still prevails in this city, the report of the Bureau of Contagious Diseases for the past week showing five hundred and thirty-one new cases of the disease. There were thirty-six deaths. This is much larger than the average for the past few months, although that has been unusually large.

Notification of Infectious Diseases in Connecticut.—Dr. C. A. Lindsley, superintendent of registration of vital statistics of the Connecticut State Board of Health, writes: "In your issue of April 18th I notice an error of statement on page 559. It is there stated that in Connecticut the plan is, or was, in existence, 'to pay the physician 25 cents for each notification of a case of infectious disease or a birth.' Physicians have never been paid for reporting infectious diseases in this State. But they are paid 25 cents for each certificate of birth and death rendered to the town registrar, if rendered monthly as the law requires. The legal question of the power of the legislature of Connecticut to authorize the enactment of ordinances requiring physicians to report infectious diseases without compensation was decided in the affirmative by the Supreme Court in 1887. See report of decision in Annual Report of Connecticut State Board of Health for 1889."

The Late Professor Semmola.—In the obituary notice of Professor Semmola, in last week's issue of the *MEDICAL RECORD*, the name was incorrectly printed Mariani; it should have been Mariano Semmola.

The Young Man may have His Fling, but he should not fling pies at the cook's head, as did the internes of one of our hospitals not long ago. The house staff of the hospital in question had been suffer-

ing long from an economically furnished table, and one day, when some more than normally sclerosed pies were offered for their digestion, they rose in rebellion, and seeing the offending chef resting from his labors in the hospital yard, they hurled the alleged comestibles at him. Their aim was good, and the chef obtained the necessary lead-and-opium wash from the apothecary without charge.

The Study of Diphtheria in Switzerland.—The Swiss government has instituted a collective investigation of diphtheria on a national scale, which is to be continued for two years from March 1, 1896. Every case of the disease, whether under the care of a private practitioner or in a hospital, is to be notified to the local sanitary authority, and every week a report is to be sent to the Swiss health office at Berne. Forms for this purpose with addressed wrappers are supplied to each practitioner. In order to insure completeness, and as a measure of justice to the physician, a small fee will be paid by the authorities for each form duly filled up and dispatched.

Philadelphia County Medical Society.—At a meeting of the Philadelphia County Medical Society, held on April 22d, Dr. H. A. Hare reported a case of epileptiform convulsions of toxamic origin in which the attacks ceased on removal of the condition on which they depended; also a case presenting rhythmic contractions of the recti abdominis muscles in a hysterical individual with cessation of the spasm after lavage and the adoption of appropriate dietary regulations; third a case of intestinal obstruction associated with appendicitis with partial recovery following abdominal section and removal of the obstruction due to a band of adhesion and also of the appendix; and finally a case of typhoid fever in which a relapse appeared to be induced by an early return to semi-solid food. Dr. H. G. McCormick, of Williamsport, read a paper dealing with "Some of the Therapeutic Uses of Guaiacol," in which he detailed the excellent results obtained from topical applications of the drug named to the cutaneous surface with friction, in the reduction of the temperature in cases of typhoid fever especially. The doses employed varied from two to twenty-five drops. The medication proved safe, convenient, and simple of application, and its use was attended with no bad effects. The drug is further a useful intestinal antiseptic. It may also be employed in the treatment of neuralgia and myalgia applied to the surface or injected hypodermically, and as a local application to the throat in cases of diphtheria and to healthy throats to prevent infection. For internal administration the dry carbonate or salicylate may be substituted for the liquid. Dr. Joseph Price read a paper entitled "Recto-Vaginal Anastomosis and Complete Extirpation of the Vermiform Appendix." He recommended the first procedure in cases presenting extensive involvement of bowel, uterus, and adjacent parts, to obviate the formation of an artificial anus or the spontaneous establishment of abnormal communications between the bowel and neighboring viscera. Price advocated in suitable cases excision of the appendix with suture of the stump.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, April 21, 1896.

REYNOLD W. WILCOX, M.D., CHAIRMAN.

The Treatment of Pulmonary Tuberculosis.—DR. IRWIN H. HANCE read the paper (see p. 622).

DR. BEVERLY ROBINSON opened the discussion. He said he had been glad to listen to the reading of the paper, because the writer had had such excellent opportunities to judge of the value of the measures discussed. Regarding the preparation of creosote, he had always come back to the alcoholic solution, which he thought was the best means of giving it internally. It was a mistake to give very large doses; the stomach would rebel. Dr. Robinson had confidence in creosote inhalations, which he employed by adding an alcoholic solution of the drug to hot water in a croup kettle. The patient breathed this medicated vapor for hours every day. Occasionally it caused headache. His impression was that creosote acted in two ways, namely, by improving the nutrition and by rendering the soil unfavorable for the tubercle bacilli. He believed the microbes were less active and less objectionable after the prolonged use of creosote than before.

So far as high altitudes were concerned in climatic treatment, his own observation had led him to believe that patients did better in the Swiss Alps than in Colorado. They showed less tendency to hemorrhage in the Alps. Some patients who could stand the cold did well in the Adirondacks; the other class might do well in Asheville or in the warmer region of the so-called sandhills of Georgia. Dr. Robinson felt that Sulphur Springs, other things being favorable, furnished a climate beneficial for consumptives. This view was confirmed by experience in the south of France.

DR. ANDREW H. SMITH thought we were now justified in approaching a case of phthisis with some degree of hopefulness. Unless the disease were far advanced, we could regard the case as fairly within the possibility of rescue. The fact should be recognized that tubercle bacilli never become implanted in the healthy system. There was always an anterior abnormal condition, and it was that condition which should receive our first attention. Next, the treatment should consist of careful attention to many details. The patients should receive the advantage of every little aid which we could extend to them. The ideal treatment would embrace climate and everything which would tend to improve the nutrition. By sufficiently improving the nutrition we lifted the patient above the plane on which the tubercle bacillus flourished. The diet had to be adapted to the individual case. It was quite possible to overfeed and thus disturb the stomach. It might be necessary to resort to rectal feeding in order to improve the circulation, nutrition, and indirectly the digestive power of the stomach. Out-of-door treatment was best, but where it was impracticable he thought benefit was to be derived from the inhalation of oxygen gas. The condition of the blood should be studied, for some florid patients had anæmia. If the hæmoglobin were down to sixty or seventy per cent, we were not doing all we should to improve the quality of the blood. Pulmonary gymnastics could be employed to prevent the development of tuberculosis, and especially to prevent the formation of a nidus for the bacilli at the apex of the lung. The use of wind musical instruments was recommended. Creosote came in for diminishing catarrhal condi-

tions. As to climate, the best results seen by Dr. Smith had come from El Paso. The only drawback to the place was want of suitable accommodations.

DR. SIMON BARUCH thought the most important point was to treat the patient, not the disease. The physician should treat him methodically, judiciously, and hopefully. He should be regarded as very sick, even in the incipient stage, for if the disease were allowed to go on the end would likely be fatal. The first thing to be done was to study the patient's temperament and psychical condition. In the majority of cases he would tell him the nature of his disease in order to get his co-operation in the treatment. The tripod of treatment rested upon air, water, and diet. Since so great a variety of climate had been advised, it would seem there could not be much virtue in climate of itself. He thought that benefit depended rather upon living out of doors in a pure, dry air, free from dust, excessive moisture, and rapid temperature fluctuations. He had seen many patients improve and even recover in New York City. By air treatment he meant exposure in pure, fresh air day and night. The patient should occupy the best room in the house, one having if possible a southern exposure, well lighted and ventilated, and ample provision for heating with window open day and night; no carpets nor hangings should be permitted. Let the patient avoid exposure to draughts and bask in the sunshine. Dr. Baruch said his views of water treatment had been mentioned in the paper. The effect of this treatment was to improve appetite and digestion, so that the dietetic treatment was made easier. The selection of food must be based on the demands of the individual case. He would emphasize the value of two articles, Philadelphia cream cheese and steamed rice. Creosote disturbed the stomach and thus interfered with our best ally in the battle.

DR. H. P. LOOMIS thought the facts put forward in the paper were well founded. With regard to tuberculin, however, he had not seen beneficial results, and the question had suggested itself to his mind whether it had anything to do with what seemed to him the unusual number of cases of hemorrhage at Saranac Lake. He quite agreed with the author as to the necessity for informing the patient of the nature of his disease in order to get his immediate co-operation. He, too, had found the best results from creosote when it was put up with bismuth. The climate to be selected depended upon the patient. Speaking of diet, he said if one could not cause the reduced patient to gain weight, he could rest assured that his pulmonary condition was not improving. From the point of view of dietetic management three stages could be recognized: 1, that in which there was no disturbance of the stomach and nutrition; 2, where there was inability to take solid food; 3, inability to take liquids. The treatment of the three stages would vary. Often there was inability to get enough nutrition with but three meals a day. In such cases a glass of milk taken between meals would result in improvement. Stimulants had not been mentioned at this meeting, although much discussed on other occasions. Dr. Loomis thought they were capable of doing as much harm as good. During the first stage they were better let alone.

DR. WALTER B. JAMES said he would emphasize the importance of the patient's mental attitude toward his disease and its influence upon the disease itself. There was a battle going on between the tissues and the bacilli, and he thought the nervous impulse going to the tissues was of a decided aid. Now and then we met a person who became phthisical immediately after some very depressing mental influence. Again, most of us were familiar with cases of phthisis remaining chronic or latent until excited to activity

by mental depression. The power of some men to inspire hope and confidence in their patients might account for their greater success. It was only by telling the patient of the nature of his disease that he could be induced to make those radical changes in living which were quite necessary for a cure. The speaker had hope that further tests would yet show healing virtues in tuberculin. He confessed to a belief that creosote had some other action than simply that of improving the nutrition. Otherwise it ought to improve nutrition equally in other diseases, which had not been the case in his experience. Perhaps it fortified in some slight degree the powers of the tissues to resist the germs. Small doses of opium in some form were useful, even in the early stage. As to climate there was no general law, but patients did better on leaving the place in which they had acquired their disease. If at the seashore, they would probably do better inland.

DR. ACHILLES ROSE would advise cultivation of the soil or life in sanatoria for consumptives, rather than in homes where others were liable to be infected.

DR. HUTCHESON, of Buffalo, thought all that had been said at this meeting pointed toward improving the resisting power of the cells of our bodies; to the fact that we have within us the healing and the cure of the disease; that phthisis was emphatically a disease of weaklings, using the term in relation to the tissues as well as to the individual. The treatment could be summed up in the words of Dr. Loomis—everything which would improve the general condition of the patient would help the disease. Among the lower animals as well as among men, it was observed that consumption was most prevalent among those whose habits or surroundings lowered the resisting powers: examples, on the one hand, were lions, tigers, dogs; on the other, cattle, domestic fowls. The Tartars were exempt; the Chinese in cities were not. Again, in the lungs we had the youngest tissue of the body in embryological development and in the ascent of the race. The last to come was first to go. The weakest point in the lung, too, was the first to become involved, and this law was equally true in tuberculosis of the long bones and vertebrae. The purpose of treatment should be to build up the tissues, strengthen the vitality, and place the individual in condition to repel the intruder.

DR. HANCE said that during the time he was at Saranac Lake there were fourteen physicians there as patients. Most of them came soon after learning of the nature of their disease, and in consequence eight of them were able now to do a day's work in the localities where they had taken up their residence. If patients were told of their disease early, they, too, would follow advice in time to be cured. Where hemorrhage had occurred at Saranac Lake it had usually been due to walking too rapidly up hills, contrary to instruction.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, April 23, 1896.

WILLIAM R. PRYOR, M.D., CHAIRMAN.

Anomaly of Anterior Branch of Internal Iliac; Ligation of Both Internal Iliacs Suggested for Inoperable Cancer of Uterus.—The chairman, DR. PRYOR, presented some dissections showing inconsistency of the anterior branch of the internal iliac artery. He had himself found no anterior branch in at least half of about fifteen dissections, and a foreign investigator, S. N. Jastschinski, was quoted as having found it present in only seventy per cent. of six hundred and forty dissections. Moreover, in half of the seventy per cent. the anterior branch was too short or too irregular to permit of surgical ligation. Further, some of its branches, including the vaginal, not infre-

quently sprang from other vessels. These facts were against Dr. Polk's proposition to ligate the anterior branch of the internal iliac, for, besides being impracticable in a large percentage of cases, in a certain proportion of the others it would not control the circulation on the posterior surface of the uterus and upper vagina. Dr. Pryor suggested ligation of both internal iliacs in order to control the circulation in cases of inoperable cancer of the uterus, in accord with some experience of Dr. Bryant, Dr. Dawbarn, and other surgeons in controlling the growth of inoperable malignant tumor in other parts of the body, especially of the maxilla, by cutting off the blood supply of the parts.

Ligates the Anterior Iliac in Hysterectomy.—DR. WILLIAM M. POLK demonstrated the pelvic circulation on the cadaver and gave his reasons for tying the anterior iliac instead of simply the uterine artery in hysterectomy, especially for cancer. Ligation of the uterine artery, in addition to the ovarian, was not sufficient to control the bleeding while operating on the pelvic tissues, nor to check in any efficient degree the free blood supply to the parts in malignant disease. By a study of the anatomy of the parts he had found free collateral circulation established through the pubic, the obturator, and the middle hemorrhoidal. A posterior vaginal branch from the middle hemorrhoidal was seldom mentioned in the books, yet in some cases it was of unusual size and contributed more to the circulation of this area than did the uterine artery with which it was collateral. These facts had led him to go back of the uterine artery, and tie the larger branch from which those named were offshoots, namely, the anterior branch of the internal iliac. Regarding the practicability of tying the latter, he said it was simply a question of anatomical fact. It could be done in a large percentage of cases, for while there was considerable irregularity in the manner in which the several smaller branches were given off, yet in the vast majority of instances the internal iliac was found to divide into an anterior and a posterior branch, and ligation of the anterior branch would give a bloodless field for operation. As already stated, ligation of the uterine branch alone did not give a bloodless field. Dr. Polk did not approve of Dr. Pryor's suggestion to ligate the internal iliac in inoperable cancer, for it would result in cutting off the circulation through the posterior branch, a result which had little bearing upon the matter; or, if the glandular involvement had extended to such a degree, other parts must have become involved quite beyond the nutrient sphere of the internal iliac.

Cystic Ovary and Cystic Gall Bladder.—DR. BERNARD GORDON presented specimens from a woman, aged thirty-two, mother of five children, the youngest four years of age. There was a history of severe attack of colic in the epigastrium fourteen years ago, lasting ten minutes, and there were recurring attacks every three weeks for two years, with nausea and vertigo. The last year and a half she had had pain in the pelvis, mostly on right side; menstruation was painful. Operation was performed in the Trendelenburg posture, and one cystic and one purulent ovary were removed. The larger cyst which had been felt before operation had disappeared, but came into view when the patient was returned to the horizontal position. It proved to be the cystic gall bladder, nine inches long, containing three gall stones and a gelatinous fluid. The incision was a very long one, but the patient made a rapid recovery.

Multilocular Fibroid of Uterus, Cyst of Ovary, Primary and Secondary Operations.—DR. JOHN O. POLAK, of Brooklyn, presented specimens from a case of multilocular and pedunculated fibroid of the uterus and cyst of one ovary. The interest in the case was the great extent of the adhesions, involving the sigmoid flexure,

the rectum, part the of colon, and fully eighteen inches of the ileum. Hysterectomy was done by the method of Baer or Golfe, the patient made an uninterrupted recovery, but after two months he reopened the abdomen for supposed pus mass and found only a firm mass of adhesions between the coils of intestine. This was broken up, the cavity washed out and drained, and the patient made a good recovery.

Speculum for Vaginal Hysterectomy, etc.—DR. H. J. GARRIGUES showed a self-retaining speculum, modified from Auvard's, for use in operations by the vaginal route.

Reflex Symptoms Due to Abnormal Conditions of the Uterus which Cause Subinvolution or Chronic Enlargement.—DR. W. GILL WYLIE read the paper. Twice before he had written articles upon the same subject, the last one of which was published in the *MEDICAL RECORD*, August 4, 1894. Since that date he had seen many cases which had strengthened his convictions as therein stated. The kind of reflex symptoms were of three types, or spoken of in different terms by different men, namely, melancholia, hysteria, and nervous depression. In some cases the diagnosis of melancholia had been made by Dr. Sachs and other neurologists. The nervous symptoms, melancholia, hysteria, or nervous depression, had been coincident with enlargement of the uterus, and had disappeared upon return of this organ to its natural size under the influence of treatment. In several cases there was a family neurotic history, and it was possible that the uterine condition had simply awakened a hereditary tendency. Most of the women had borne children, most of them had had some backache or dysmenorrhœa; in some the enlargement of the uterus seemed to be simply a state of subinvolution, but usually there was also a laceration of the cervix, follicular change, fibroids, or other disease. At any rate, he had so frequently found melancholia associated with enlargement of the uterus that he had become satisfied that there was a direct relationship. He did not mean to say, however, that every woman who had an enlarged and more or less abnormal uterus would have melancholia or hysteria. The latter were more likely to develop if there were an inherited or acquired predisposition. Relief was to be obtained by reducing the uterus, or, if demanded, by removing it. By some older writers these cases were called lacteal insanity when the insanity came on some weeks or months after labor. Dr. Wylie had found almost invariably that reduction of the uterus or removal of the cause of enlargement would cure the lacteal insanity. In addition to treating the uterus itself, it was necessary to give attention to the general health. The most intractable of all forms of chronic uterine enlargement were seen in endometritis complicated by fibroid degeneration. In one instance of this sort Dr. Wylie found that the fibroid had become free in the omentum, and its removal by laparotomy resulted in cure of melancholia for a period of two years. Recurrence of the melancholia having taken place, he found that other fibroids had developed in the uterus, and as nothing else could be done he performed hysterectomy. There had been no further return of the melancholia. Dr. Sachs had seen this patient in Dr. Wylie's hospital and had been unable to cure the nervous symptoms by such means as were at the command of neurologists.

DR. W. EVELYN PORTER said he had had opportunity to observe a number of Dr. Wylie's cases. In most instances there was, he thought, a predisposition to some nervous or mental disease. The uterine condition was an exciting cause, just as ophthalmologists sometimes found ocular troubles the cause of nervous manifestations. Not many of the cases showed subinvolution alone, but also fibroids or other disease. In some there was tubal trouble. The result was better

when the treatment was more radical than simple curettage. It should be remembered that in all lines of surgical work insanity occasionally followed an operation, and this fact would be against operative interference in mild cases. The mental condition in these cases was more apt to be aggravated than benefited by the so-called rest cure. He would rather try systematic exercise, hygienic measures, and mental diversion.

Not New.—DR. PAUL F. MUNDÉ said he had heard nothing new, but simply a repetition of indications for pelvic treatment which had been laid down many years ago, but which were then considered more or less doubtful. He had himself read a paper before the neurological section, March 3, 1886, entitled "Clinical Observations on Reflex Genital Neuroses in the Female," which had covered very much the same ground as the paper of Dr. Wylie, but in a much more extended form. In it he had expressed the conviction that gynecologists might see women with pains and aches which were not dependent upon the pelvic organs; that women could have hallucinations, melancholia, and mental disturbances of various kinds which were not dependent on disease of the sexual organs; that there might be coexisting disease of the latter organs without causative relation; and that cure of the pelvic disease might be followed by disappearance of the nervous symptoms. He could operate four or five times more frequently if he could make up his mind that repair of a cervix, perineum, etc., would cure such nervous symptoms. Women with enlargement of the uterus were much benefited by reduction of the organ to its normal size, yet he saw many such cases and others with laceration of the cervix, etc., unattended by neurosis. As to removal of the whole uterus because a woman was a little out of her mind, he would draw the line there. Probably removal of a toenail would do just as much good. Nor would he remove the uterus for insanity if it contained a fibroid, unless the tumor itself were an indication.

Medical Gynecology.—DR. E. H. M. SELL related one or two cases of enlargement of the uterus with hysterical symptoms treated successfully by non-operative measures. There were two remedies in particular which he would recommend in medical gynecology, namely, iodide of barium and fluoride of calcium. If there were more medical gynecology there would be less operative gynecology.

DR. HERMAN L. COLLYER related one of several instances known to him in which women had been sent to the insane asylum by neurologists when disease of the pelvic organs had passed unnoticed or had not received treatment. In the given case Dr. Grandin cured the disease of the uterus and tubes and the insanity disappeared. An accurate diagnosis was too often wanting. He agreed with Dr. Wylie, that operations would often cure mental disturbance.

DR. H. J. BOLDR did not take it that Dr. Wylie was going to operate to cure insanity. Then we should not forget the influence on the mind of a change of surroundings, etc. A woman had been having twenty to thirty hystero-epileptic attacks a day. He operated for endometritis, and the epileptic seizures ceased. Why? Not because of the operation, but because of the mental influence, change of surroundings, etc.

DR. J. RIDDLE GOFFE thought we were on uncertain ground when we taught that disease of the pelvic organs or of other organs of the body would cause mental disease, and that cure of the pelvic disease would cure the mental trouble. He thought the explanation lay in a change of scene and impressions upon the mind.

DR. PRYOR believed there were hundreds of women in the lower walks of life, without any one to defend

or care for them, who were sent to an asylum for the insane three to five months after confinement while suffering from chronic inflammation, say subinvolution with slight temperature, who could be relieved by operative treatment. As to the influence of operations on the mentality, he did not believe it was deleterious. On the contrary, he thought it was much more harmful to take such a melancholiac or hysterical woman and subject her to repeated minor gynecological treatment for a period of some months.

DR. WYLIE would take even stronger exception to Dr. Goffe's remarks than to Dr. Mundé's. He had never claimed that disease of the uterus produced disease of the brain or of the nervous system. The paper had distinctly stated that he had found certain reflex symptoms associated with enlargement of the uterus, and by curing the latter the former had been relieved. Some of the speakers had attributed the result to change of surroundings, but the same surroundings had had no influence without the operation. Moreover, the reflex nervous symptoms had usually disappeared a short time after the operation, not immediately; sometimes even five or six weeks had first elapsed. Regarding Dr. Mundé's very critical remarks, he felt that he had been born too late to bring out anything new in medicine, for he had been born after Dr. Mundé. But what he had started to say was, that no matter what one might write about, it would be found that somebody else had written upon it before him. Dr. Mundé's paper had been more general.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 20, 1896.

JOSEPH E. JANVRIN, M.D., PRESIDENT, IN THE CHAIR.

Hypnotism as a Therapeutic Agent.—DR. LOUIS LICHTSCHEIN read a paper on this subject and hypnotized two patients. He said that according to Charcot or the school of Salpêtrière, hypnotism was an artificial neurosis capable of being produced only in hysterical persons; that it was of limited utility, its dangers exceeding its value. Leopold held a different view, and claimed that suggestive therapeutics was nothing else than suasion facilitated by a certain psychical condition. This latter was natural with some, and could be secured by hypnotism in others. The three stages described by Charcot had not, he said, been observed outside of Salpêtrière.

Were hypnotism and hysteria associated, or were only the hysterical hypnotics? Dr. Lichtschein said he must formulate a negative answer. While we could hypnotize the majority of persons, there were some who could not be hypnotized. The more one could centralize his thought the easier he could be hypnotized, and the sounder his brain the better.

The school of Nancy held that everybody was more or less suggestible, and its adherents based their theory of the therapeutic action of the agent upon suggestion. Leopold and Bernheim divided the hypnotic state into nine stages, but not all subjects passed through all the stages. The influence might be motor, vasomotor, peristaltic, and secretory. An abstract conception might act upon the individual more powerfully than a concrete conception or one having an adequate excitant from without the body, and by taking advantage of this fact hypnotism could be used for curative purposes. But no one who made suggestive treatment a special study would think of superseding other methods by it. The best results were obtained from employing it in conjunction with other measures. It was self-understood that we could not treat certain diseases, such as scarlet fever and cancer, by this agent.

Functional neuroses of all kinds were favorably influenced by suggestion. The nervous disorders of writers and artisans yielded in a short time. The writer would except epilepsy and paralysis agitans, although for these one or more writers had claimed benefit. Different writers concurred in the opinion that it was difficult to hypnotize neurasthenics, but time and perseverance gave good results. The same was true of hysteria and hystero-epilepsy. Mental diseases were not at all, or but very little, influenced by suggestion. Alcoholism was. The author had had four cases where the desire for alcohol was readily controlled. The Keeley cure was probably based on suggestion, and would probably be more successful if it consisted of suggestion and nothing else. Morphinism responded with greater difficulty, but he had cured four cases. The habitual use of chloral and other hypnotics yielded easily. Nervous asthma could be so cured, and neuralgias in various forms, especially that of the fifth pair, were favorably influenced, but comparatively deep sleep was necessary. Suggestion could be used in various diseases for which one could find no adequate cause, as in insomnia and a great many pains, habitual headache, even migraine without anatomical lesions. The peristaltic action of the intestine could be influenced, and he had checked diarrhoea and removed chronic constipation. Menstrual phenomena were much influenced. By producing local anæsthesia of the skin, one could do minor operations. Neurasthenic conditions in the sexual sphere were markedly benefited by suggestion. For masturbation it might be regarded as a specific. It did not promise as good results in perverse sexual appetite. Enuresis was often relieved and cured.

Hypnotism in the hands of the ignorant and not given soothingly might injure the subject after a time and end by unbalancing his nervous system. For this reason public exhibitions and the practice of hypnotism except for therapeutic reasons ought to be prohibited by law, as had been done in Europe and in some western States.

The author then read the histories of some cases cured or relieved by hypnotic suggestion—cases of ulcer of the leg, enuresis, vomiting, nervous hemorrhage from the uterus, and masturbation.

He then made his demonstrations, first on a young man, then on a girl of about seventeen years. Both were put in hypnotic sleep by a steady, severe gaze for a moment and the command to sleep. In this state the young man held the arm out in cataleptic state, being able to raise, lower, or bend it only when commanded to do so. He smoked a pencil for a cigarette, was disgusted when given the end supposed to be lighted, believed water to be beer and then wine, imagined himself drunk, etc. The girl was carried to the ninth stage and was told that she would on awaking testify that she had seen the president whip a child on Fourth Avenue. On opening her eyes she positively affirmed this to be a fact, and Dr. Lichtschein said she no doubt would so testify in court weeks hence if he were not to disabuse her of the belief by placing her again in hypnotic sleep. In this manner testimony could be made to order.

DR. ERNST SCHMID, of White Plains, in opening the discussion, expressed his belief in the views of Leopold and Bernheim as opposed to those of Charcot. The action was by suggestion. We have two minds, the subjective and the objective. The objective took cognizance of external things, while the subjective mind acted by intuition. The one might act upon the other. He warned physicians to watch the Keeley cure and State legislatures.

DR. W. M. LESZYNSKY had expected to hear more of the dangers of hypnotism. It was not unusual for neurologists to have patients sent them for an opinion

as to whether hypnotism would not benefit them. He thought its sphere of usefulness was limited. When carried up to the major degree it had a deleterious influence on many patients. It was not his purpose at all to question the genuineness of the demonstration to-night, but he would simply remark that it had not differed from many others he had seen, as to which it would be impossible to say that the subjects had not deceived the doctor if indeed they had not deceived themselves.

THE MEDICAL ASSOCIATION OF GEORGIA.

Abstract of the Proceedings of the Forty-Seventh Annual Meeting, Held at Augusta, April 15, 16, and 17, 1896.

The association met in the Richmond County courthouse, and was called to order by the president, Dr. Frank M. Ridley, of La Grange.

The address of welcome was delivered by Dr. EUGENE FOSTER, of Augusta, and was responded to by Dr. E. R. ANTHONY, of Griffin.

PRESIDENT RIDLEY then delivered his annual address, in which he forcibly and eloquently dwelt upon several topics of interest to the profession.

Treatment of Pneumonia.—The first paper read was by Dr. W. J. MATHEWS, of Middleton, entitled "The Treatment of Pneumonia." The author had never seen a case in which he thought the symptoms warranted abortive treatment. Having satisfied himself that he has a case of pneumonia to deal with, his first step is to make the patient comfortable. To meet this end he envelops the affected side with counter-irritants, preferably turpentine. To relieve restlessness, pyrexia, and pain, he gives phenacetin. Should phenacetin fail he gives morphine hypodermically. To reduce hyperpyrexia he administers phenacetin in sufficient doses every three or four hours in connection with a stimulant, the purpose being to reduce the temperature to 101° or 102° F. In his experience phenacetin does not, like some of the other coal-tar products, depress the heart. He advocates the application of blisters. He had never seen a case calling for venesection. To control the pulse he gives veratrum viride every three or four hours with whiskey.

Dr. J. W. DUNCAN, of Atlanta, seldom blisters an adult. In the beginning of the initial stage a blister might do some good. He does not give the coal-tar preparations in pneumonia, for the reason that if they are given to reduce temperature they are liable to produce cyanosis. He frequently uses veratrum viride and considers it a sheet anchor in this disease.

Colles' Fracture was the title of a paper read by Dr. J. B. MORGAN, of Augusta. The diagnosis of this fracture is not difficult. The history of the accident, the characteristic deformity, the pain and seat of the lesion, point at once to the nature of the fracture. Every case of Colles' fracture can be readily reduced by strong, forced dorsal flexion. This is best done under an anæsthetic. The best temporary permanent dressing is Wyeth's modification of Pilcher's. The plaster-of-Paris dressing is an excellent one and is to be preferred in old people in whom there is firm impaction which the surgeon does not care to break up, or in cases in which the fragments are more or less comminuted. It should be applied from the lower border of the metacarpus to the middle third of the forearm, with the patient's hand in the straight position. A straight dorsal splint may also be employed, but it is not so desirable as the plaster of Paris. Under no circumstances should the angular, crooked, or pistol-shaped splint be used, and no form of splint should be allowed to project beyond the metacarpus. The fingers must remain freely movable to prevent stiffness

of the joint. Limited motion should be encouraged at first; later it may be active and free. In aged patients, in whom we have more or less impaction of the broken ends, reduction should not be attempted, as it is better to have a crooked, deformed wrist than a failure in bony union, and impaction favors the consolidation of the fractured bone.

Urinary Examination and Life Insurance.—Dr. W. L. CHAMPION, of Atlanta, contributed a paper on "The Importance of Careful Chemical and Microscopical Examination of Urine in Applicants for Life Insurance." Within the past few weeks the author had examined patients with kidney lesions, who a few days or weeks previously had applied for life insurance and had been recommended as good risks. Cases were cited by the author to demonstrate that a great many practitioners are too prone to overlook the condition of the kidneys, not to make a careful and thorough examination of the urine in examining applicants for insurance. A desire to formulate a correct diagnosis in diseased conditions should lead them to do so. He urged the extension of chemical and microscopical investigations in this line of work.

Dr. A. W. STIRLING, of Atlanta, in the discussion, called attention to some experiments which he had made some years ago, and which formed the basis of a graduation thesis at the University of Edinburgh. To ascertain the actual number of persons in whom albuminuria was present in health, he examined three hundred and sixty-nine boys between the ages of twelve and sixteen, who belonged to one of the large training-ships on the Thames, near London. He examined each one with four different reagents, and found albumin most common three hours after the boys got out of bed and assumed the erect posture, when the percentage was by examination 20.8. Among the boys that played in a band the percentage of those having albumin was about sixty, while among those that did not play in the band it was only 12.8.

Dr. Stirling says that the urine is usually found to be absolutely free from albumin while the patient remains in bed, and it makes its appearance within a variable but generally short time after the assumption of the erect posture, and independently of food and all other conditions. The albumin continues in the urine for only an hour or two, or perhaps in varying quantity throughout the day, but, as a rule, it is disappearing in the afternoon, and is entirely gone by bedtime. The ingestion of food has little effect in producing the albumin, and it is not breakfast which causes its frequency of appearance in the morning.

He examined ninety-two other persons, whose ages varied from five to ninety-four, with the result of showing that with advancing years there was an increase in the percentage of people having albuminuria. From 20 to 30 years he found the quantity of albumin to be only 10 per cent.; 30 to 40, 25 per cent.; 40 to 50, 36.4 per cent.; 50 to 60, 66.6 per cent.; 60 to 70, 75 per cent.; 70 to 80, 75 per cent.; 80 to 90, 83 per cent. These observations were confirmed by Grainger Stewart.

With regard to the advisability of insuring cases of cyclic albuminuria, he would suggest that in the present state of our knowledge the most satisfactory method of dealing would be for the companies to accept an apparently healthy albuminuric at a high premium, agreeing to rearrange this on its being satisfied of the disappearance of the albumin for such a length of time as would give reasonable expectation of such disappearance being permanent.

The Modern Treatment of Skin Diseases.—Dr. BERNARD WOLFF, of Atlanta, read a paper on this subject, in which he outlined in a succinct manner the progress that has been made in the province of dermatology within the last twenty years.

DR. M. B. HUTCHINS, of Atlanta, said the modern treatment of skin diseases should embrace internal as well as local or external treatment. The patient's constitution should not be overlooked, although if he had to choose between local and internal treatment he should prefer the former in the treatment of ninety-nine per cent. of the cases of affections of the skin.

Appendicitis.—A paper on this subject was read by DR. SAMUEL LLOYD, of New York City. It was largely statistical. In making his compilation the author began with the very earliest recorded cases, and it covers a greater number of medical than of surgical cases. The total number examined up to April 5, 1896, was five hundred and fifty-eight, and the result was found to be that two hundred and sixty-three recovered and two hundred and ninety-five died. Of this number two hundred and twenty-six were operated upon; one hundred and ninety-two recovered, and thirty-one died. On the other hand, in direct contrast to this, two hundred and sixty-five cases were treated conservatively; sixty recovered, while two hundred and five died.

A case was cited which the author had seen in consultation, illustrating the course of extraperitoneal abscesses.

Of four hundred and forty-five cases out of five hundred and fifty-eight that were examined, seventy-nine per cent. resulted in abscess, perforation, peritonitis, etc.

The following table gives the full data:

Perforation without given cause, 11; with abscess, 10; with ulceration, 16; with peritonitis, 32; with concretion or foreign body, 41; with gangrene, 7; with gangrene and concretion, 19; with inflammation, 13; with hardened faeces, 1; with concretion and peritonitis, 24; with foreign body and peritonitis, 7—181.

Abscess without perforation: Uncomplicated, 136; containing concretion, 19; with perforation, 2; sloughing appendix, 2; foreign body, 1—160.

Foreign bodies, 36; faecal concretions, 26; inflammation of the appendix, 8; enteroliths, 2; gangrene of the appendix, 9; gangrenous appendix with concretion, 2; inflammation with concretion, 3—86.

General peritonitis: With concretion, 5; foreign body and gangrenous appendix, 1; foreign body, 3; ulceration, 1—10.

Total, 437.

This is a dismal showing for the conservative treatment of appendicitis. The author believes that no case of appendicitis should ever be considered as purely medical. When one is called to a patient it is his duty to immediately prepare for operative interference. He would advise operation in every case, after studying the subject carefully, in which the symptoms showed any tendency to increase. If a tumor was present and the symptoms suggested the possibility of the presence of pus, he would surely operate.

Medical Side of Appendicitis.—DR. E. A. RICHARDSON, of Atlanta, followed with a paper on "The Medical Side of Appendicitis." He cited the opinions of eminent practitioners both in this country and in Europe in favor of non-operative interference in a large proportion of cases.

DR. W. H. ELLIOTT, of Savannah, said the foremost difficulty in cases of appendicitis was to know when and when not to cut. No man was fit to treat appendicitis who was not absolutely willing at any moment it might be necessary to open the abdominal cavity.

DR. WILLIS F. WESTMORELAND, of Atlanta, was quite sure that in every case of relapsing appendicitis he had seen there were adhesions from previous attacks. Some of the patients had died. If they had been operated on in the primary attack, the chances would have been better for their recovery. He would open the abdomen as soon as appendicitis was diagnosed, if the patient would permit it.

DR. JAMES A. WRIGHT, of Augusta, considered the operation for this disease very difficult, for the reason that no two cases were alike. It was an easy matter to cut down, but if pus and adhesions were found around the appendix, the operation was extremely difficult.

DR. J. W. DUNCAN, of Atlanta, had seen and treated medicinally several cases of appendicitis during thirty years' practice, one of his patients having died from a recurrent attack a few months after the primary one. He was satisfied that many cases operated upon were nothing but typhoid fever, and that other cases thought to be typhoid fever were really appendicitis.

DR. J. B. S. HOLMES, of Atlanta, considers the disease a surgical one, and thinks it is safer to operate as soon as a diagnosis is made. The only cases he had lost were those that had been treated medicinally from two to four days previous to operative interference. If an early operation is performed, the mortality should be small.

DR. WILLIAM H. DOUGHTY, of Augusta, maintained that it was not prudent to operate upon every case of the disease as soon as the diagnosis was made, for the reason that the surgeon does not always see the cases in their incipiency. If he did it would be safe to remove the appendix, as the chances were that at this time there would not be pus formation. In other words, the surgeon would have a comparatively clean condition within the abdominal cavity, and the mortality of operations done under these circumstances ought to be small.

DR. M. L. BOVD, of Savannah, took the position that, if all cases could be diagnosed early, it would be wise to operate at once.

DR. GEORGE H. NOBLE, of Atlanta, thought it was extremely unfortunate that the general practitioner should view appendicitis from a prejudiced standpoint. There were undoubtedly many cases of the catarrhal form that were relieved temporarily, or cured by purgation, possibly permanently. Where we have rupture and the discharge of the contents of the appendix into the peritoneal cavity, we have the fulminant form of the disease, and in such cases very prompt and active measures must be instituted. He advocated early operation.

DR. L. C. HARDMAN, of Harmony Grove, said that while there were cases of appendicitis calling for the services of the surgeon, there were others that could be treated successfully by medicinal measures. Of fifteen cases which had come under his care, only two were operated upon. All recovered, both the operative and non-operative cases. In the cases operated on suppuration had occurred, and one of the patients, a physician, was present.

Some Albuminuric Complications of Pregnancy.

—A paper on this subject was read by DR. HOWARD J. WILLIAMS, of Macon. He said this complication was present in from six to fifty per cent. of all pregnancies. On the other hand, puerperal eclampsia was comparatively rare. From January 1, 1891, to March 31, 1896, he had encountered ten cases of albuminuria or toxæmia in one hundred and sixty-three pregnancies, and two cases of eclampsia in these ten cases.

The cardinal indications are to promote elimination of the toxic materials circulating in the blood and to restore the excretory organs to their normal functions. If, however, the poisoning is excessive and the life of the mother and the fœtus is at stake, then the indication is to promptly empty the uterus.

Remedies to promote elimination by the kidneys were then dwelt upon. Nervous excitement should be controlled by sedatives and narcotics, though not to the extent of interfering with eliminative measures. If elimination of the waste products has failed to restore the functions of the excretory organs and the

condition is urgent, eclampsia being imminent or other complications alarming, the uterus should then be emptied.

Orator's Address.—DR. R. B. BARRON, of Macon, delivered the orator's address. He dwelt upon and pleaded for higher medical education. Relative to practising medicine purely for money, he said that with the true physician money was of secondary consideration; that the real incentive for the best works with those practitioners who achieve success was that broad humanitarianism which impelled with resistless force the commissioned agents of God Almighty to relieve suffering, to stay the pangs of agonizing pain, to fight to the bitter end humanity's implacable and unconquerable enemy—death—regardless of any other consideration.

The After-Treatment of Tracheotomy Cases of Membranous Croup was the title of a paper read by DR. R. M. HARMON, of Rome, in which he drew the following conclusions:

1. Croup, whether diphtheritic or membranous, is almost invariably fatal without surgical treatment, and the few cases that recover by medicinal treatment alone are not to be considered.

2. So far as the practical indications for tracheotomy are concerned, it makes no difference whether croup be diphtheritic or membranous.

3. Tracheotomy has the advantage over intubation in that it gives a better means of expectorating the membranes and furnishes free drainage from the site of septic infection.

4. Tracheotomy is a justifiable surgical procedure, and should be performed in all cases in which our therapeutic resources have been exhausted and in which the patient is in imminent danger of suffocation. It should be done in apparently hopeless cases, since it either offers a chance for the patient or promotes euthanasia.

5. Tracheotomy keeps the patient alive until the pseudo-membrane disintegrates and resolves into a muco-purulent liquid, and is expectorated through the tube.

6. The after-treatment is the most important part of the procedure, and the author attributes the successful results reported to the persistent use of lime-water.

DR. J. S. B. HOLMES, of Atlanta, reported several interesting cases.

A Case of Enormous Ventral Hernia Cured by a Plastic or Flap Operation.—By DR. GEORGE H. NOBLE, of Atlanta. The patient was a very large woman who came to him from a neighboring State, giving a meagre history, saying that the protrusion first appeared after severe straining and grew rapidly until it reached the size of an adult head. The treatment she had received consisted in local applications only, no attempt at operative measures having been made. The case is of considerable interest on account of such a large hernia in this region, and because the expansion of the ribs prevented closure of the ring by approximation of its margins, necessitating therefore a plastic or flap operation to close the aperture, which was large enough to pass a closed hand through without resistance.

The operation consisted of: (1) Trimming away the excess of the sac and uniting the peritoneum with buried catgut sutures. (2) Four strong tension sutures were passed through the abdominal walls, piercing the semilunar lines down to the peritoneum, but not implicating it. (3) The semilunar flap was carefully outlined upon either side over the recti muscles with a straight or vertical side upon their outer margins, and the convexed borders turned toward and extending to the hernial ring. The aponeurosis of the external oblique and the outer layer of that belonging to the internal oblique muscles were cut through, the flaps liberated, except where their bases joined the

ring, and turned over the opening, the edges accurately abutting, in which position they were stitched with buried silk sutures. The convexed borders coincided with the margins of the ring to which they were made fast. (4) The recti muscles were brought in direct apposition by surrounding them with the large catgut, thus adding another layer of strong tissue over the hernial opening. (5) The skin and fatty tissue were then brought together and the tension sutures tied over all, the wound dressed antiseptically with firm pad, roller bandages, etc. The wound proved entirely aseptic, and the result was very gratifying.

In another such case the reader said he would use buried silver sutures instead of absorbable materials.

Treatment of Skin Disfigurements by Electrolysis.—DR. M. B. HUTCHINS, of Atlanta, read a paper on the "Treatment of Skin Disfigurements by Electrolysis." That electrolysis has a wide application and a legitimate use, he was convinced by his own experience during the past five or six years. To do the work outlined in the paper a few galvanic cells, a sponge electrode, a needle holder, and for accurate work a milliamperemeter, are necessary. In most cases the needle should be attached to the negative pole. The current used is weak, and varies from three to seven or eight cells. The strength of current used in these operations is harmless to the patient, and is not felt upon the unbroken epidermis.

For the removal of superfluous hairs on the face electrolysis was the only method. Dr. Hutchins had never seen any injury result from the treatment of moles by electrolysis. He had removed one by excision which had become epitheliomatous through a razor cut. There was no recurrence. The author then dwelt upon electrolysis in the treatment of epithelioma, small fibromata, milia, sebaceous cysts, keloids, and hypertrophic scars, comedones, angiokeratoma, etc.

DR. M. L. BOYD, of Savannah, followed with a report of a few interesting surgical and gynecological cases.

The Use of Subconjunctival Injections of Mercury in Certain Forms of Eye Diseases.—By DR. DUBAR ROY, of Atlanta. In this paper the author tabulated twenty-five cases of eye affections, and his experience leads him to the following conclusions: (1) In infected processes of the cornea, ulcers, abscesses, wounds, etc., this method of treatment is quicker and therefore more satisfactory for clinical purposes than those usually employed. (2) In acute iritis it does not seem to exert any beneficial influence, but produces great pain, while in other cases the pain is mitigated. (3) In chronic iritis and iridocyclitis the pain and congestion are often markedly influenced for the better, but it has no effect whatever upon adhesions of the iris to the lens or the capsule. (4) In post-operative infection and panophthalmitis it is by far the best method to which we may resort for good results. (5) In pannus of the cornea absolutely no effect was produced one way or the other. (6) With lesions of the choroid and other deeper structures of the eye he had had no experience, but expects to try this method whenever a case presents itself.

Glaucoma in Relation to General Practice.—DR. A. W. STIRLING, of Atlanta, read a paper on "Glaucoma in Relation to General Practice." He said that glaucoma was to the ophthalmic specialist one of the most interesting of diseases, comprising one per cent. of all ophthalmic troubles. While he believes that every case of the disease requires the most skilled advice that can be obtained, still it is the "first and foremost affection which comes within the province of the general practitioner, and with him lies frequently the ultimate safety or destruction of the eye involved. The reader reported several interesting cases, after

which he dwelt upon the variability in tension. Coming to the treatment he counselled against the indiscriminate use of mydriatics, especially atropine, scopolamine, and cocaine, in affections of the eye. Glaucoma had often resulted from the use of these agents and is almost always accentuated by them. In myotics, and notably in eserine and pilocarpine, we have a fairly certain means of temporarily benefiting many cases of glaucoma and of saving valuable time till the most suitable method of treatment can be decided on.

Election of Officers.—The following officers were elected: *President*, Dr. George H. Noble, Atlanta; *First Vice-President*, Dr. J. B. Morgan, Augusta; *Second Vice-President*, Dr. R. B. Barron, Macon; *Secretary*, Dr. R. H. Taylor, Griffin; *Treasurer*, Dr. E. C. Goodrich, Augusta.

Macon was selected as the place of meeting in 1897.

OUR LONDON LETTER.

(From our Special Correspondent.)

ANTITOXIN IN THE HOSPITALS OF THE ASYLUMS BOARD—KINGSBURY VERSUS HART—DEMONSTRATION OF THE NEW PHOTOGRAPHY—CLINICAL SOCIETY—ENTERECTOMY—DUODENAL ULCERATION—MEDICAL SOCIETY—EXTRA-UTERINE FETATION—HOSPITAL SCANDAL—SMALL-POX AT GLOUCESTER.

LONDON, April 10, 1896.

THE Metropolitan Asylums Board has published a report on the antitoxin treatment of diphtheria in the hospitals under its charge. This report, which has been looked for with considerable interest and even a little impatience, is signed by the medical superintendents of the six hospitals of the board, and includes all the cases treated in 1895. Some statistics of the previous year are also given for the purpose of comparison, as in 1894 only a few cases were treated with antitoxin, and those few are omitted. The report is moderate in expression, as such a document should be, and consists for the most part of the facts of practice in the six hospitals. It appears that 3,529 cases were treated, with 796 deaths, a mortality of 22.5 per cent., as compared with 29.6 per cent. in 1894. There is a table showing the deaths at various ages, from which it seems 41.1 were under five years. Among these the mortality was 34.2 per cent. as against 47.4 per cent. in 1894. Only 46.4 per cent. of those under five years of age received antitoxin, with a mortality of 37.4 per cent.

The earlier the antitoxin was given the greater the success. In cases admitted on the first two days of the disease the mortality was reduced by about half. Thus, among those treated on the first day it was only 11.7 per cent., as against 22.5 per cent. in 1894, and among those on the second day it was 12.5 per cent., as against 27 per cent. Among the third-day admissions the mortality rose to 22 per cent. (against 29.4 per cent.). Among the fourth-day admissions it was 25.1 per cent. (against 31 per cent.). Among those admitted on the fifth day or later the death rate rose to 27.1 per cent. (against 30.8 per cent.). Thus, although antitoxin kept the mortality at all ages below that of 1894, its great value was proportionate to timidity in its administration.

In laryngeal cases the reduction of the mortality was still more remarkable, and there was uniform improvement at every hospital in the results of tracheotomy. The clinical course of the disease was also beneficially influenced, as evidenced by decreased faucial swelling, less nasal discharge, limitation and early separation of membrane, and improved general condi-

tion of patients. Even in cases which resulted fatally life was prolonged more than by any other treatment. With regard to complications, of which so much has been made in some quarters, the report points out that, though the figures indicate a larger percentage, the more efficacious treatment by tiding the patient over a severe illness tends to increase cases presenting complications, since a larger number of those having severe attacks survive, and the opinion is expressed that on the whole, notwithstanding some drawbacks, they are insignificant considering the lessened mortality which has followed the use of the remedy.

This careful report concludes with the following statement: "We are of the opinion that in antitoxic serum we possess a remedy of distinctly greater value in the treatment of diphtheria than any other with which we are acquainted."

The local medical society has held a special meeting to consider the explanations of its honorable secretary, Dr. Kingsbury, who lately obtained a verdict of £150 damages against Mr. Ernest Hart for libel in the *British Medical Journal*. It seems Dr. Kingsbury was desirous of the opinion of his society, preferring to accept condemnation or vindication from his professional brethren, although the jury had pronounced in his favor. He has every reason to be satisfied with his professional neighbors' views. The society unreservedly accepted his explanations and passed resolutions condemning in the strongest manner the attack upon him and the refusal of the editors to insert a letter from him sent since the trial.

In this letter Dr. Kingsbury said, now that he had vindicated himself, he had requested the two hydropathic establishments to remove the plates with his name on and not to put his name on their publications. This he declares he would have done any time during the past twelve years had the journal or any correspondent suggested it. You may remember that the trial arose out of an answer to a correspondent calling himself "Ethics," who complained of Dr. Kingsbury having his name plate at each establishment. This is no more than has always been done, and Dr. Kingsbury says the presidents of branches have met him in consultation at these establishments and the proprietors of one of them entertained the members of the association when they met in a neighboring city. Furthermore, the *Journal* regularly advertises the names of medical officers to asylums, insurance companies, and so on, while that of the president of the Midland Branch may be seen at nearly every railway station in the kingdom in connection with a hydropathic establishment.

This question of medical advertising has been growing for several years. It is not so very long ago that authors and publishers were attacked by medical journals for advertising in the newspapers. Yet at the very time of their bitter onslaught on this practice those journals were advertising weekly their table of contents and even exhibiting them on boards at the railway stations. Certainly some of these contents were not fit subjects for such publicity. *Nous avons changé tout cela*, but whether we are superior to our predecessors is another question. Jealousy and suspicion are so rife that trifles are magnified, and the medical journals are being asked to pronounce on such questions as whether it is more proper to send a lithographed circular than a printed one, whether it is "ethical" to put up a notice that Dr. — has removed to No. — in the next street, and whether a newly arrived doctor who has seen the other practitioner but has not been introduced to his wife ought or ought not to take off his hat to that lady when meeting her. These are samples on which our "ethical editors" have actually delivered more or less accordant judgments.

Prof. Silvanus Thompson has given a demonstration of the new photography before the Clinical Society. Needless to say, the meeting was a crowded one. The learned professor showed the actual process of obtaining the photographs and discussed the theory of their production. This demonstration was in every way successful and the professor received an enthusiastic vote of thanks.

At the ordinary meeting of the Clinical Society Mr. Mayo Robson brought forward the results of his personal experience of enterectomy, consisting of twelve cases, to which he added, by permission of his colleagues, the other cases which had been operated on in the Leeds Infirmary, thus making a total of twenty-six operations. He heard that Czerny was successfully employing sutures alone, but said that with the continuous sutures there is always risk of subsequent stenosis. He admitted the great danger of operating on a distended colon, but there is not always free choice, and when possible to dispense with previous colotomy it is better for the patient. Lateral anastomosis involves excessive suturing, but when indicated, Mr. Robson said, it can be done very well by the aid of two bobbins. He had suggested a larger flange to Murphy's button to obviate the occasional difficulty of inserting the end into the distal intestine.

At the same meeting Mr. A. L. Dunn reported a case of perforating duodenal ulcer successfully operated on. This led Mr. Bland Sutton to say that years ago he had come to the conclusion that duodenal ulcer was pathologically distinct from the gastric ulcer of chlorotic girls. He found that patients with the former were mostly spirit drinkers and therefore bad subjects for surgery. He also said that in flushing the abdomen he never used water under 110° F. or over 115° F. Mr. Dunn said he had often let the water fall to 100° F. without harm.

At the Medical Society meeting fourteen cases of extra-uterine foetation were brought forward, four by Mr. Alban Doran and the other ten by Mr. Harrison Cripps. In the discussion Dr. L. Lewers remarked on the difficulty of deciding the precise indications for operating in each case; for though some patients recover without operating, others would perish if left without interference. The appearance and feel of the breasts he thought to be often of value. Dr. Routh said he had seen many cases of hamatocele apart from pregnancy. He thought the discharges should be carefully examined for decidual membrane, and recommended his binaural vaginoscope, which gave reliable information in many doubtful cases.

Another hospital scandal threatens us, this time at Liverpool. The committee of the Lying-in Hospital want to alter their rules so that patients shall come under the sole care of the matron and not be seen by the medical officer unless she sends for him. The staff is unwilling to be thus placed under an unqualified person, and resignation is the consequence. We shall see whether other practitioners will degrade themselves by accepting appointments vacated for the honor of the profession. Too often men have been found to do such a thing. I hope Liverpool men will set a better example.

Small-pox still rages at Gloucester, new cases occurring at the rate of thirty a day. Between eight hundred and nine hundred have been stricken in the last seven weeks. A sad object lesson indeed. The dean has appealed in the *Times* for funds to help the poor and has well pointed the moral of neglecting vaccination.

A Popular Remedy in Germany for the treatment of epilepsy is made from the eyes of magpies which have been killed on Sylvester Abend.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE RAGE FOR OPERATING AMONG GYNECOLOGISTS, AND THE REACTION—THE GASTROSCOPE—THE SECRETION OF BILE AND JAUNDICE—STILL ANOTHER NEW METHOD OF WOUND TREATMENT—PRACTICAL FOOD PRESERVATION—RENAL TUBERCULOSIS AND THE BACILLI OF SMEGMA.

BERLIN, April 17, 1896.

As in other countries, so with us, there has arisen a powerful reaction against the furor operationis of the gynecologists. In one of the latest sessions of the Berlin Medical Society, Abel brought up this question, and his paper was the occasion of a very stormy discussion, which will, it is hoped, have the freshening and cleansing effect of a thunder shower. Abel reported a case of Cæsarean section which had been necessitated by reason of mutilation of the uterus in previous not absolutely necessary gynecological operations. These operations were amputation of the cervix and ventro-fixation of the uterus. The os had been converted into a rigid, unyielding ring, which it was found absolutely impossible to dilate, and the fundus was so fixed at a point between the umbilicus and symphysis pubis that the axis of the child's body was directed antero-posteriorly in relation to that of the mother. The speaker had no other recourse but to perform Cæsarean section in order to save the woman's life. In the light of this case and of other similar ones which have recently been reported, it may well be asked whether the present prevailing surgical treatment of women's diseases may not be an actual menace to the community, and whether it is not in many cases the cause of more harm than good. That ventro-fixation of a retroflexed uterus especially is a two-edged sword was sufficiently shown by the case above referred to. Statistics show that this operation may even cause death—and this for the relief of a condition that in no way threatens life. Abel favored the conservative orthopaedic treatment of retroflexion, and held that an operation was justifiable only in cases of the most dire necessity.

A short time before this, in the same society, Mackenrodt read a paper upon the operative treatment of diseases of the adnexa, and spoke against the too long-continued palliative treatment of the general practitioner. He reported thirty-one cases of operation upon the adnexa through the posterior cul-de-sac of the vagina for relief of adhesions, tubal occlusion, follicular degeneration of the ovaries, tubal pregnancy (six cases), suppurative salpingitis, myomata, etc. All the patients recovered and were able to sit up at the end of a week. The speaker recommended the employment of this method only in those cases in which it is possible to press the tumor back into Douglas' space; but in such cases he thought it was to be greatly preferred to operation through the anterior cul-de-sac or to laparotomy, which latter is in many cases too dangerous to be justifiable.

These two communications gave rise to a most interesting discussion, in which many of our leading gynecologists took part, a majority of them condemning the operative fury. Landau condemned with special emphasis the methods devised by Dührssen and Mackenrodt of vagino- and ventro-fixation of the retroflexed uterus, whether by the abdominal or by the vaginal route. Simple retroflexion is usually a symptom of general enteroptosis, and to operate upon a movable retroflexion is senseless. When such an operation relieves the distress, its action is simply that of suggestion. Olshausen and others believed that in most cases of retroflexion the gymnastic treatment was successful, and that only in certain cases was an operation necessary, but in these cases it was absolutely necessary. Dührssen, an adherent of the operative

party, if we may borrow this simile, said he had operated through the vagina two hundred and forty times; one hundred and seventy-five of these operations were for the relief of retroflexion, and he had had scarcely one failure. If the treatment were too much of an expectant order the woman was in very great danger of contracting the morphine habit. The sense of the members present at these discussions was very unmistakably against indiscriminate operation in gynecological practice.

In consequence of the latest invention of Rosenheim we are now able to look into the stomach of a patient. His gastroscope is a modification, adapted to the different conditions of the œsophagus and stomach, of Nitze's cystoscope. It consists of a rigid metallic tube, eleven to thirteen millimetres in length, at the stomach end of which the optical apparatus is attached, which is also provided with an arrangement for washing out the stomach and for dilating it with air. Rosenheim has used this instrument in two hundred cases and has seen no evil results when proper precautions were used. In one case of carcinoma, the patient being anæsthetized, an injury was produced. This furnishes a warning against its employment by unskilled hands. Rosenheim advises also very strongly against the use of anæsthetics. The main point is to introduce the instrument from the right side of the mouth, which enables us to slide the tube readily past the diaphragmatic deflection of the œsophagus. Contraindications to the employment of the gastroscope are emphysema, cardiac disease, gastric ulcer, and advanced cirrhosis of the liver; but with these exceptions the method may be applied to all cases, even those of out-door patients. The examination should always be made when the patient is fasting, for anything in the stomach obstructs the view. All parts of the wall of the stomach can be inspected by means of this instrument, especially the region about the pylorus. Rosenheim was able, for example, on two occasions to see an ulcer at the pylorus. According to the inventor's experience the method is practically useful only in cases in which it is necessary to decide as to the advisability of operation. The ideal gastroscope, one whose application is free from danger and which can be used by any one without previous experience, is not yet invented; but Rosenheim hopes that this instrument may render real service in certain cases. From the writer's experience with it, he would conclude that it is hardly an instrument for general use, but should be employed only by one skilled in the technique of operations in these parts.

In a recent paper Renvers argued against the theory of catarrhal jaundice, that it was the result of obstruction to the flow of bile caused by swelling and inflammation of the ductus choledochus. The trouble, he believes, is usually of an infectious and toxic nature, arising from the action of toxins formed in the intestine.

The influence of various substances upon the excretion of bile has been studied experimentally by Stadelmann. We can refer here only to the results of these experiments which are of practical value. He found that the salts of sodium and potassium and the drastic cathartics were wholly without effect upon the secretion of bile. A diminished secretion was caused by alcohol, olive oil, pilocarpine, and atropine. Of doubtful influence were antipyrin, caffeine, and many of the alkaloids. The only remedies which increase the secretion of bile were sodium salicylate and the biliary acids.

Another method of wound treatment has been brought forward by Salzmann. It consists in the application of protecting capsules of celluloid, made of a size and shape corresponding to different portions

of the body. They are transparent, prevent pressure on the wound, keep it clean, and act as a warm moist dressing. When applied securely by means of good American adhesive plaster, they make every other form of dressing superfluous. Doubtless this discovery will be turned to good account in minor surgery.

At a recent meeting of the Medicinische Gesellschaft, Mendelsohn exhibited a metallic vessel with double walls, by means of which it is possible to keep drinks for the sick warm for hours. This is accomplished by means of acetates, which are contained in the space between the two walls of the vessel and act as non-conductors. Plates, cups, pails, and vessels of various shapes are constructed in this way. They will be found of special service in keeping fluids and other materials for the nourishment of the sick warm during the night, and so ready for use at any time without the trouble and delay of heating them over again.

The subject of the diagnosis of renal tuberculosis has been discussed from a very practical point of view by Leyden and Mendelsohn. It is not uncommon to find an incorrect diagnosis of tuberculosis of the urinary tract made in cases of pyuria, the mistake occurring through the discovery of tubercle bacilli in the urine. These bacilli are, however, the smegma bacilli, the same which were once taken by Lustgarten for the bacilli of syphilis but which afterward passed into oblivion. Physicians cannot be too emphatically warned against this error. The case which served as the text of the paper of Leyden and Mendelsohn was one of a woman suffering from a renal calculus, but which the attending physician, deceived by the bacilli which he found, diagnosed as tuberculosis. In this case the value of catheterization of the ureters was shown most strikingly, for the seat of the disease was thereby exactly localized, the healthy condition of the other kidney was demonstrated, and so the operation was rendered possible.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE FRENCH GOVERNMENT PROVIDES FOR ITS AGED AND INCURABLES—HANDSOME APPROPRIATION—WOMEN DOCTORS AND LAWYERS IN CONCLAVE—CONGRESS OF THE LEARNED SOCIETIES—AN EPIDEMIC OF CATALEPSY—DEATH OF DR. CONSTANTIN PAUL.

PARIS, April 15, 1896.

THE French government is really setting an example to the rest of the world in all matters regarding public health, sanitation, the regulation of the practice of medicine and pharmacy, the construction of asylums of different kinds, etc. After taking in hand the subject of laboratories for which a large appropriation is projected, the government is now giving its attention to the organization for aiding the aged and incurable. Aids of this kind are more readily obtained in a country like France, where such procedures are historic and where the nominal republic is a government administered largely in accordance with monarchical ideas and practically by the code Napoleon, than they would be in the United States, where more is done in the way of private charity and public subscriptions. The measure now proposed in Paris is to some extent subordinate to the creation of a fund for workmen no longer valid, and by such providence and economy the number of those whom age or disease might leave without resource for society to take charge of would be sensibly diminished. The Chamber of Deputies, which has always the last word to say in making the laws and appropriations, has decided not to wait until the governmental project is fully matured and presented.

but to take certain necessary steps at once, and has in accordance therewith voted an order of the day resolving to organize with the briefest possible delay such aid to the aged infirm and incurable, by means of the combined taxes of the communes and departments, taking a certain percentage from the amounts thus collected and inviting the government to propose for the budget of 1897 a credit that might form a first basis of the organization contemplated. It is as a reply to this invitation that the government is about to propose the vote of a first credit of 600,000 francs.

In order to appreciate the necessities of the case, the minister of the interior sent out some time ago a circular asking the prefects to inform him as to the following points: 1. The measures taken in their respective departments to assure aid to the aged and infirm. 2. The method of assistance adopted, whether at home or in the hospital. 3. The amount of expense thus incurred. 4. The importance of the sums disbursed for that object by the departments, communes, benevolent bureaus, and hospitals. The inquest is now terminated; the result is most interesting and a valuable contribution to French demography. The figures of the last census were taken as a basis—the total census of France, viz., 38,133,385. It appears further from the official returns that there are 121,278 aged, infirm, and incurable, of whom there are 60,000 already in the hospitals, so that there remain actually 61,278 requiring assistance either on account of senility or disease, or both, and it is to relieve these that the government will devote its first credit of 600,000 francs.

These individuals will be aided in their homes; the government considers this mode of relief more economical and more moral than those usually in vogue—hospitals, houses of refuge, homes for invalids, infirmaries, etc.

The "International Feminine Congress" has just gone to the other extreme and thinks that children from earliest infancy to majority should be taken charge of by society. This congress now in session is largely attracting the attention of the medical and legal professions as well as that of the laity. There are two sittings a day, generally uproarious and enlivened by a quarrel or two in which the socialistic male students admitted take a prominent part. Day before yesterday's sitting was particularly stormy. A resolution was, however, finally adopted in the following sense: the congress is agreed that a child from its birth to its majority should be taken charge of by society as regards its physiological maintenance, development, and education; moreover, it should be constantly protected and watched over, as much in the interest of society as of itself.

The pathological development—and there is pretty sure to be one or several—is of course to be taken care of by the physician, who likewise would be expected to look to society for his remuneration.

The delegates to this turbulent assembly count among their number doctresses of medicine, law, and philosophy, who pass their time after the daily session in visiting the public institutions, such as the Female Hospital, Prison of Saint Lazare, the Asylum of Vésinet, the Maternal House at Belleville, the Institution for the Young Blind, etc.

Yesterday's sitting was devoted to the consideration of plans for the abolition of legalized prostitution—that is prostitution as it exists in Paris to-day and as guaranteed by regular medical supervision, examination, and police license. A doctress of medicine, Madame Edwards Pilliet, proposed the suppression of standing armies and the granting to priests the right to marry, as the only means of abolishing prostitution. Another delegate proposed universal free love as a sovereign remedy for the social evil. The follow-

ing resolutions were the outcome of this meeting: The necessary abolition of all police regulations having for result the humiliation of woman; in order to guarantee the family against the horrible scourge of contagious and hereditary disease, those proposing to marry shall in future present to the mayor of each district a special certificate of good health; ability of minors to marry without consent of their parents; abolition of vice regulated by the State; creation of public sewing-establishments and allotment of work by the State. It will be seen that everything is to be thrown upon society and the State and thus to be had for nothing or next to nothing. In this way it is contended that a sort of social utopia will be reached which is the dream of all communists and socialists—and these two elements are the prominent ones in the present feminine congress. After a street row with the police and a still more boisterous session, the congress adjourned until 1900.

More dignified *séances* are being held by the Congress of the Learned Societies, also at present in session. The section of medicine, of which Dr. Ledé is president, reported to-day, when papers were read by Drs. Nepveu, Lemoyne, Dupuy, and Peirret. The section of zoology is presided by Prof. Mathias Duval of the Faculty of Medicine; Dr. Troussart presented an elaborate monograph on the "mode of topographical distribution of the species inhabiting our littoral." Other reporters were Drs. Javal and Perrin.

We seem just now to be on the verge of an epidemic of catalepsy; besides several cases at the Salpêtrière, no less than five patients have been admitted into the hospitals in the last forty-eight hours. Several of these were found sitting upon benches in the public squares—some in a state of ecstasy, others plunged in a cataleptic sleep. These cases are rather symptomatic than essential, as catalepsy is never found except in hysterical, epileptic, or hystero-epileptic subjects.

It is with deep regret that we chronicle the death of Dr. Constantin Paul, for so many years a brilliant light in the medical profession of both hemispheres. Dr. Constantin Paul graduated in 1866 and was sixty-three years of age, having held various prominent positions. He was a professor *agregé* at the Faculty of Medicine of Paris and a member of the Academy of Medicine since 1880, having been physician successively to the Saint Antoine, Lariboisière, and Charité Hospitals. The latter position he held at the time of his death. He devoted most of his long and active professional career to the study of the pathology and therapeutics of the different forms of cardiac disease. His untiring work won for him the cross of the Legion of Honor, with which he was decorated in the courtyard of the Hôtel Dieu. His contributions to medical literature were many, the best known of which is his "Diagnostic et Traitement des Maladies du Cœur." Not the least important of his labors was the part he took in editing the new edition of Trousseau and Pidoux's "Traité de Thérapeutique et de Matière Médicale." He gave his services frequently to the poor without remuneration, while his frank and genial manner endeared him to the numerous confrères, patients, and friends that mourn his loss.

Lingual Tonsil in Singers.—This is more often the cause of trouble than varix. As symptoms we have: 1. Sensation of foreign body in throat not relieved by swallowing. 2. Sensation of constriction around throat at level of upper border of thyroid. 3. Occasional reflex irritable cough. 4. Constant endeavor to clear throat. (This the editor questions.) 5. Quick laryngeal fatigue. 6. Occasional hoarseness. Galvano-cautery and cold-wire snare are recommended. —RAY in *Medical News*, October, 1895.

PROGNOSIS IN PNEUMONIA.¹

BY ANDREW H. SMITH, M.D.,

PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, NEW YORK; EMERITUS PROFESSOR OF THE PRACTICE OF MEDICINE, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE prognosis in pneumonia is modified by a number of pre-existing conditions, the principal of which are sex, age, season of the year, habit as to the use of alcohol, and the presence or absence of certain chronic diseases.

It is conceded that while pneumonia occurs more frequently in men, it is more fatal in women. Of two hundred and twenty-three patients with pneumonia admitted into the Presbyterian Hospital, one hundred and seventy were males, with a mortality of twenty-eight per cent.; fifty-three were females, with a mortality of 31.2 per cent.

Before the age of two years lobar pneumonia is a very rare disease. After that age the mortality is greater in proportion as the patient is older. In sixteen cases under ten years of age at the Presbyterian Hospital, there were no deaths; in the cases occurring in the second decade 18.7 per cent. proved fatal; in the third 19.6 per cent.; in the fourth 28.3 per cent.; in the fifth 39.4 per cent.; while of those fifty years of age and upward 40.6 per cent. died.

The relative mortality of pneumonia in the different seasons of the year is variously stated by different writers. In the above two hundred and twenty-three cases the spring months gave the lowest mortality, the summer showed a slight increase, while in the autumn and winter the death rate attained its highest percentage.

The habitual abuse of alcohol unfits the system to bear up against pneumonia. Of eleven such cases referred to by Ewing as occurring at the Roosevelt Hospital only three recovered. In the records of the Presbyterian Hospital the subjects of chronic alcoholism are not distinguished from those who habitually use alcohol though not to excess, the use of beer being included. With this wider definition of the alcohol habit the latter seems not to add materially to the mortality.

A pre-existing rheumatic habit has generally been observed to add to the gravity of the prognosis. It was present in twenty of the Presbyterian Hospital cases, and was attended by a mortality of forty per cent. As the rheumatic habit, however, is more pronounced as life advances, the influence of age in these cases must not be overlooked.

The prognosis is extremely unfavorable in diabetic patients. The combustion of the sugar, already imperfect, is diminished in proportion to the impairment of the respiration. Death in such cases is preceded by delirium and coma.

The pre-existence of chronic nephritis makes the prognosis of a pneumonia more grave in proportion to the renal insufficiency and the accompanying cardiovascular changes.

Pneumonia occurring in a subject of advanced car-

diac disease is likely to prove fatal. The prognosis is less grave before secondary changes have taken place in the right side of the heart.

Coming now to the conditions arising in the course of the disease, and which seem to influence the mortality, the first is the initial chill. This occurred in one hundred and forty-four out of the two hundred and twenty-three cases, with a mortality of thirty-four per cent.; while the remaining seventy-nine cases in which the chill was absent gave a death-rate of only nineteen per cent. From this it is evident that the chill is an expression of a severer grade of infection, and I have observed that usually a prolonged rigor with tardy reaction presages an unusual degree of muscular and nervous prostration.

As to the location of the lesion, the right lung is more frequently affected than the left, and also gives a higher mortality. Of ninety-four cases implicating the right lung alone, twenty-eight ended fatally, giving a mortality of 29.8 per cent.; while only sixty-two cases involved the left lung alone, of which sixteen, or 25.5 per cent., were fatal. In thirty-nine cases both lungs were involved, with a mortality of nineteen, or 48.7 per cent.

A feeble pulse, that is frequent in relation to the respiration and temperature, has much the same prognostic significance as a heavy and prolonged chill. In my experience it indicates a profound specific infection that is likely to carry off the patient at or before the crisis.

The respiration is always frequent in pneumonia, but when extreme frequency is associated with a high temperature, it has less significance than when it occurs without this association. In the former case it is due in part to the fever; in the latter it denotes extensive lung implication and probably œdema, a perilous condition, but one which is often susceptible of being relieved. Up to 105° F. the danger does not seem to increase materially with the rise of temperature. Thus in forty-five cases with the maximum temperature ranging between 100° and 103° F., the mortality was 26.6 per cent; while in ninety-nine cases with a temperature between 103° and 105° F., the mortality was 26.3 per cent. The conditions that raise the temperature above 105° F., however, immediately tell upon the death rate. In forty-nine cases with a temperature between 105° and 106° F. the mortality was 32.1 per cent., and thirteen cases at 106° F. and upward gave 58.5 per cent. of deaths. Recovery, however, may take place though the temperature has attained an extraordinary height. Wagner¹ has reported such a case in a boy five years old, the temperature having reached 109.2° F. Indeed, it is an error to attach too much importance to the temperature alone, so long as the condition otherwise remains favorable, and measures intended merely to control the pyrexia are indicated only in extreme cases. It cannot be too often repeated that to give the coal-tar preparations according to indications furnished by the thermometer is to expose the patient to a real danger in an effort to relieve him from a fancied one.

There is a physical sign to which I called attention some years ago that I regard as important in the prog-

¹ Read before the Association of American Physicians, Washington, D. C., May 2, 1896.

¹ "American Universal Medical Science," 1895, vol. 1.

nosis of pneumonia. I refer to the character of the valve sound heard in the pulmonary area. The resistance in the pulmonary circulation which always exists in these cases must necessarily increase the tension in the pulmonary artery, provided the force of the ventricular systole is not impaired. With this increased tension come a sharper recoil of the blood against the valve cusps and a greater intensity of the valve sound. It follows, other things being equal, that in this intensity we have practically a measure of the degree of obstruction to the blood current in the lungs.

It is generally very easy to note as consolidation progresses the constantly increasing sharpness of the pulmonary second sound, and in favorable cases this accentuation, after reaching a certain point, is maintained with little change until commencing resolution renders the circulation easier, when the valve sound loses in intensity in proportion as the pulmonary condition improves.

But, unhappily, loss of accentuation of the pulmonary second sound does not always depend upon relief of the pulmonary circulation. It may signify instead a weakening of the right ventricle and a lessened power to force the blood into the artery. This comes when the right heart begins to flag, either from exhaustion, from excessive labor, or because of the depression arising from the specific infection. In either case, when we find the pulmonary second sound becoming weaker without any evidence of a favorable change in the condition of the lung, we may draw the conclusion that the right heart is failing and that the tendency of the case is toward a fatal termination.

The information furnished by the pulmonary-valve sound is much more reliable than that supplied by the radial pulse, for in most cases the chief peril is of failure or exhaustion of the right heart, and of this the condition of the radial pulse will give only indirect and inconclusive evidence. The right ventricle may be on the verge of exhaustion, while the left retains almost undiminished vigor, and the radial pulse then will simply indicate that less blood than usual is flowing beneath the finger.

Unfortunately, it will sometimes happen that the region of the pulmonary area is occupied by noisy râles, so that it may be difficult or perhaps impossible to appreciate the action of the valve. But unless the dyspnea is extreme the breath can be held for an instant, and for the practised ear the briefest moment is sufficient. An emphysematous condition of the left apex may also obscure the sound of the valve or render it inaudible.

As to the prognostic value of the data furnished in this way, I can only say that I have never seen disaster come in a case of pneumonia unless it was preceded by a period in which the pulmonary-valve sound was progressively losing in intensity. Or, to put it in other words, I have never seen a case with a sharp and distinct pulmonary-valve sound in which a favorable prognosis as to the immediate future was not justified by the event.

The weakness of the right heart that is indicated when the valve sound becomes less intense, takes place chiefly in two classes of cases. The first is that in which the system is overwhelmed by the virulence of the infection. These cases are marked by a severe and protracted initial chill, great muscular prostration, a small and relatively frequent pulse, and marked involvement of the nervous system. We may well believe that in such cases the heart muscle is poisoned, and that consequently the right ventricle with the increased labor thrown upon it early becomes exhausted. Such cases are apt to prove fatal before defervescence takes place. If they can be carried beyond this period the prognosis is greatly bettered.

The second class of cases is made up of those in which from age, intemperance, previous illness, or other cause, the integrity of the circulatory apparatus is compromised in advance. Here we have a constant tendency to the invasion of fresh areas of the lung and to the supervention of œdema. This tendency, while it increases the labor required of the ventricle, is itself increased in proportion as the ventricle weakens under its burden.

In the medical literature of fifty or sixty years ago we find frequent reference to the "buffy coat" observed on the surface of blood drawn for the relief of inflammatory affections, and especially inflammation of the lungs, and it was held that the thickness of this coat was roughly in proportion to the severity of the inflammation. To-day we speak of leucocytosis as associated with many morbid conditions, and notably with pneumonia, and admit a certain relation between the number of leucocytes and the intensity of the process which causes their increase.

The connecting link between the old conception and the new was furnished by the discovery of Virchow some forty years ago, that the buffy coat did not consist wholly of fibrin, as before supposed, but that it included a mass of white blood corpuscles, afterward called leucocytes.

The exact relation between temperature and leucocytosis in pneumonia is not yet fully determined: but in general terms it may be stated that a high temperature in a vigorous subject carries with it a large number of leucocytes. From a prognostic point of view this is of great importance. Whether we consider the leucocytes as scavengers and assume that they destroy the cocci which are the medium of infection, or whether we assign to the white cells a share in the production of antitoxin, certain it is that severe cases in which there is marked leucocytosis do better as a rule than similar cases in which the increase of white cells is relatively slight.

When the leucocytosis is considerable it will generally be found that the system is not reacting energetically against the infection, a condition which suggests an unfavorable prognosis. On the other hand, there may be a high degree of leucocytosis which is due, not to the pneumonia pure and simple, but to some complication, as pleuritis or pericarditis; and if this is not taken into account a faulty prognosis may result.

Ewing, in an excellent article in the *New York Medical Journal* of December 16, 1893, gives the count of the white cells in one hundred and one cases, of which thirty-seven were fatal. He says: "An examination of the deaths will show that in severe forms of lobar pneumonia a slight leucocytosis is a very unfavorable sign. In six fatal cases the number of leucocytes was subnormal. In eleven fatal cases the average number was nine thousand. Not one case recovered in which the disease was of even moderate severity when the number of leucocytes fell below fourteen thousand. In several instances, again, a slight leucocytosis seemed at the time the only unfavorable prognostic sign in cases ending fatally."

M. Laehr, in an article on "Leucocytosis in Pneumonia," published in the *Berliner klinische Wochenschrift* in 1893, maintains that in pneumonia there is an unmistakable connection between the temperature and the leucocytosis. When the disease is at its acme the count of the white cells is at its highest, while at the crisis there is a falling off. In pseudo-crisis and in deferred resolution the leucocytosis continues though the temperature falls. In the generally constant agreement of the course of the fever, the amount of lung infiltration, and the leucocytosis, the author sees a dependence upon a fourth factor, viz., the intensity of the infection; that is, the quantity and quality of the bacillus poison and the power of reaction of

the individual. He goes on to say: "Still more important is the prognostic significance. If the number of leucocytes does not fall with the decline of the fever, we may conclude that the process has not yet arrived at a standstill. If it falls with the fall of the temperature, but rises again the following day, we must be prepared for a renewed attack of the fever or the occurrence of some form of complication."

R. C. Cabot¹ gives the count of the white cells in forty-nine cases of pneumonia. Leucocytosis was present in forty-one cases with ten deaths, absent in five cases with five deaths, doubtful in three cases with two deaths. He says: "As far as these figures go, therefore, it would seem that, while the presence of leucocytosis is not a very hopeful sign, its absence makes the outlook bad. Moreover, in two of these five cases the other reasons for giving a bad or guarded prognosis were not present. The individuals were both under fifty, were not at all alcoholic or weakly, and there was nothing in the condition of pulse, temperature, or the physical signs in the chest to lead one to expect a fatal result. Yet both went down with surprising rapidity, and without any reaction to vigorous stimulation and supportive treatment."

In a subsequent paper² he adds twenty-four new cases, without materially changing the conclusions to which his figures would point.

A remarkably high leucocytosis, especially if associated with a low temperature, suggests a suppurative complication. Thus, in a case of pneumonia at the Presbyterian Hospital, the temperature on the seventh day was 103° F. and the count 54,500. The crisis occurred the next day, but with a temperature of only 99° F. there was still a leucocytosis of 42,000. Examination showed that empyema was developing. In another case with a similar complication the count was 44,000, while the temperature was 101.8° F.

In eight uncomplicated cases the highest in eighty-one daily counts was 41,000. At the Presbyterian Hospital, in cases in which we wish to follow the leucocytosis from day to day, we have adopted the plan of recording it on the temperature chart, allowing for each additional 3,000 leucocytes a space on the chart equal to one degree of temperature. Regarding 9,000 as the normal, this figure would correspond with the normal temperature line; 13,000 would be recorded on the 100° line; 16,000 on the 101° line; 19,000 on the next line above, and so on, the tracing being made in red ink. In this way the relation of the count to the temperature is apparent at a glance.

Haig's Theory.—(1) When there is an increase in the alkalinity of the blood there is also an increase of uric acid in the blood, while a reduction in the alkalinity of the blood results in a precipitation of uric acid in the tissues, especially the liver and spleen. With a decreased alkalinity there is a corresponding increase in the acidity of the urine, which therefore indicates the condition of the blood. (2) The ratio of the formation of uric acid to urea is constant. Urea is eliminated as formed, and as the relation of uric acid to urea in the urine is variable, this variability is accounted for by retention or excessive elimination of uric acid. (3) The uric acid daily excreted is derived from three sources: (a) that formed by nitrogenous metabolism along with some urea, about one of uric acid to thirty-five of urea; (b) uric acid and other members of the xanthin group introduced with the food; (c) that stored in the body which passes into the blood when the alkalinity is increased.

ON THE TREATMENT OF RUPTURE OF THE URETHRA BY IMMEDIATE SUTURE AND BLADDER DRAINAGE.

By ROBERT F. WEIR, M.D.,

PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

WHILE the suturing of a ruptured urethra is mentioned and advised in nearly all the recent works on surgery, yet it appears from the comparatively few cases reported to have been unduly seldom resorted to. Perhaps, however, this is a wrong inference, and, as the method is so rational a one and so generally followed by success, it may have been quietly accepted and followed. Without doubt the customary perineal incision, which is justly considered proper in all urethral traumas that are associated with marked hemorrhage, and especially if a tumor or difficult urination and catheterization exist, singly or conjoined, will suffice to save the patient from the serious risks of infection and also, to a moderate extent, from the contracting effects of the necrotic and inflammatory damage of the soft parts. But whether the rupture of the urethra be a partial one, or, more particularly, if it be a total one, the gap in the broken wall of the urinary conduit is filled up with scar tissue which must largely contribute, with the contraction of the perineal soft parts, to bring about the well-known severe and intractable traumatic stricture. Therefore, while urging that early suture of a ruptured urethra is to be practised when possible, it must be admitted that such a procedure even when successful does not of itself guarantee totally against a subsequent stricture of the urethra.

It has, nevertheless, seemed to me for some time past that to the perineal incision, which liberates the already effused blood and urine and which thereby eliminates one source of contracting tissue, should be added, where practicable, the suturing together the separated urethral ends. Besides this a third indication is to be met, that is, to take away the irritation, mechanical and otherwise, of the urine. This has usually been done by the insertion of a rubber catheter into the bladder, and over this the ends of the canal are sutured by catgut or silk and the catheter is left in for drainage. It is not always satisfactory, though this has been resorted to in the majority of the sutured cases, either because some urine would be unavoidably forced out between the catheter and urethral wall, or because the catheter caused bladder irritation (cervical cystitis), which necessitated the withdrawal of the instrument. Suprapubic cystotomy comes in best, in my judgment, to meet this indication, conjoined with intermittent siphonic drainage of the bladder. When one can find the bladder end of a completely divided urethra the performance of an epicystotomy is not at all difficult, even though the bladder be empty. The viscus can be raised up above the pubis by the end of a steel sound, and over its point close to the pubis a small opening can be made, under sight, and the peritoneum easily avoided. When the divided urethra cannot be found, the epicystotomy is a somewhat more difficult procedure—a larger incision of the soft parts is required, but by still keeping close to the pubis the bladder is duly reached; then the finger being introduced to recognize the urethral opening, a sound, either the ordinary steel one of about the size 20 F. or one of Benique's curve of a similar size, is passed from the bladder forward into the perineum, and through or to the ruptured end of the urethra. This retrograde catheterization and the enhanced difficulty of opening the bladder can be avoided, as I have personally tested in a number of instances, by directing a fine douche of hot water on the perineal wound for at least five or ten minutes, or until under the prolonged use of the water and the vigorous rubbing with

¹ Boston Medical and Surgical Journal, August 3, 1893.

² *Ibid.*, March 22, 1894.

the finger ends the blood-stained parts are washed out, when the urethra will be more or less distinctly revealed. It is an expedient well worthy of trial.

The treatment of urethral ruptures will probably demand more attention than formerly, since it appears that an additional cause for such injuries has appeared in the use of the bicycle. Two cases have been reported—one by Moinet,¹ in which the lesion resulted from the wheel and its rider plunging suddenly into a ditch nearly two feet deep; and a second by Anderson,² in which case the rider, jumping backward off his wheel, straddled the latter and produced the laceration in the usual way. These ruptures were, as could be expected, situated in the customary place, anterior to the triangular ligament; the lacerations, associated with pelvic fractures or produced by kicks from behind, being as is well known more often found in the membranous or prostatic urethra. In the latter variety one must keep in mind the possibility of the extravasation taking place in the cavity of Retzius and of its presenting symptoms similar to those of rupture of the bladder. For the differential diagnosis of this condition and its treatment, if due to the latter, I beg to refer to an article which was published in the *MEDICAL RECORD*, 1884.³

The following cases of suture of the ruptured urethra will exemplify the foregoing suggestions:

CASE I.—Rupture of Urethra; Suture of the Separated Ends; Suprapubic Drainage; Recovery.—F. W. L.—, aged twenty-three, was admitted to the New York Hospital, January 28, 1896, with the history that in attempting three days previously to jump from a tug he fell astride the rail of the boat, striking his testicles and perineum. The pain was intense and the scrotum immediately began to swell. The bladder was empty at the time of the accident. Since then he has been able to pass a small amount of bloody urine four or five times a day. Two days after the injury there was vesical tenesmus, and the patient noticed that a swelling (the distending bladder) was appearing in the hypogastrium. Three days after the injury voluntary micturition ceased and the patient entered the hospital. The scrotum in size and appearance resembled an egg plant. The perineum was slightly swollen and discolored. The bladder extended half way to the umbilicus. An unsuccessful attempt was made by the house surgeon to pass a rubber catheter and then a filiform bougie, but with care a black silk-webbed catheter coudé, No. 17 F., was passed into the bladder and thirty-five ounces of dark bloody urine withdrawn. It was alkaline and of foul odor, specific gravity 1.022.

On the following day (the fourth from the injury) the case was brought to my attention, and under ether an attempt was made to introduce a bougie prior to the operation. This failing, a median incision was thereupon made in the perineum three and one-half inches in length, and the urethra easily exposed. It was found to be completely divided in its bulbous portion and there was a separation of the ends of the canal of three-fourths of an inch. Prolonged irrigation with hot salt solution brought out the structures more clearly and defined sharply the torn ends of the urethra. The superior wall of the torn urethra was first brought together, and then a 26 F. steel sound was passed to the bladder. The sides and floor of the urethra were then sutured. These sutures were of black silk and included all the layers of the urethra. The ends were left long enough to hang from the perineal wound.

With the point of the sound as a guide, pressing for-

ward just above the symphysis, a small suprapubic opening was made into the bladder, and a soft rubber catheter inserted therein for drainage. The perineal wound was partially closed with silkworm gut to give some support to the urethra, but free drainage was secured with iodoform gauze. Perfect drainage of the bladder was secured by the simple suction apparatus (see diagram) suggested by Cathcart¹ and improved slightly by Keen.² By this latter device, which worked admirably, not a drop of urine passed per urethram.

On the sixteenth day after the operation the last stitches had come away, the drainage tube was removed, and a 22 F. sound was passed to the bladder without the slightest hitch or arrest. On every second day thereafter gradually larger sizes were passed, until 32 F. was reached, and then the patient was taught to

pass the sound himself. Six weeks after the accident he left the hospital, both wounds being closed and micturition perfectly normal. Twelve weeks after the operation a 30 F. sound was passed with ease to the bladder.

The following case illustrates the complications that may, however, nullify the favorable result that may be anticipated in a typical case.

CASE II.—Rupture of the Urethra with an Old Stricture; Immediate Suture of Divided Urethral Ends; Drainage by Perineal Catheter; Recovery.—H. E.—, aged forty-three, slipped into a hole in an engine room, November 26, 1894. One foot only passed into the hole, and as the other remained on the floor he struck his perineum against the sharp edge of the opening with considerable force. The pain was not great and he continued at work for some hours, but was unable to pass water. Unsuccessful attempts at catheterization were made by two physicians, and nine hours after the accident the patient entered the New York Hospital, suffering from a distended bladder. The scrotum was discolored and swollen to the size of two fists. Aspiration of the bladder yielded twenty-eight ounces of bloody urine.

Thirteen hours after the accident median perineal section was made by a free incision under ether, and the urethra was found to be divided transversely and completely in the bulbous portion just anterior to the triangular ligament. The ends of the canal were sep-

³ "On Rupture of the Bladder and Its Treatment," March 29, 1884, by R. F. Weir.

arated nearly an inch. In the anterior urethra was a long stricture reaching back nearly to the site of the rupture and which admitted only a fine probe. This was divided so as to receive a 30 F. sound, which was passed into the bladder, and over this the divided urethra was sutured with fine silk. The suturing was difficult, as the urethral walls easily tore out, owing to previous degeneration. Only the upper and lateral parts of the canal could be made to hold. The inferior part, where the tumor was greatest, was necessarily left open, and through this a catheter was passed into the bladder and left in position, the perineal wound being packed with gauze.

The catheter was removed on the tenth day, and sounds (18 and 20 F.) were passed on the twelfth day, and these were gradually increased up to 26 F., beyond which the dilatation progressed slowly and with difficulty, from the contraction of his old stricture. An internal urethrotomy was advised, but was refused by the patient. At his own request he was discharged in one month. The perineal wound had not then quite healed, but from it scarcely any urine escaped.

This case presented two complications—the previously existing gonorrhoeal stricture and the weakened urethral wall, which prevented the junction of the divided tube. This latter would, I am now convinced, have been better approximated had the urethra been freed to a greater extent from its natural attachments.

Remarks.—Though Henry Morris, in 1874, twice sewed up ruptured urethras, his work was apparently not imitated until 1884, when Symond¹ published a successful case. Since then some twenty-six cases have been put on record. Before, however, entering on the consideration of these it may be of interest to allude briefly to the older methods of treatment. They were: 1. Aspiration. By this method, Kaufmann² reports, were treated twenty-one cases, in which nineteen per cent. of the patients died. Forty-four cases were treated by the use of a permanent catheter, with eighteen per cent. of mortality. In this connection he states strongly that the use of a permanent catheter is absolutely to be rejected. By immediate perineal incision in ninety-one cases he found nine per cent. mortality. By delayed perineal

incision, *i.e.*, in eight to ten days, in twenty-four cases there resulted twenty per cent. mortality.

In all of the twenty-nine cases of immediate suture of the urethra, including the two herewith published, the operation was successfully carried out and the patients recovered. Data as to the method of bladder drainage are given in but few, but a permanent catheter was largely used. In Nogué's collection of nineteen cases it was employed sixteen times. In a few cases bladder-drainage was conjoined. Badling³ was the first to do this. It was only in exceptional cases, such as those in which there was but slight blood extravasation and no apparent urinary infiltration, that the perineal wound was tightly closed after the urethral sutures had been effected; and, indeed, this is not to be recommended, though a certain amount of approximation to support the newly joined urethra is advisable; but here, too, ample space for drainage should be left in all cases. The material for suture was commonly catgut, and the mucous membrane was not included in the stitches. As to this I differ. I prefer pure silk, going through the mucous membrane and other coats of the urethra and supplemented by two or three extra-urethral sutures, to prevent tension on the urethral sutures. These sutures are left long enough, at least one end of them, to hang out of the wound, so that traction may be made on them after a week or ten days. As to the ultimate results in my own cases, one is too recent to determine this point, and the second is clouded by the complication of a previous stricture. In respect to this point in the other cases, reference must be again made to Nogué's collection. In nineteen cases six complete successes were observed from seven months to eighteen months after the suturing, and in three others examined three, four, and five months afterward, the urethral calibre was uncontracted. For the bladder drainage I have never had such satisfactory results as since using Cathcart's procedure, which has been somewhat elaborated by Keen.² This plan for re-establishing a siphon action whenever it is broken, which so often occurs with our older method, has resulted well, not only in the instance herein reported, but in several other cases of epicystotomy for stone, prostatectomy, etc. Dawbarn's³ still simpler device places the use of this method within the easy reach of every surgeon, and I venture here to reproduce the diagrams of both the contrivances.

A summary of the foregoing is: 1st, In an injury of the perineum with painful or difficult urination, accompanied with a free flow of blood, with or without a perineal or scrotal swelling, a free perineal incision should be made and the urethra exposed. 2d. If this canal be ruptured partially or totally, the separated ends should be sewed together with silk or catgut. 3d. Drainage of the bladder should be employed either by a catheter per urethram, or preferably by a suprapubic opening. To aid in carrying out the latter, Cathcart's or Dawbarn's method of siphonage should be employed.

Ill-Ventilated Rooms.—The discomfort produced by crowded, ill-ventilated rooms, in persons not accustomed to this condition of things, is not due to the excess of carbonic acid, nor to bacteria, nor, in most cases, to dusts of any kind. The two great causes of such discomfort, though not the only ones, are excessive temperatures and unpleasant odors.—DRS. J. S. BILLINGS, S. WEIR MITCHELL, and D. H. BERGEN in *Smithsonian Contributions*; also *Appleton's Popular Science Monthly*, February, 1896.

THE MANAGEMENT OF IRRITABLE SPINE.¹

BY VIRGIL P. GIBNEY, M.D.

At the request of Dr. Bull, whose place I take for this evening, I selected for discussion a subject which would be of sufficient interest to the members of the Practitioners' Society.

I have nothing new in the way of definition to offer. At the same time I am aware that the term "irritable spine" varies in definition according to the individual practitioner. Many do not regard this as a disease or an affection of itself, but simply a group of symptoms dependent upon organic disease of some kind. I wish, therefore, to say that I do not employ the terms as symptomatic of disease.

It is well known that irritable spine, spinal irritation, spinal anæmia, spinal hyperæmia, spinal neurosis, hysterical spine—all bring up a train of symptoms that is frequently met with, not only by the general practitioner but by specialists. These symptoms are spinal tenderness, various pains in the course of the nerves, a weak back, fatigue on little exertion, lack of symmetry between the scapulæ, obliquity of the pelvis, etc.

I see a number of cases during the year in consultation, and I am called upon to decide as to the existence or not of curvature of the spine. To the credit of the physician who usually calls me in consultation, I would say, furthermore, that he has usually made the diagnosis of irritable spine pure and simple, but has been harassed by the importunities of the patient or of the patient's family into getting an opinion as to whether there be disease of the bones or disease of the spinal cord. He has usually had examined for him the pelvic organs, and in some instances has had the opinion of an ophthalmologist.

A typical case would be about as follows: A lady who has borne one or two children has for a year or more complained of her back; has had remissions of pain followed by rather sharp exacerbations; has been quite active at times, and has fretted because she was not able to be more active at other times; has presented a tenderness over the spinous processes and lateral masses, with pains occasionally in the course of the lumbar or lumbo-sacral nerves, and has got into the habit of standing awkwardly in order to rest herself. This awkward position has produced an obliquity of the pelvis and a compensatory scoliosis, a simple lateral deviation of the column. I find her fairly well nourished and get a pretty good history negatively of the internal organs. Examination of the column reveals, as just indicated, a lateral curvature in the lumbar region to right or left side, very slight, and an inequality of the ilio-costal spaces, also very slight; sometimes a lack of symmetry between the scapulæ, sometimes an antero-posterior curvature of the spine, the correction of which causes increased pain in the back, a spinal tenderness, and sometimes tenderness on concussion. By equalizing the two sides of the pelvis I am able usually to demonstrate the compensatory nature of the curvature, and by testing the column as to flexibility I am able to rule out any bone lesion. When I am satisfied that there is no reflex irritation present—that is, irritation reflected from the pelvic organs or from the eyes—I am in the habit of prescribing counter-irritation in conjunction with tonics, graded exercises, an out-of-door life, and, in rare instances, a posterior spinal assistant of some kind. I dislike, however, to put a brace on a patient with irritable spine, and do so only after other means have been exhausted.

In young women or girls between the ages of ten

and twenty, one finds occasionally atonic spasm of certain muscles, such as the psoas and iliacus; the flexor muscles of the leg, and the extensor muscles of the foot—in other words, a deformity with disability, which leads one to suspect disease at the hip-joint, knee-joint, or ankle. Also one finds a very marked curvature of the spine, with spasm in the course of the muscles supplied by the brachial plexus. I might further add that torticollis is sometimes dependent upon an irritable spine. Usually, however, we look upon these deformities as hysterical in nature, but the difficulty in distinguishing between the typical hysterical condition and a condition dependent upon irritable spine is sometimes very great. Many years ago, while an interne at the Hospital for the Ruptured and Crippled, I found relief to follow promptly the application of a Spanish-fly blister to the tender portion of the spinal column, and have seen deformities disappear during a night. In a paper presented to the American Neurological Association many years ago, I detailed a large number of such instances and employed the term spinal irritation in that paper. These cases depended usually upon some shock to the system, such as cold bathing early in the season or late in the season. I found the deformity and the spinal tenderness in both sexes.

The irritable spine, however, to which I wish to call attention this evening is a little different in nature. It is not accompanied, as a rule, by any deformity or any muscular spasm. The treatment for the milder cases is the Paquelin cautery applied three times a week for about a month or six weeks. I am in the habit of making very light strokes, not over ten or fifteen at a visit, and aim to get the strokes as near the exit of the nerves from the spinal column as possible. When the tenderness is very pronounced and when the cautery fails to give the desired relief, I resort to a fly blister, applied at night and removed in the morning. The blistered surface is poulticed with flaxseed meal for two or three days. In very mild cases or in cases where it is inconvenient to use the cautery, I have found the application of small mustard plasters every night for one or two weeks a very good substitute. After the immediate effects of the cautery or the counter-irritation have passed, I am in the habit of employing strips of adhesive plaster over the sensitive area. The details of this are very simple: I cut the strips about three or four inches in length, have them one inch in width, begin at the bottom of the column, and apply them obliquely over the spinous processes—criss-cross, so to speak—every one overlapping the preceding by about one-half inch. A great many patients find this of decided benefit, express themselves as very much relieved, are able to go about and attend to their social or other duties with comparatively little discomfort. A set of plasters can remain on for a week, sometimes a little longer. They need to be repeated usually three or four times before they can be replaced by an ordinary binder, or, sometimes, by an abdominal belt. In the more severe cases, when all these things have been tried and relief has failed to come, I find nothing quite equal to the posterior spinal assistant. Such a one I have for your inspection this evening. It consists simply of a pelvic band, two uprights extending up on either side of the spinous processes, terminating just below the shoulders, and held in place by shoulder straps and a narrow abdominal belt. The employment of a more complicated support is, I think, entirely unnecessary, as this simple one answers the purpose. Occasionally I have found relief to follow massage and douches to the spine, but not sufficient to warrant me in making this a routine practice, nor have I found galvanism or faradism of much assistance: but static electricity has in some instances acted like a charm.

¹ Read before the Practitioners' Society of New York, April 3, 1896.

In illustration of the difficulties attending the management of a case, let me cite that of Miss H—, twenty-three years of age, who came under my care on May 19, 1894. Four years prior to this she had a good deal of headache and complained of pain in her back. An examination by a local physician resulted in his diagnosis of curvature of the spine, so she reported. When I saw her she had worn steel braces, a plaster-of-Paris jacket, had had her eyes examined by an oculist, had worn glasses, and her conviction was that she had grown steadily worse under every course of treatment.

She was very anæmic, poorly nourished, apathetic. Her spinal column presented a general antero-posterior curve, but a curve that was easily corrected. The tenderness was quite marked in two or three localities—in the mids dorsal region, in the dorso-lumbar region, and over the sacrum. There was no fixation of the column at any point. She was quite tender in the left iliac fossa, but no tumefaction could be encountered.

I found her a most obstinate case to manage. She had come to me through Dr. David Webster, and he very kindly examined her eyes, sending her back to me with glasses. Dr. George M. Tuttle wrote as follows: "There is nothing wrong with the pelvic organs in the case of Miss A. H—. Everything is in normal condition and position. The case impresses me as one of nervous origin."

I used the Paquelin cautery in her case, had valuable assistance from a trained nurse and masseuse, and was enabled to improve her nutrition after having employed tonics and nutrients. She returned to her home at the end of six weeks very much improved, complaining less, and able to walk longer distances. Gratifying reports have come from time to time, yet not sufficient to enable me to pronounce a cure. I am quite sure that there was an hysterical element in this case.

Hydrotherapy is recognized as a valuable method of treatment, and I think the case which I am about to narrate will bear me out in this statement.

A young lady, nineteen years of age, Miss G—, came under my observation on April 13, 1890. The diagnosis made was slight rotary curvature of the dorsal spine to the left. There was also associated with this a hyperæsthetic spine, and, as I subsequently had occasion to learn, various neuroses bordering closely on hysterical manifestations. The curvature of her spine was really of very little account. What pain she had was referred to the subscapular space on the right side, where I found some tenderness. The heart sounds were normal and no pleuritic friction sounds were heard in this locality. There was really very little spinal tenderness at the time of my first examination.

I saw her again on December 28th of same year, and found her spine very irritable, with marked tenderness in the upper dorsal region. She was anæmic and depressed, and tired very easily. The curvature had not increased.

Coming as she did from a malarious country, I feared that she might have some latent form of malarial poisoning, and I had in consultation Dr. Ball, who found the spleen normal in size and such other negative evidences of malarial poisoning that he deemed it entirely unnecessary to submit her blood to an examination. He advised that she have the wet pack and iron, and furnished me with an expert masseuse who was familiar with this method of treatment. He concurred with me as to the value of the cautery and in having her eyes examined. Dr. David Webster made an examination on the same date, reporting: "Good vision in both eyes and no lesion of the media or fundus. . . . No manifest insufficiency or rather want of balance of her ocular muscles. . . . All weak,

her abduction being only 4° instead of 8°, and her adduction only 13° instead of 20° or 30°. . . . Manifest hypermetropia [the formula I omit] and some conjunctivitis." He advised the use of glasses to correct her hypermetropia, and thought that the ciliary strain might be an element in the causation of her nervous troubles.

The baths were employed in the following three or four weeks. It was learned on March 6th that she had been subject to occasional fainting spells. This led me to suspect epilepsy, but on a pretty thorough examination into her case I was convinced that these were hysterical in nature and not epileptic. My friend, Dr. Ball, after going into her history as carefully as I did, came to the conclusion that they were not epileptic. In April it was discovered that she had perforation of her right drum, which continued to exist during the spring. Her fainting spells became less frequent. There developed a pretty well marked otitis media in both ears. She returned home in May, 1891. Reports from that time to the present have shown a gradual improvement and return to health.

As bearing upon the question of support, I should like to submit one or two illustrations. A lady, twenty-two years of age, Miss T—, from New York State, was referred to me by Dr. Bull, April 29, 1895. I got the following history:

Eight years before this she fell from a second-story window in a fit of somnambulism. On being picked up she complained of her wrist. About six months afterward she began to complain of pain in her back. During the following years she had peculiar creeping sensations, and got relief from various plasters. Two and a half years later, about the same season she had an attack of neuralgia, possibly an attack of the grippe. On getting up from her bed she complained a good deal of pain in her back. A year or two later she still complained, and a plaster-of-Paris jacket was applied. This gave her a certain amount of relief, but whenever she discontinued the jackets she would have a return of the pain.

I found great hyperæsthesia of the skin; indeed, of the deeper structures in the neighborhood of the knee and thigh. She could flex the left knee to 90° and bring it perfectly straight. She complained somewhat of the knee, and on further examination, finding the dorso-lumbar spine quite tender, I came to the conclusion that she suffered from an irritable spine with a neurotic knee or hysterical knee.

The jacket she wore was rather heavy. I found her so reliant on the support that I made a steel brace for her and applied it on May 7th. On December 19, 1895, she called to report that she had recently been in a runaway accident, and following this a good deal of pain in the left side of her chest had developed. I found no tenderness on concussion or pressure, none on lateral motion. She is able to dispense with the apparatus part of the day.

A lady, twenty-five years of age, was seen by me in consultation with Dr. Sachs, November 7, 1895. Our diagnosis was irritable spine with marked neurasthenia. She had suffered for about a year. I traced her trouble to a fall. She had been an invalid practically since the date of her fall. Her spinal column was very sensitive, especially so to light pressure, but not so to deep pressure. The tenderness extended from the nape of the neck to the coccyx. There was no deformity, no spasm of any part of the column, but she was able to walk only short distances and would then become much fatigued. Dr. Sachs had employed the cautery and massage *secundum artem*.

We agreed perfectly on the necessity for a posterior spinal assistant, and during that month and the following I was enabled to fit one satisfactorily. I found that the pressure must be firm from the nape of the

neck down to the lumbar spine, and it required considerable alteration in the apparatus as first constructed to secure this object. I have recently learned that the patient gets great relief from the apparatus, although she objected very much at first, and would not under any circumstances part with the support.

I am familiar with cases that have been through gynecological hands: some were permanently relieved, others aggravated. I, of course, have made no mention of such cases in detail, but have preferred to hear from men who are more familiar with cases of this kind. We are all familiar with irritable spine relieved by the ophthalmologist.

In conclusion, let me again request the members of the society to give their individual methods of managing cases of irritable spine, even if they are unwilling to adopt the terms employed in this paper.

Progress of Medical Science.

Post-Typhoid Bone Lesions.—Dr. Harold C. Parsons has considered the question of bone disease following typhoid in an article in which he has given the history and the present knowledge in regard to it (*The Boston Medical and Surgical Journal*). Since the identification of the Eberth-Gaffky bacillus as the specific cause of typhoid fever, the nature of the bone lesions following these conditions has been more accurately studied. The different opinions which have been held in regard to the influences of the bacillus on the bone are considered, and there seems to be some reason for believing that although the typhoid bacillus plays an important rôle, the condition is one secondary to pyogenic cocci. Five cases are reported which present more or less different phases of this condition. In all but one the pure culture of the bacillus was found, and all but one required operation. The results of the operation show that more or less radical measures must be used to remove all of the diseased area, as simple incision and drainage required a second operation. Pus was found in greater or less quantity, but it is doubted by some whether this should be called pure pus. The disease seems to have been attended with considerable destruction of bone tissue, so that the fluid obtained in an incision contains a considerable quantity of detritus mixed with leucocytes. The peculiarities of this disease are that it may present itself a long time after recovery from the fever, from ten to eighteen months, and may present a long period of quiescence before the attack fully develops. In one case only the local condition appeared within a few weeks after the typhoid, and one case only has been reported in which the complaint of pain, usually sharp, and also tenderness complained of during convalescence, and the point of attack is usually found to correspond with this locality. The symptoms present more or less remissions for the months intervening; later there develops marked pain, tenderness, swelling, and redness over the site of the lesion; incision discloses at times œdematous and phlegmonous conditions of the soft parts, thickened periosteum, and destruction of the bone, with greater or smaller amount of pus. The operation requires thorough removal, and in instances cited the wound was usually packed with iodoform gauze. The typhoid bacillus has been found in different tissues of the body, and has given rise to conjecture why these lesions were not more frequent. It is supposed, however, that it may be a secondary infection; that the bacillus is present in the marrow; that with a presupposed condition of lower vitality and susceptibility in the tissues the necrosis is set up by the presence of other

bacteria; and that in the process resulting these other bacteria are destroyed, leaving the typhoid germ alone. The effect of strain and trauma is one of consideration. In one of the cases resolution took place, although, of course, no culture could be obtained; in this it corresponded closely with the clinical signs of the others.

Chorea.—Dr. J. Madison Taylor (*Philadelphia Polyclinic*, January 11, 1896) suggests the following therapeutical measures in the treatment of chorea: 1. Specific medication—arsenic, with antirheumatic or antimalarial drugs. 2. Rest to the body and proper sleep. 3. Nutritional repair, to counteract the depreciation and devitalization of the tissues due to their overaction. 4. Re-education of co-ordination, an item very important but little noticed. Put the child to bed warmly clad and give a diet containing an abundance of milk, fruit, and vegetables, and no red meat. Bathe twice daily with tepid water, giving spinal douches followed by brisk rubbing and massage. During the first week give a laxative every second or third day to do away with any intestinal irritation of faecal toxins. Give cod-liver oil for the anæmia, preferably in capsules, rather than iron. Re-educate the limbs by gymnastics and Delsartean exercises, always insisting on rest after the exercises. Use salicylates for rheumatic pain, either ammonium salicylate with ammonium bromide in liquor amonii acetatis or elixir calisaya. Fowler's solution of arsenic, increased from three drops thrice daily by addition of one drop a day until toxic symptoms are produced, is the most satisfactory general method of treatment.

Sterility.—Dr. Vedder, of Christiania, Sweden, in the *Norsk Mag. for Lægevid.*, 1895, No. 5, reports the results of examination of three hundred and ten married women who had never been pregnant, though married at least one year. In fifty of these cases he was able to examine the husband also. He draws the conclusion that in seventy per cent. of the cases the husband is to blame for the sterility, either through azoospermia or impotence or through infecting his wife with gonorrhœa. In only thirty per cent. is the woman at fault, and then for the most part through neoplasms or atrophy of the uterus.

Hysteria.—Among the hysterical, and it must not be thought that these are met with exclusively or even preponderantly among females, for they are quite as often, perhaps oftener, found among males—among the hysterical, as among the degenerates, the first thing which strikes us is an extraordinary emotionalism.—MAX NORDAU, *Degeneration*, p. 25.

Diphtheria.—Local applications should be used early and vigorously employed from the first. The purpose of local treatment is both cleanliness and germicidal. As a germicidal remedy I have used during the past year Loeffler's solution with success. The formula used by me is:

R. Menthol.....	gr. vi.
Liq. ferri sesquichlor.....	ss.
Toluol.....	ss.
Alcoholis.....	q. s. ad
M. Applied as a swab to throat three or four times a day.	ci. i.

Loeffler states that this remedy will kill diphtheria bacillus in ten seconds, and reports having treated seventy-six cases of diphtheria in a severe epidemic without a death. I also use, as a cleansing fluid to the nares, a five-per-cent. solution of liquor sodæ chlorinatis: used frequently as a spray throughout the disease.—DR. GAY, *Alabama Medical and Surgical Age*, April, 1890.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 9, 1896.

THE USEFULNESS OF DRUGS.

It is something unusual in these times to find a practitioner of large experience proclaiming boldly his belief in the efficacy of drugs. Dr. William R. Gowers, of London, however, in an address "On the Use of Drugs," delivered before a London medical society, takes the position that medicines do serve a most efficient purpose in the treatment of disease. Dr. Gowers calls attention to the fact that a great many of the non-medicinal measures for combating human ills which are now so frequently recommended cannot really be used by the every-day practitioner. The patients whom he serves cannot afford to take rest, to travel, to spend two months at some "cure," to inhale oxygen, to undergo massage or elaborate methods of hydro-therapeutics or of mechanical therapeutics. They cannot afford even, in many cases, the dietaries which are often so highly approved; and, on account of their daily work, almost the only means of help outside of surgery is, in many instances, some medicine. Now, the point made by Dr. Gowers is that the average practitioner does do a great deal of good with his drugs, and that they really have efficacy in lessening the severity and the mortality from disease. The lecturer goes on to explain in detail the reasons why he thinks it is possible that drugs should be able to modify the course of the activities of the human body. He shows that arsenic, for example, is known to directly influence the constitution of the nerve cell; so also are phosphorus and iron, and in the processes of metabolism, both the building-up and the breaking-down of living tissue can be modified by pharmaceutical agents. He next dwells upon the fact that from the most ancient times, drugs have been used and recognized as efficient. Dr. Gowers is especially positive as to the methods by which these useful drugs are discovered. He believes that most of our best modern remedies were discovered by chance and used empirically. He says:

"We smile at the popular herbal remedies. But it is to these that we owe the majority of our most useful drugs. I cannot conceive a therapist surveying a list of the chief drugs on which we depend in our daily work—and do not depend in vain—without a sense of wonder and perhaps of humiliation. We disinfect our rooms with burning sulphur; and so men

did before the time of Homer. We purge sometimes with rhubarb, especially when some subsequent astringent influence is desirable, and so did the old Arabians for the same special reason. The value of castor oil in its chief use was familiar, probably for ages, to the natives of the East and of the West Indies before it was made known in Europe by a physician from Antigua one hundred and fifty years ago. Aloes was employed in the same way long before the time of Dioscorides and Pliny. The knowledge of the influence of ergot in parturition we owe to the peasants of Germany, and the use of male fern for tapeworm goes back to the old Greeks and Romans. The employment of mercury in syphilis by inunction and fumigation, which our nineteenth-century therapeutists regard with such satisfaction, seems to go back to the time of the Crusades, and it is said that its use can be traced in Malabar as far back as the ninth century. Podophyllum as a purgative we owe to the North American Indians. If we go through the list of all the drugs on which we most rely, we find a similar story. Even in the case of those which are the latest additions to our resources, we find that, with very few exceptions, their use arose from what we must regard as pure empiricism. It was by accident that the local anæsthetic influence of cocaine was discovered."

Dr. Gowers admits that he is often unable to tell why a drug does good, but he is nevertheless convinced that there are many which must be classed as useful and effective. He finally recommends that there be a more systematic attempt to study and select those drugs which all agree have some value.

Dr. Gowers' audience was evidently impressed by his reasoning, for, as a result of his address, a special meeting has been arranged to discuss the value of certain drugs.

THE TREATMENT OF HICCOUGH.

CURRENT medical literature contains, at rather frequent intervals, contributions to the therapeutics of hiccough. These show a very wide range in the mechanical and medicinal measures which are resorted to in this affection. Hiccough is at most times a somewhat simple though embarrassing phenomenon, being the cause of amusement rather than sympathy. The ordinary attack of hiccough is due to some irritation of the nerves of the stomach, and is put down as a reflex spasm, involving the sensory branches of the vagus and the motor fibres of the phrenic. Persistent hiccough occurs in the terminal stage of a good many fatal maladies, and is then due to dilatation of an enfeebled stomach with gas and pressure upward upon the diaphragm. The more serious cases are due to central causes involving the nuclei of the vagus and phrenic nerves, or their peripheral branches. Chronic hiccough is sometimes a manifestation of hysteria, and again, perhaps, a form of chorea or of convulsive tic. Inflammation of the pleura or of the peritoneum, aneurisms, mediastinal tumors, fractured ribs, are all placed among the causes. Hiccough occurs in affections of the abdominal viscera other than the stomach,

such as renal or biliary calculi, and in strangulated hernia. A good many obstinate cases, however, occur in which the most searching investigation does not reveal any very certain explanation of the condition, and it is in these obscure cases that various and novel remedies have been reported as having a curative effect.

The common remedy for hiccough is swallowing a glass of cold water or the use of a little aromatic spirits of ammonia or spirits of chloroform. Musk is said to be a specific, probably because it is too expensive to be often tried. In the chronic cases mechanical measures of the most various kinds have been recommended. A very common procedure is to take a deep inspiration and hold the breath for some time. Another is to bend the head forward as far as possible and press firmly upon the base of the thorax. This is called relaxing the diaphragm. Still another much-recommended measure is to lay the patient upon a bed and place under his back a number of hard pillows, so that the spinal column will be bent backward. The head is then forcibly extended as far backward as possible, and this position is retained for half an hour or more if necessary. This is called stretching the phrenic nerve. Another measure that has been commended is that of taking a swallow of water in the mouth, pressing the fingers tightly into the ears, and then swallowing, this process being repeated several times.

Professor Lepine, of Lyons, has lately described the case of a girl who for four days had been afflicted with hiccough. The patient was not hysterical. Various medicinal remedies were employed in vain. Finally, Dr. Lepine had her protrude the tongue. Traction was then made upon this organ and was maintained for several minutes, with the result of causing the symptoms to disappear.

This cure of hiccough is said to have been first devised by M. Viaud in 1894. Pressure upon the phrenic nerve and galvanic currents along the nerve are other measures that have been resorted to. Injections of morphine, apomorphine and other emetics, nitroglycerin, and hyoscine have also been tried. The great difference in the various measures which, in different countries and at different times, have proven successful in the treatment of hiccough, show that the essential thing in most cases is the psychical effect of the treatment upon the patient.

THYROID THERAPY.

It has been pretty firmly established that in myxœdema extract of the thyroid gland does more for the average patient than any form of treatment previously employed. It has also been incidentally discovered that we possess in this remedy a valuable addition to our means of reducing corpulency. Goitre is among other diseases in which it has been extensively tried. Insane patients have been found to improve in their mental condition while under this treatment, especially at the puerperal, adolescent, and climacteric periods. The MEDICAL RECORD has recorded instances

of malignant syphilis which appeared to be decidedly benefited, and in literature are to be found instances of cretinism and a variety of dermatological states which have been cured. Skin affections, as a rule, have not been so favorably influenced as the early experimental trials of the gland treatment led us to hope they would be. Pityriasis rubra, ichthyosis, lupus, and psoriasis have all had cures attributed to its use, but an extensive observation of its effects upon psoriasis has resulted in disappointment. The energy of action would seem to be expended upon the subcutaneous fatty tissues to a much greater extent than upon the skin proper, though undoubted amelioration has been observed in a variety of dermatoses during its administration.

In one of the latest meetings of the Vienna Medical Club Dr. Hock presented a myxœdematous infant of only twenty-one months, whose physical and psychical conditions had been improved very much under the use of the fluid extract of the thyroid gland. He also showed a child of four years afflicted with idiocy treated in the same way, but in this case an amelioration of the psychic state alone could be looked for.

While there exists in the extract a property of reducing fat, it would seem to possess also a quality of increasing height, if we are to judge from a case reported by Kassowitz. Besides causing other improvement in the person of a man of twenty affected with myxœdema and cretinism, a course of thyroid treatment resulted in a decided increase of stature.

Bourneville pointed out the same effect in two of his patients in a paper read at the Congress of Alienists and Neurologists held last August in Bordeaux, and he suggested the employment of thyroid in stunted children. If at the same time these dwarfs are obese, as is often the case, the gland treatment should be doubly efficacious.

Many prefer to give the gland in a fresh state, either cut up into small pieces and eaten with bread and butter or taken with bouillon, but cooking detracts from its value, if indeed it does not deprive it of all its therapeutic worth.

Vigier has suggested a means of preserving the fresh gland for an indefinite period, which obviates the objections some have to the use of tablets and the difficulties of obtaining a fresh supply of the gland when needed. After removing the fat and all extraneous matters from the gland, it is made into a pulp and mixed at once with biborate of soda and powdered wood charcoal. The mass is divided into capsules, each containing ten centigrams. They have been well spoken of by a number of physicians in France who have used them.

As we have previously pointed out, many dangers attend the indiscriminate and protracted use of the thyroid remedy. Severe symptoms are likely to supervene, if as a daily dose over sixty grains of the powdered gland are given, and it is safer to keep much below this quantity, unless the patient be most carefully watched. Excessive dosage may even be followed by the development of Basedow's disease, as Bécclère has indicated, and experiments upon dogs have confirmed the view that hyperthyroidization

may produce a train of symptoms analogous to those of the latter disease. This would go to show that exophthalmic goitre depends upon a thyroid intoxication and gives weight to Ballet's theory that it is a secretory perturbation of the thyroid body, due to moral or physical causes acting upon the bulb; and, secondarily, to the thyroid intoxication which results. It is admitted, we believe, that there exists a toxic property in the normal organism which, unless destroyed, neutralized, or in some way antagonized by the thyroid body, leads to myxædema. Eulenburg mentions a case in which very severe nervous and heart symptoms followed the self-administration of thyroid tablets for their antifat effect, and such instances could be duplicated by every physician of large experience in localities where, as in this city, the layman has learned enough about the subject to make him dangerous to himself and friends. Self-prescription and amateur practice in reduction of weight by thyroid tablets is apt to have an occasional grave result, unless physicians give timely warning of the dangers.

THE STORY OF A PICTURE.¹

IN the estimation of professional service, the anxiety of the doctor is the only element that cannot be itemized and is consequently beyond the power of compensation. It is the unknown quantity to the patient, but the ever-present and weighty responsibility with the one who is called to assist in the dire emergency. Every physician has felt it time and again, and has bravely and willingly bowed his best energies to the pressing burden. Its realization banishes all selfish purposes and focusses his best thoughts on the balance of chances between life and death. His only reward is the consciousness of highest duty done. Even the grim fatality of an inevitable defeat cannot cheat him of the crowning satisfaction of doing his best. It is comforting to know that such service is often appreciated by such as are in direct touch with the thrilling experiences of his life work. The sister professions are ever ready in their sympathies with failure and triumph, and are always generous in their tributes to the lofty purposes of oftentimes futile endeavor. The influences of such stimulation keep the doctor where he is, encourage him to do and dare alike in hovel and in palace, and place his best services beyond the power of gold to buy. Art more particularly has paid its homage to that better sentiment and has illumined it with the master touch of an interpreting genius. Thus, the doctor has become the central figure for the high light in many a pathetically truthful picture of our better humanity. And this is one of them that we study with more than ordinary interest. The scene is in a humble cottage; the sick one, a weakly, dozing child, is tenderly pillowed on chairs in the centre of a poorly furnished room. The good doctor, with bending head and troubled brow, is gazing anxiously on the face of the little patient, the lamp shade tilted to give him the better view. It is the early hour of

dawn. The glimmer of the coming day outlines the tired forms of the anxious parents at the adjoining window. The stern-faced father, weary with the night vigil, is resignedly awaiting the verdict. The heart-broken mother, overcome with anxiety, is resting her aching head, face downward, on the table. The empty baby-chair finds its significant place in the general disorder which marks the unconcern of a supreme trouble. It is the telling picture of sickness of an only child in the poor man's home, with the helpful doctor and the weak patient in the foreground. The high light is thrown on both with the grimness of an impending fate in the darkened offset.

The doctor's figure is the real study. His head is the expression of inherent power and his face the embodiment of assertive reliance. Every energy of a strong and generous nature is focussed on the mute appeal of a helpless and prostrate sufferer. The panting breath keeps time with the clock tick; the fluttering pulse is bearing away the life wave on the outgoing tide. The temperature is running its hot race with gaining death. What to do or not to do is the question of the moment. The interpretation of indications must be balanced by the logic of natural laws. And through it all he calmly weighs the record of his experience against an apparently inevitable decree. Never flinching until the end, his is the last appeal until the curtain drops. Thus he sits watching, while we interpret the higher motives of his broader mission. The beautiful picture has the simple title of "The Doctor," but needs not even that to indicate the apt suggestiveness of the true ideal. There is the stimulus of an actual presence with an ever-living experience which finds its response in the history of every professional life. It is among the poor that we perhaps see it in its better color, with the father the watcher, the mother the nurse, and the doctor the only earthly helper—the three offices exemplifying the cardinal virtues, faith, hope, and charity. Thus the picture and the moral go hand in hand to encourage us in our work and to reward us in its doing. Every physician who can look at or own such a picture must needs be proud of his title and glory in his calling. It is an inspiration in trouble and a crown in victory.

Pathological Society of Philadelphia.—At the meeting of the Pathological Society of Philadelphia held on April 23d, Dr. B. Meade Bolton, chief of the bacteriological division of the Board of Health, read a paper on "The Theories that have been Advanced to Explain Immunity from Infectious Diseases." The consensus of opinion seemed to be that none of the theories is sufficient to explain all of the facts of immunity and it is probable that many factors are operative in the production of this result. The most plausible are the so-called humoral and cellular theories, according to the first of which the fluids of the bodies possess bactericidal properties and according to the second the cells of the body are capable of repelling the invasion of attacking micro-organisms. A well-attended reception at the University Club followed the meeting.

¹ "The Doctor," by Luke S. Fields, R.A., Copyright, 1895, Wm. Wood & Co., New York.

News of the Week.

The Canadian Medical Association.—The next annual meeting of this association will be held in Montreal on August 26th, 27th, and 28th.

The Gynecologists of New York are the subjects of a sketch by Dr. L. C. Prevost, of Ottawa, in the *Montreal Medical Journal*. The writer seems inclined to think that they are not such a bad lot, in which opinion we agree with him.

The Sewerage of Marseilles.—A new system of sewerage has been adopted in Marseilles and is now nearly completed. The entire sewage of the city will be carried into the sea. The cost of the work has been about \$6,000,000.

A Virtuous Service.—The British Indian Medical Service of the present day holds the palm for virtue and manly purity, theoretical at least, among all bodies of men that have ever existed within speaking-distance of charmers of the other sex. A surgeon-major of this immaculate corps was recently dismissed the service because he asked a married lady for a kiss. Hereafter the amatory surgeon-majors will probably snatch their kisses without asking for them, since the penalty can be no greater and the bliss will at least have been theirs.

Reorganization of the Newark Board of Health.—The common council of Newark, N. J., has agreed to a plan of reorganization of the health board of that city proposed recently by Dr. Herold. It provides that the board shall consist, as heretofore, of ten members, five physicians and five lay members, equally divided politically: four members to be appointed for three years, three for two years, and three for one year, the members to be appointed by the mayor and confirmed by the common council. The city dispensary and the city physicians are to be under the authority of the board.

A Chair of Comparative Pathology at Harvard.—Through the generosity of a merchant of Boston, whose name is not made known, Harvard University is to have a department of comparative pathology. The benefactor advances \$100,000 for the endowment of the chair. The professor is to be a member of the medical faculty of Harvard College, and he is to study the conditions and causes of disease common to both men and animals and the means of avoiding and curing them.

The British Association for the Advancement of Science will hold its sixty-sixth annual meeting in Liverpool on September 16th and the following days, under the presidency of Sir Joseph Lister.

Miss Cobbe, a reforming lady who is better known in England, we are glad to say, than in this country, spends much of her time in uttering antivivisection protests. But having apparently exhausted the possibilities of inanity in that subject, she has actually come out in a protest against the dissection of dead rabbits.

The University of Edinburgh has recently received a bequest of \$100,000 from the late Earl of Moray as an endowment fund for the promotion of original research.

The Perils of the Army Surgeon's Life.—An army surgeon is called a non-combatant, but his life is by no means secure on that account. Out of twenty surgeons on the battlefield of Abba Carina, in Abyssinia, seventeen were killed in action.

Alcohol as a Medicine.—At the annual meeting of the governors of the London Temperance Hospital a letter was read from Sir Benjamin Ward Richardson, in which he stated that his conviction as to the uselessness of alcohol as a medicine was still as strong as ever.

An International Journal devoted to the history of medicine and to medical geography will appear shortly in Holland. It will contain articles in English, French, and German.

The Wisconsin State Medical Society announces that its fiftieth annual meeting will be held at Madison, Wednesday, Thursday, and Friday, June 3, 4, and 5, 1896. It is proposed to celebrate the occasion of this fiftieth anniversary by a new departure from the usual programme in devoting the entire session to a discussion of "preventive medicine." The committee has invited a number of men in the State, members of the society and others, to read papers at this meeting.

Colleges with Four Years' Courses.—The Rush Medical College of Chicago has had since 1894 a compulsory course of four terms of eight months each. The Woman's Medical College of Pennsylvania also requires four years of graded instruction. The names of these two were omitted from the list referred to in the issue of April 11th.

The Mitchell District Medical Society.—The forty-ninth semi-annual meeting of the Mitchell District Medical Society will be held at Shelbyville, Ind., June 29 and 30, 1896. An elaborate programme is being arranged. The Shelby County Medical Society will entertain the visiting society.

The Medical Department of the University of Wooster has become the medical department of the Ohio Wesleyan University, and is to be known as the Cleveland College of Physicians and Surgeons. All the members of the faculty resigned in a body from Wooster and were elected to the same chairs in the new college. But the trustees of Wesleyan have promised to erect a new college building.

The Goat has Succumbed.—Dr. Aronsohn, of Berlin, has succeeded in inoculating with tuberculosis a goat, an animal hitherto regarded as immune to this disease.

The Pennsylvania State Sanitary Convention will be held at Williamsport on May 21st. Among the subjects for discussion are the prevention of the contagious diseases of childhood, the communication of disease from animals to man, and food adulteration.

Health of Rome.—Malaria is being gradually extinguished in Rome. The deaths from the disease have decreased from 650 in 1881 to 254 in 1891, while for the last five years the average has been 149, the number in 1895 being 125. The population of Rome has increased from 300,000 to 467,000. An equally remarkable diminution has taken place in the death rate for typhoid fever and all other infectious diseases.

Professors and the Advertising Postal Card.—We have just received an immense post card by mail, which contains in type so large that any one may easily see the tremendous advantage to be gained by going to a western city of the United States to attend the polyclinic. Though we have had something in this line before, our nervous systems were hardly prepared for the shock of an advertisement such as might be sent out from a patent medicine firm or a modern departmental store. We notice that all those who are to give instruction are professors—that “no effort will be spared to make the course eminently practical to the general practitioner.” Special prominence is given to surgery, gynecology, skin and venereal diseases—and all for “the special low fee of \$35.” Here surely is a chance that we should not miss—a sort of a “Friday bargain day” in four weeks, during which time, if one might judge from the alluring nature of the $8\frac{3}{4}$ by $4\frac{3}{4}$ inch post card, the careful student would surely come out a specialist in most of the subjects. We regret to see on this card the names of men from whom we might expect a higher type of ethics.—*Canadian Medical Review*.

A New “Jag” Cure.—The last suggestion in orthotherapy, according to the *Medical Press*, is the injection of the blood serum of dogs which have been subjected to large daily doses of ethylic alcohol. According to Dr. Toulouse, the injection of twenty-four cubic centimetres thrice repeated of this serum produced markedly beneficial effects in a case of alcoholic delirium. He is now about to institute researches with the object of finding out whether the serum acts as an “antialcoholic” serum, or merely *quid* serum. It would perhaps have been more in accordance with scientific principles if he had made his control experiments before taking up the time of the Academy of Medicine of Paris with an observation which is calculated to bring orthotherapy into contempt.

Louisville Medical Colleges.—The Louisville Medical College graduated a class of sixty-three at its twenty-seventh commencement on March 25th. The University of Louisville graduated a class of fifty-nine at its fifty-ninth commencement on March 30th. One hundred and twenty-two new doctors!

Accidental Injuries.—An analysis of 2,000 accident policies on which benefits were paid shows 531 persons injured by falls on pavements, 243 by carriages or wagons, 75 by horse kicks or bites, and 47 by horse-back riding; 117 were cut with edged tools or glass, 96 were hurt by having weights fall on them, and 72 were hurt in bicycle accidents, while 72 were hurt by falling down-stairs.

Poisoning by Boracic Acid.—Dr. Arthur Hall reports a case of probable poisoning by boracic acid. The case was that of a boy who had been seriously burned and was treated with boracic-acid ointment. On the fifth day he developed an extensive erythematous eruption over the limbs, trunk, and face, for which Dr. Hall was asked to see him. During the next few days he gradually became worse and died on the ninth day. At the necropsy nothing was found to account for death, and previously to the eruption the boy was doing very well. There were no throat symptoms whatever; there was delirium at night; the rash developed more each day. Dr. Hall quoted many recorded cases of similar groups of symptoms occurring definitely from boracic-acid poisoning.

The Franklin County (Pa.) Medical Society met at Chambersburg on April 21st and listened to an address on surgery by Dr. Joseph Price, of Philadelphia. Dr. H. G. Chritzman read a paper entitled “Organizations.”

Vanderbilt University, Nashville.—Dr. Ernest B. Sangree, assistant professor of pathology in the Medico-Chirurgical College of Philadelphia, has been elected professor of pathology and bacteriology in the Vanderbilt University, at Nashville, Tenn.

Medical Students in Vienna.—According to a report which has just been published, the Vienna School of Medicine was attended by 3,674 students during the past winter half-year, comprising 2,211 ordinary and 1,463 extraordinary students. The teaching staff consisted of 29 ordinary professors, 34 extraordinary professors, and 93 privat-docents and assistants.

A Compounder of Drugs.—The *Medical Press* relates an amusing episode which took place in a dispensary in a small town in Tipperary, Ireland. One of the dispensary patients was dissatisfied with her medicine and began to abuse the medical officer, who ordered her to leave the dispensary. As she would not go, he went out to fetch the porter, whereupon the patient locked herself up in the pharmacy, of which the key happened to be at hand, and occupied herself until the door could be broken open in mixing the contents of all the bottles. Before she could be removed she had compounded a shotgun prescription to the value of about \$250.

To Sterilize the Water of Paris.—An offer has been made by an inventor to the municipality of the city of Paris to sterilize five thousand cubic metres daily of water for public consumption at his own expense. After preliminary inquiry the municipality has decided to obtain an expert report upon the value of the proposed measure, and if it is found to be of practical utility the inventor's offer will be accepted as a preliminary to adopting the system in case the experiment is satisfactory.

Dr. A. R. Baker, for many years editor of the *Cleveland Medical Gazette*, has retired and has given over the editorial management of the journal to his associate for the past ten years, Dr. Samuel W. Kelley.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 3, 1896.

ANDREW H. SMITH, M.D., PRESIDENT, IN THE CHAIR.

The Thyroid Theory of Graves' Disease, with Its Bearing on the Surgical Treatment of the Disease.—DR. FRANCIS P. KINNICUTT read the paper, the discussion of which was postponed until the next meeting (see p. 541).

Suture of Ruptured Urethra.—DR. R. F. WEIR presented the patient and read the history of the case (see p. 651).

DR. CHARLES MCBURNEY inquired how long the suprapubic fistula remained open. Dr. Weir replied two weeks for drainage, and it was about two weeks longer before it healed.

Dr. McBurney remarked although the result in this case was nearly perfect, he thought it was quite open to discussion whether the means was worthy of adoption. In the first place, such injuries behaved beautifully under a much more simple method of management, the old-fashioned one which Dr. Weir himself had made use of probably a great many times, external urethrotomy and the subsequent use of sounds. Any one who had done this often could not have failed to be struck by the perfect repair which took place under such management. He was quite sure that personally he had never had failure. The moment that external urethrotomy was made, if it were free, the patient was removed from danger; the parts were drained, the passage of fresh urine over them never gave rise to complications, and the return of the urethra to practically normal condition was proven by examination with instruments many months, and even years, afterward. This was so universally true in cases of injured urethra that he thought it might fairly be questioned whether it was worth while or desirable to run certain risks—and there certainly were some risks—by sewing up the wound. There were not only some risks connected with sewing up the wound in the perineum when the urethra had been ruptured and there was infiltration of urine, but also in making the suprapubic opening into the bladder. Not infrequently there was difficulty in getting closure of the opening above the pubes. Altogether, it did not seem to him that the argument in favor of sewing up the urethra was a very strong one. If resection of the perineum in such cases were frequently followed by contractions of the urethra which gave rise to subsequent grave trouble, it would be another matter, provided these difficulties could not be overcome by other methods. But this had not been his experience. When he had a patient with rupture of the urethra he cut the perineum freely, subsequently used sounds, and if the urethra were clean he felt that the patient would be perfectly safe and would not have difficulty with the urethra, provided the use of instruments were kept up to prevent the possible occurrence of extra-urethral contractions.

DR. J. D. BRYANT congratulated Dr. Weir on his extraordinarily good result. Personally he had had no experience with opening up and suturing the ruptured urethra, but had always met the condition by making perineal section, referred to by Dr. McBurney. He thought it was always important in discussions of this kind to consider whether the operation which was brought before the profession for the first time was one of such simple nature or practical application that it could be employed by those not especially experienced

or favorably surrounded, with as great safety as an older and perhaps simpler method. It was not so much a question what Dr. Weir could do, or others engaged in hospital work, in which they were constantly called upon to meet the exigencies of the occasion, but rather what was the proper course to pursue by those with more limited experience.

Dr. Bryant would regard the introduction of the drainage tube into the bladder through a suprapubic incision as an additional element of danger.

DR. WEIR rejoined that we must, in the first place, consider the question in its true light. Sewing up the perineal wound partially or completely was purely a side issue. It had not often to be done. Nor was it often necessary to drain the bladder by suprapubic incision. One could get a good result without either of these procedures. It could be secured by leaving the catheter in the urethra to draw off the urine from the bladder, and by leaving the perineum open, simply stitching the urethra together, perhaps imperfectly. He could conceive great advantage in suturing together the ends of the completely divided urethra, or even the partially divided urethra. He did not agree with Dr. McBurney regarding safety from stricture of a patient with rupture of the urethra which had been treated simply by perineal incision. He had seen stricture result so many times that he did not attach much value to such treatment as a preventive of stricture. It was, however, a simple and efficacious method of preventing serious septic troubles from infiltration of urine in the perineum. But analogy would lead one to feel that here, as elsewhere, it was good surgery to closely approximate the parts and drain the bladder through a tube. In the thirty-five cases reported, the mortality had not been increased at all by this treatment; on the contrary, it had been less even than after perineal section. Also with regard to stricture, so far as these few cases had any bearing upon that question, the treatment was an improvement upon the older method.

The Management of Irritable Spine.—DR. VIRGIL P. GIBNEY read the paper (see p. 654).

Irritable Spine from the Standpoint of the Ophthalmologist.—DR. CHARLES S. BULL was called upon to discuss the paper from the standpoint of the ophthalmologist. He said that of the several classes of cases of irritable spine, there was only one in which he found the correction of any existing errors in the eyes of practical benefit. In this class there was no anatomical defect in the spinal column and no history of traumatism. He referred to those neurasthenic patients, mainly women, suffering from some optical error, usually astigmatism. It was well known that almost everybody had some optical error, usually astigmatism of low degree, and we were unable to tell until the accommodation had been paralyzed whether the defect was sufficient to require correction. It was necessary, also, to take into consideration the personal factor, for many persons with a given amount of astigmatism went along and attended to all their duties, perhaps using their eyes sixteen hours a day without complaining, while others required the correction of a quarter of a dioptré. In many of these cases he had noticed that the symptoms which the patients had located in the spine disappeared at once when the accommodation was paralyzed by atropine. It was very rare to find a young American of either sex who had not some muscular defect in the eyes; indeed, it was so common that our German confrères called it the *amerikanische Krankheit*. It was a singular fact that when the muscular error was considerable its correction by prismatic glasses almost never relieved the irritable spine.

From the Standpoint of the Neurologist.—DR. CHARLES L. DANA thought Dr. Gibney had presented

very accurately the neurologist's view of the condition known as irritable spine. Apparently the gynecologists, the general practitioners, orthopædists, oculists, and others had taken hold of these cases so extensively that few now reached the neurologists compared with former times. Still, the patients who consulted him belonged to the class Dr. Gibney had described, and required similar treatment. In cases of traumatic origin there was sometimes a surgical lesion, as rupture of ligaments, strain of muscles, which gave rise to symptoms in addition to the psychical element. In the general run of cases, seen mostly in women, and being more or less idiopathic origin, so to speak, he believed the underlying cause was a defect in the nervous and muscular structure of the individual. In other words, he believed the spinal irritation was, in a great many cases, a teratological defect. Such patients were born, apparently, with weak nervous centres, and were not able to stand the strain of life upon their feet. One might almost class irritable spine among occupation neuroses, because it came from the continual use in the erect posture of muscles which supported and moved the trunk and which were unable to do so without pain. He believed that the underlying condition which we had to treat in almost all cases was asthenia, and if he should differ at all from Dr. Gibney regarding the treatment it would be in laying much more stress upon the importance of rest and gradual training of these muscles and nerves into stronger organs. He did not believe that the Paquelin cautery or counter-irritation in itself ever effected a cure. It had a good psychical effect. Dr. Dana was becoming more and more skeptical about there being reflex forms of spinal irritation. Not but what the eyes and uterus would, sometimes, produce symptoms of severe character, and symptoms which would disappear on treatment directed to the eyes, the uterus, or other pelvic organs, but, as a rule, they would not disappear permanently unless other treatment were given at the same time. The tendency of neurological thought now was most decidedly against belief in reflex neuroses. He thought he was safe in expressing the belief that there were no constitutional reflex neuroses. There were some reflex symptoms, but no reflex neuroses.

From the Standpoint of the Gynecologist. DR. WILLIAM M. POLK discussed the subject of spinal irritation in so far as it seemed to be connected with diseases commencing at the vulva and extending up to the kidney. He sometimes found conditions about the uterus, more especially backward displacement, the correction of which was followed by relief of spinal symptoms. Of course these people were liable to have the sensitive ovaries which belonged to hysterio-epilepsy, and since Dr. Dana did not admit reflex neuroses it might be that the ovaries were diseased in such instances, although the gynecologists had not been able to satisfy themselves that they were sufficiently diseased to set up the train of symptoms which had been attributed to them, for other ovaries which were much more diseased did not produce any condition at all similar.

After the gynecologists had gone over the pelvic region pretty thoroughly without getting much satisfaction in the treatment of so-called spinal irritation, etc., they turned their attention to the kidneys. He was ready to confess that they had found floating kidney, or, at any rate, displaced kidney had a very decided bearing on many such cases. He presumed this would account for the fact that Dr. Gibney had found the abdominal bandage so frequently of benefit. For a long time before the real nature of such cases was understood it was the custom to put on a binder over a pad, and the patients would go out feeling better. The supposition was that the relief was due to taking

off pressure from the pelvic organs by supporting those within the abdomen. In the light of late experience Dr. Polk thought it was more especially due to supporting the kidneys, which were disposed to sag.

He supposed that gynecologists relieved at least fifty per cent. of the cases of so-called irritable spine which came under their observation by paying attention to the condition and position of the uterus, while they accomplished very little in the other fifty per cent. if no operation were indicated. Regarding the location of the spinal irritation, when it was in the upper part of the spine, he must confess that they were able to accomplish very little by attention given to the organs which received treatment by gynecologists.

DR. R. F. WEIR thought the remarks of Dr. Polk, with reference to spinal irritation being caused by floating kidneys, went to support the view which Glenard published in 1889, and which had been lately revived by Treves, that when there was dropping or pulling down of the upper abdominal organs one was apt to see such irritation. The kidney was only one of those organs, but the one whose displacement was easiest to recognize. The general condition had been demonstrated on the cadaver, occasionally on the operating-table; very rarely could it be proven before the knife was used. Since Dr. Weir's attention had been called to it, he had been able to recall several cases in which, while doing laparotomy, he had found this condition of things, which he was then unable to interpret correctly—a dragging downward of the abdominal contents, including the small intestine, mesentery, stomach, kidney, etc. In all these conditions the patients often derived much benefit from an abdominal band, which may have been suggested to them by their tailor.

DR. KINNICUTT thought it was possible that one explanation of failure to give relief by fixation of the kidney in marked displacement of this organ was to be found in the suggestion of Glenard, taken up by others, that the displacement of the kidney was only a part of the falling down of many organs. Fixation of the kidney removed one factor in the production of the symptoms, but not all.

DR. POLK, in order not to be misunderstood, said we should make a distinction between kidneys displaced without displacement of other abdominal viscera and those displaced with the other viscera.

DR. WEIR: Of course the cases can be separated, but they are often associated.

DR. POLK: Yes. In thin women we sometimes feel that the kidneys are loose, while the other abdominal organs are firm. A patient came to me just the other day, whose kidneys could be shoved down to the brim of the pelvis on both sides.

DR. KINNICUTT thought it was often very difficult to determine whether there was or was not displacement of the other organs, and unless one made a very careful examination he was liable to be deceived.

DR. POLK said he based his judgment on the ordinary outlines of the stomach as made out by percussion, by the firmness of the abdominal walls as the patient stood, by the muscular strength, and the fact that the kidneys were disproportionately movable. Not that they could simply be displaced an inch or two, but could be carried well down toward the brim of the pelvis. He would admit, however, that there was some difficulty in distinguishing between the two classes of cases.

DR. DANA thought it would be unfortunate if it were allowed to go out as the expression of the opinion of the society that prolapse of the kidneys or of the abdominal viscera was at all identical with spinal irritation as described by Dr. Gibney and as it was seen every day. He had read the original paper of Glenard when it was first published, and had followed

up the literature, but while he thought abdominal ptosis undoubtedly had much to do with the symptoms which Glenard had described, these did not correspond with the symptoms of spinal irritation, and he did not believe we could often cure spinal irritation by anchoring the kidney or applying an abdominal belt. These measures might relieve some of the pains, but not all.

The President, DR. ANDREW H. SMITH, thought that if dislocation of the kidney was a cause the patient's symptoms should usually be referred to the right side, as the right kidney was the one dislocated in far the larger number of cases.

DR. WEIR said that personally he did not know that spinal irritation could be regarded as one of the symptoms of displacement of kidney.

From the Standpoint of the General Practitioner.

—DR. BEVERLY ROBINSON said that after all the specialists—gynecologists, surgeons, and others—had been consulted, there could be no doubt but what there remained in the wards of our hospitals during the course of the year a certain number of cases of irritable spine which could not be accounted for except on the broad ground that there were a number of women, both young and old, whose general nervous system seemed to be weak or impaired, which condition expressed itself in irritable spine. There was at present in his ward a young woman for whom almost every thing possible had been done by way of treatment, but without success, and for whose condition no cause could be assigned except that for six years she did not get good food, was overworked, and had little or no mental distraction. He felt certain that other physicians not infrequently met with similar cases. Under these conditions the cautery would relieve the symptoms as nothing else would.

DR. KINNICUTT remarked that his experience agreed with Dr. Robinson's, that in the majority of cases of irritable spine which came under his observation he could find no lesion to account for the condition. He could appreciate what Dr. Dana had said regarding an inherited weakness.

DR. POLK: With reference to Dr. Dana's comment on my suggestion concerning the influence of the kidneys in producing symptoms of irritable spine, you will, perhaps, recall the fact that in my remark I stated we found that the uterus seemed to be sometimes responsible for that set of symptoms and we sometimes found that the symptoms appeared to be due to the kidneys. All that I can add is simply this, that the irritable spine seemed to be relieved by treatment directed to the doubly displaced kidney. I could relate three such cases if time would permit.

Cyst of the Parotid Gland Removed Unruptured.

—DR. CHARLES MCBURNEY presented a specimen which he said was novel to him, an unruptured cyst of the parotid gland, fully as large as an English walnut, removed by enucleation without injury to the gland. The fluid contents were clear. The patient was a lady, seventy-three years of age; the tumor had existed three years, and had shown marked increase during the last six months. The facial nerve did not come into view during the operation.

Fresh Specimens of Appendicitis.—DR. MCBURNEY presented three fresh appendices, remarking that he did not think such specimens were of value unless seen in the fresh condition, before having been placed in alcohol or other preservative fluid. The first one was remarkable for its size, being over six inches long. It had been removed from a man, twenty-six years of age, during his first attack, a very acute one, of appendicitis. The chief cause was a marked constriction by bending at the attachment of the appendix to the colon, interfering with drainage. The second specimen had also been removed during a primary attack, but the condition which had brought it on had

evidently been of gradual development, although the man had been quite well. He was fifty-one years of age, had never been conscious of any difficulty in the abdomen, except that he was fat, until this acute attack of appendicitis developed, for which Dr. McBurney operated at the end of thirty-six hours. The specimen showed six strictures at points throughout the length of the appendix, there being a concretion between each constriction. Only one of these had caused perforation and given rise to this acute attack—the one immediately adjoining the colon.

The third specimen was from a boy, nine years of age; primary attack, very sharp symptoms, operation at the thirtieth hour. There were three concretions separated by more or less complete strictures. The distal one had caused perforation; the orifice was sloughing, and had the case been allowed to go on, no doubt the sloughing process would have quite destroyed the distal end, and if the boy had recovered it was probable the other concretions would have given rise to subsequent attacks. Slitting up the remaining portion of the appendix with the scissors, he called attention to the fact that the strictures separating the concretions did not completely occlude the calibre of the appendix and prevent all drainage. He thought almost all cases of appendicitis could be brought under the usual head of defective drainage. Whether the defective drainage was due to concretion, to stricture, or to flexure of the appendix, beyond that point one was likely to have disease. In almost all cases some such explanation was to be found. It was a rare thing to find a case in which the whole length of the canal was wide open and drainage into the colon was perfect.

ASSOCIATION OF AMERICAN PHYSICIANS.

Eleventh Annual Meeting, Held at Washington, April 30, May 1 and 2, 1896.

A. JACOBI, M.D., OF NEW YORK, PRESIDENT.

First Day, April 30th.

The President's Address.—DR. A. JACOBI, in his address, first referred to the work of the association. Whatever conduced to make up internal medicine, from the special biological study of a coccus to the prognosis in a particular disease, from the etiology of a morbid condition to its therapeutics, from the consideration of a local disorder to that of public hygiene, was well represented in the programme. He found it far from difficult, though perhaps superfluous in the presence of the representatives of what was best in American medicine, to express in a few words what he considered to be the relation of medicine as it was exhibited in this association and on its programme to medicine as it was taught and practised, either divided or in its specializations, and of this association to its national sister societies. At a time when a number of national special organizations had been in existence several years, it was founded, he took it, because the leaders felt that the natural tendency to the division of scientific labor should be, not checked, but guided by a controlling hand. From this point the president's remarks related chiefly, either directly or indirectly, to the dependence of specialties upon general medicine. He once asked one of the wisest members of the association what he had done in a certain case. The answer was, among other things, "I prescribed a surgeon." Even surgery belonged to medicine; only its art constituted a specialty. The advance of internal medicine growing out of special study was illustrated by reference to the work of Laen-

nec, Auenbrugger, Skoda, Wunderlich, Hebra, Karl Ludwig, Schmidt, Wormley, Richardson, Brown, Frazer, and others. We were amply justified in believing that internal medicine would soon reap many of the fruits grown on the fields of biological, and especially bacteriological, laboratory work, but which had thus far been harvested by external medicine only.

The normal vital processes depended upon two powers, the cells and the blood. The very structure and function of the former was acted upon or built up by the latter. Thus it appeared, as our master Virchow had but lately pointed out, that finally we returned to a species of humoral pathology, but not, indeed, to the crazes and diatheses of old. The president hoped soon to see a great work on hæmato-pathology containing the demonstration of the connection of external causes of every description which were working their general changes in the blood and through it in the tissues. Most of that book would be chemical. We would meet our old acquaintances leucin, tyrosin, lactic acid, etc. We would learn that the injection of chloroform and ergotin caused tetany in animals, that there were phosphorous symptoms resembling acute yellow atrophy of the liver, and the explanation of these and many other relationships.

The association had lost during the year Dr. James Edmund Reeves and Dr. J. West Roosevelt, both of whom had done valuable work and exhibited a highly scientific spirit.

Pasteur Memorial.—On motion of Dr. STERNBERG, the secretary, Dr. Huhn, was requested to receive contributions to the Pasteur memorial.

Vivisection before Congress.—DR. SAMUEL C. BUSEY, of Washington, called the attention of the association to the bill before Congress which would prohibit vivisection in the District of Columbia. It was a matter of interest to the entire profession of the country, not alone to that in the District of Columbia. The Humane Society, which had presented the bill to Congress, accompanied it with a memorial signed by many physicians, bishops, and others throughout the country, favoring absolute prohibition of vivisection. Dr. Busey moved that a committee of five be appointed to memorialize Congress in opposition to the bill. The motion was adopted unanimously.

The president appointed Drs. Welch, Vaughan, Edes, Pepper, and Theobald Smith.

The "X" Ray in Medicine.—DR. F. H. WILLIAMS, of Boston, showed an improvised tube made of a roll of cardboard with black velvet over one end, tungstate-of-calcium diaphragm, for use as a fluoroscope in connection with the Crookes tube. Dr. Williams related three cases of pulmonary tuberculosis in which he had been able to make out by physical examination an area of dulness, etc., in one lung, and by use of the fluoroscope had confirmed the diagnosis. The diseased area was darker than the remainder of the lung as viewed by means of the "X" ray. By the same means he had confirmed the diagnosis of hypertrophy of the heart as determined by percussion. One surgical case was related—bullet located by the fluoroscope in the arm, then removed by a surgeon.

The "X" Ray not a Germicide.—DR. GEORGE M. STERNBERG read a letter from Dr. Stone, medical officer at Fort Leavenworth, giving results of experiments on bacilli with the "X" ray. They were negative—the bacilli developed under culture as freely as those not exposed to the "X" ray.

DR. WILLIAMS said a similar result had been obtained by Mr. Keith, of Boston. Replying to a remark of Dr. Ernst upon the newspaper accounts of a depilatory effect, Dr. Williams said he had exposed his own head to the "X" ray and had lost no hair in consequence.

DR. OSLER had had some gall stones exposed to the

"X" ray, held in the hand or rolled up in beefsteak, and the picture failed to show them.

DR. WILLIAMS said he had had no experience with the "X" ray in gall stones.

Leucomain Poisoning.—*Continued.*—DR. B. K. ROCHFORD, of Cincinnati: "In a paper read before this association last year I made the assertion that leucomain poisoning is a most important form of auto-intoxication, which may manifest itself in at least three distinct but closely allied clinical forms, viz.: (a) A true migraine or leucomain headache. (b) A migrainous epilepsy or leucomain epilepsy. (c) A migrainous gastric neurosis or leucomain gastric neurosis.

"My studies during the past year have not only convinced me of the truth of these assertions, but they have also strengthened the belief which I had at that time that leucomain poisoning is largely responsible for the yet larger group of nervous symptoms so commonly associated with chronic alcoholism, chronic lead poisoning, and with other phases of the so-called gouty or uric-acid diathesis.

"The purpose of this paper is to present the evidence upon which this opinion is founded."

Cases were related of what is commonly called bronchial asthma, of lead poisoning, of alcoholic poisoning, and certain other conditions with nervous manifestations, in all of which during the attacks the urine contained xanthin, paraxanthin, and possibly other poisonous elements. These poisons were determined by chemical tests and by their effects on mice. The latter showed stupor, followed by slight muscular twitching, passing into tonic or tetanic convulsions. During the whole period there was intense dyspnea, finally death. During the intervals between the attacks (with absence of nervous manifestations) there was absence of the poisons in the urine. Dr. Rochford said it had always been difficult to explain the headache and pain symptoms of lead poisoning by direct action of the lead on the tissues. He thought they were due to the xanthin, etc., circulating in the blood, the presence of which had been determined by his investigations. It was probable these poisons were present in the blood just before death in many instances. The urine never produced the characteristic toxic symptoms in mice when tests proved absence of the poisons named. It was an interesting fact that in ordinary epilepsy the xanthin bodies were absent, whereas in that form of nervous epilepsy which was intermittent with headaches they were present.

A Toxicogenic Germ Found in Ice Cream, and Its Chemical Products.—DRS. VICTOR C. VAUGHAN and GEORGE D. PERKINS, of Ann Arbor. In August, 1895, they had been furnished with some of the cream which had poisoned about fifty people at a social gathering. The symptoms were quite different in some respects from those observed in other cases of like kind. Among them were nausea, vomiting, diarrhoea, pain in abdomen with the vomiting, feebleness of heart action, coldness. None died. In the cream they had found and isolated a bacillus, whose action they had studied upon animals, and had attempted to isolate the chemical poison. While they had been only partly successful in the latter, they had at least become convinced that the poison was not identical with any which had yet been obtained from milk or any of its products. Some of this in a man into whom it had been accidentally introduced had caused marked temporary symptoms of poisoning, and very slight symptoms in animals.

A Statistical and Experimental Study of Terminal Infection.—DR. S. FLEXNER, of Baltimore, in this paper gave the result of bacteriological examinations in 793 post-mortem examinations made at Johns Hopkins College Hospital by Dr. Welch, Dr. Councilman, the reader, and others. Cultures were made

from various cavities and organs. Bacterial organisms might have been present in some, absent in others, but negative results did not necessarily mean absence.

Out of the 793 autopsies, 255 were in chronic heart or chronic Bright's disease, or the two combined. The result in 213 was positive, in 42 negative. In kidney cases of bacterial general infection the table showed streptococcus in 16 cases, staphylococcus aureus in 4, *M. lanceolatus* in 6, gas bacillus in 5, gonococcus in 2, etc. In heart cases without kidney disease, streptococcus was present in 9, *M. lanceolatus* in 2, staphylococcus in 1, bacillus coli in 1, etc.

Among local infections with chronic heart or Bright's disease were peritonitis, pleuritis, pericarditis, etc. Different bacteria were not infrequently present in the same organ. The source of entrance of the germs was known in some instances.

The paper as a whole brought forward evidence showing that in a very large proportion of cases the terminal event in the history of the disease was a bacterial infection, and that besides the local infectious inflammatory processes not uncommonly met with in the serous membranes, upon the endocardium, and in the meninges, examples of cryptogenetic infection likewise occurred and actual septicæmias were not infrequent. The experimental part of the paper referred to the bacteriological quotient exhibited by the blood serum of healthy human beings as compared with that of those who had suffered from some of the chronic diseases under consideration. There seemed to be diminished antitoxin power of the serum in the cases of chronic disease, more especially with regard to the staphylococcus aureus. In regard to this coccus it was observed also that the blood serum after passing through the placenta possessed no bactericidal properties.

DR. STERNBERG remarked that the latter observation, namely, that blood after having passed through the placenta had lost its bactericidal properties, favored the view which he had been supposed to entertain, that these proteid bodies when once in the circulation might perhaps be retained indefinitely.

DR. BORTON, on the other hand, cited an authority according to whose observations immunity had been transmitted from mother to offspring, presumably through the fetal circulation, and Dr. Flexner admitted that his own remarks applied with little force except to the staphylococcus aureus.

The Influence of Acute Alcoholism on the Normal Resistance of Rabbits to Various Forms of Infection.—DR. A. C. ABBOTT, of Philadelphia, said his experiments in the direction suggested by the title of his paper had been carried out in the laboratory of the University of Pennsylvania, at the instigation of a committee of fifty to investigate alcoholism. Several difficulties had been encountered, among them that of determining when the rabbits had received just enough alcohol, etc. The following was his summary:

"Under the daily administration of ethyl alcohol to the stage of intoxication, the normal vital resistance of rabbits to particular forms of infection and intoxication is seen to be diminished, while to other forms of infection and intoxication it is little, if at all, affected. This diminution of resistance is most marked in alcoholized animals that are inoculated with cultures of streptococcus pyogenes (erysipelas), an observation that accords with the results of clinical experience with alcoholic subjects suffering with phlegmonous and erysipelatosus inflammations.

The Identity of the Streptococci and a Description of a New Variety.—DR. H. C. ERNST, of Boston, in this paper, took ground against the assumption that all streptococci were the same, varying only in intensity of virulence or in minor characteristics. In support of his view Dr. Ernst described what he called

the streptococcus aureus liquefians, a coccus which he had isolated in a case of fatal puerperal sepsis. Its appearance under culture was golden yellow, the chains were longer than the ordinary but becoming shorter under successful inoculations in rabbits.

Conditions Influencing the Appearance of Toxin in Cultures of the Bacillus of Diphtheria.—DR. THEOBALD SMITH, of Boston. "Any positive additions to our knowledge of the formation of poisons or toxins by bacteria, however slight, are of considerable importance, because the explanation of the nature and of the action of antitoxins seems likely to be delayed until those of the toxins are forthcoming. It is from this point of view that I present some facts, in part already published by others, which favor or oppose the accumulations of toxins in culture fluids. We have no reason to believe that the action of diphtheria bacilli on mucous membranes differs from that manifested in cultures. A complete knowledge of the favoring and inhibiting influences upon toxin formation might possibly furnish us with antitoxic weapons other than those now contained in antitoxin serum of the horse."

The author's conclusions were: 1. In ordinary peptone bouillon the best means of obtaining a concentrated toxin from diphtheria bacilli is to first eliminate the muscle glucose, preferably by allowing the beef to partly decompose. 2. A working hypothesis which interprets the variable phenomena of toxic production very satisfactorily assumes the toxin to be an intermediate product of metabolism of the diphtheria bacillus consumed in the course of growth. When the life of the culture is long drawn out by the presence of muscle sugar, the toxin is formed slowly and in part disappears, but may be made to reappear by adding more peptone. When the life of the culture is made short by keeping it in an alkaline medium and favoring aerobic growth, much toxin is produced and but little consumed. This hypothesis places all the phenomena on a strictly biological basis, and makes oxygen, acids, etc., act upon the bacteria by favoring or inhibiting their activity, and not upon their products. 3. The virulence and toxicity of diphtheria cultures are probably identical and should signify the toxin-producing power of diphtheria bacilli. 4. The increase in virulence of bacteria in mixed cultures may in most cases be due solely to a change of the culture fluid by one bacterium favorable to the toxin-producing power of the other. 5. The production of disease by bacteria should be studied quantitatively in bouillon as free from muscle sugar as possible, to which definite quantities of dextrose have been added. The amount of muscle sugar present is always to be determined by control cultures.

Diphtheria Antitoxin Sometimes Found in the Blood of Horses not Injected with Toxin.—DR. B. M. BOLTON, of Philadelphia, had been led to make observations upon this subject by the fact that some horses had shown violent reaction to injections of toxin which had little effect upon others. Injection of the serum in animals showed immunizing power by that taken from horses manifesting little reaction, and *vice versa*. Both classes of horses, however, seemed equally useful for the purpose of furnishing antitoxin serum when they had been passed through the regular toxin treatment.

In reply to Dr. Jacobi, he was unable to say whether the age of the horses had any bearing upon the amount of natural immunizing power of their blood serum.

Diphtheria Antitoxin Obtained by Electrolysis.—DR. B. M. BOLTON also read a paper which corroborated the observation that the prolonged action of a weak electrical current upon diphtheria toxin produces a certain amount of antitoxin. This antitoxin had not been produced of sufficient strength to be of prac-

tical use because of the large quantity which would have to be injected. As the antitoxin had been produced by the interrupted and not by the continuous current, two French observers had suggested that the change was not chemical, but caused by rapid vibratory action.

The Significance of Pathogenic Spirilla in American Surface Waters.—DR. A. C. ABBOTT, of Philadelphia. "An important obstacle in the settlement of the controversy concerning the relation between the spirillum cholerae asiaticae of Koch and the many varieties of similar spirilla that have been discovered in the surface waters of western Europe since the late epidemic of cholera in Hamburg, is the fact, as pointed out by Dunbar, that many of these vibrios have been discovered in waters of localities in which cholera had been present or of those in which cholera subsequently made its appearance. It is of manifest importance that surface waters of localities that have not been visited by cholera at either a near or comparatively remote period should be subjected to careful investigation from this standpoint, in order to determine if similar vibrios are present in them also.

"With this in view the more polluted end of the Schuylkill River has been subjected to such study, with the result that a spirillum has been detected that possesses all the morphological, cultural, and pathogenic-group characteristics of the suspicious spirilla discovered in European surface waters.

"That this organism can have nothing to do with cholera is evident, as the last visitation of cholera to this city was in 1873, when eight cases were reported, six of which were of doubtful nature.

"In the event of an outbreak of Asiatic cholera in this country, it is essential for us to be familiar with the characteristics of spirilla present in polluted surface waters at times when the disease is absent, and it is for the purpose of obtaining such data that I make this contribution, hoping to induce other American bacteriologists to give special attention to our surface waters from this standpoint."

The Treatment of Anthrax in Rabbits by Intravenous Injections of Nucleinic Acid.—DRS. V. C. VAUGHAN, CHARLES T. MCCLINTOCK, and GEORGE D. PERKINS, of Ann Arbor, were the authors of a paper, a synopsis of which was presented by Dr. Vaughan. The nucleinic acid was obtained from a yeast grown by brewers. It was important that it should be pure. Some of the rabbits which had been inoculated with anthrax were used for control tests. Into the jugular vein of one set a stronger solution (ten per cent.) of nucleinic acid was injected, of another set a weaker solution. Nearly all the former died, fewer of the last named, while most of those injected with the stronger solution of nucleinic acid recovered.

Second Day—May 1.

Two Varieties of Tubercle Bacillus from Mammals.—DR. THEOBALD SMITH, of Boston. One of the cultures was obtained from a bull, the other from a bear through the guinea-pig. The nasua (bear) culture was presumably from the human subject, or the animal had been an intimate household pet of a man now dead of tuberculosis. The bovine bacilli were different from the nasua bacilli in nearly every culture examined, in being shorter and less curved. This difference was also manifest in preparations of a bovine culture isolated in 1886, which had been retained for this purpose. Furthermore, bacilli from a culture of human tuberculosis from Dr. Trudeau closely resembled the nasua bacilli and differed from the bovine bacilli.

A number of important questions were raised, he said, by these observations, but of these only one concerned

us here, that of the relation between human and bovine tuberculosis and the transmission of the latter to man. This question might be put in the following form: Were cattle attacked by different races of tubercle bacilli, or was there but one race adapted to the bovine body?

Koch regarded the tubercle bacilli in man and those in cattle as identical. Dr. Smith was inclined to the view that bacilli differed. The cultures which he had described had demonstrated this in an unmistakable manner.

Regarding the possibility of milk being a cause of transmission of tuberculosis, he called attention to the necessity for more information along the following lines: 1. The existence of races of tubercle bacilli (both human and bovine). 2. The identity or non-identity of bovine and human tubercle bacilli. 3. The effect of bovine tubercle bacilli on man. This problem could be attacked by cultivating bacilli from a case of tuberculosis contracted by drinking milk and testing them on cattle, as he had done. 4. More evidence on the subject of milk infection by tracing the source of the disease in infancy more carefully and by searching for primary foci of tuberculous infection at all autopsies on children. 5. Any existing difference between the disease produced in early life by human and that presumably due to bovine tubercle bacilli.

DRS. VAUGHAN, PEPPER, STERNBERG, and ABBOTT made some remarks, expressive of agreement with the author that these bacilli might be different.

A Case of Parasitic Chyluria with Filariæ Sanguinis Hominis Nocturnæ in the Blood.—DR. F. P. HENRY, of Philadelphia, related the case, which occurred in a female, aged twenty-nine, who in early life had lived in South Carolina and Florida, and had never been outside the United States. It was, therefore, an indigenous case, the first one in Philadelphia; the infection had probably occurred about the age of twelve; the chyluria first manifested itself shortly after normal labor. The filariæ were present in the blood of the mother alone, not in the milk, nor in the blood of the infant. They were not very numerous, and were present at night only. The urine was repeatedly examined, but only once contained filariæ. These showed remarkable vitality under cold and heat, and one specimen under the cover glass showed movements after ten days.

Regarding treatment Dr. Henry said that thymol and quinine had no effect on the disease. The same was true of methylene blue, which had been reported of value in one case by Flint. In this regard his observation was in accord with that of Lavarán.

Dr. Henry referred to Manson's writings, wherein it is stated that the embryo came from an adult parasite over an inch long, located perhaps in the thoracic duct; that the mosquito became infected and alighted on water, and that it was by drinking the infected water that man became infected. There were three forms—the diurnal, the nocturnal, and the persistent.

Dr. Henry thought it possible for this affection to become indigenous to Philadelphia and other sections of our country, although the likelihood of so large a body of water as the Schuylkill containing a sufficient number of the parasites to infect many of those who drank of it was not great. As a precaution the water could be filtered. The author thought it would be undesirable, if practicable, to kill the mother parasite in the patient's system, as this would result in fatal abscess.

DR. ANDREW H. SMITH, of New York, mentioned a case in which the filariæ were found in the blood both day and night, but they were always dead.

DR. HENRY could offer no reason why the filariæ should have been dead unless compressed under the cover glass.

The Diagnosis and Treatment of Dilatation of the Stomach.—DR. WILLIAM PEPPER read the paper, which was a joint production by himself and DR. ALFRED STENGEL, also of Philadelphia. It was concluded that the term dilatation was applicable to a larger number of cases than was generally admitted. Various modes of determining dilatation and enlargement were referred to, but those considered most valuable by the authors were distention with atmospheric air introduced through a stomach tube with bulb like that of the Davidson syringe, percussion, both simple and aided by the stethoscope, and by the introduction of a certain amount of water in mapping out the lower border of the stomach. There was under normal conditions considerable variation in the size of the stomach and in its position. The lower border of the stomach should not be below the umbilicus, but such location did not necessarily mean dilatation. Illumination offered little. The authors pointed out dangers in the use of mechanical methods to determine the size and tonicity of the stomach. It was surprising how many cases of pyloric stenosis from one cause or another had improved under operation, usually performed for them by Dr. White, although essentially nothing may have been done by way of removing the obstruction. Lactic acid was not necessarily evidence of carcinoma. In auscultatory percussion the patient could hold the bulb of the stethoscope and move it about while the physician made percussion and mapped out the organs.

A Case of Leucocythæmia.—DR. J. H. MUSSER and DR. JOSEPH SAILER, of Philadelphia, were the joint authors of the paper read by Dr. Musser. The case was a typical one of leucocythæmia, except that there was general anasarca. There was also diarrhoea for a few days at the beginning, due to ulceration of intestine. Myelocytes were found and the differential count of blood cells was characteristic. The spleen and liver were enlarged and tender, and these organs and the glands showed characteristic changes at autopsy. Besides increased formation of white cells there seemed to have been a process of blood destruction toward the end. It was supposed the marrow would show disease, but it did not. The arteries were markedly atheromatous, the thickening having appreciably increased during the several months of illness.

Notes on the Treatment of Pernicious and Other Forms of Essential Anæmia.—DR. I. N. DANFORTH, of Chicago, was the author of this paper, which was read by Dr. Lyman. A case of pernicious anæmia was related, with account of treatment. Iron had no effect except to irritate the gastro-intestinal tract.

Acid preparations of phosphorus were of temporary benefit; hypophosphites were harmful, causing gastric irritation. Intestinal antiseptics were of considerable temporary service, beta-naphthol being representative. Yellow bone marrow produced unmistakable benefit within a week, and this increased to the end of two weeks, when it became disagreeable to the patient. It was soon continued in the form of glycerin extract, and again the blood improved. But the patient tired of the remedy, discontinued it, and did not have a relapse for some months; then the bone marrow, being renewed, failed and the patient went on to exhaustion. He was confident that but for the bone marrow she would have died eighteen months sooner. Arsenic had failed. In another case of anæmia bone marrow caused marked temporary improvement, but there was a relapse and the patient, a doctor, died.

The discussion, which was participated in by Drs. A. M. SMITH, JANEWAY, GRIFFITH, HARE, and others, went to show that bone marrow, arsenic, and other remedies sometimes apparently produced marked improvement in forms of essential anæmia, but the im-

provement was only temporary, and sometimes was observed after treatment had been left off.

Certain Effects of Bromo-Toxication.—DR. S. WEIR MITCHELL, of Philadelphia, in this paper related a number of observations of the effects of large doses of bromide upon the nervous system. The father of an epileptic girl increased the dose of bromide from sixty grains a day to one hundred and fifty grains. She was found with the head dropped forward, in a state of mental hebetude, saliva running from the mouth, eyes open, pupils enlarged, and hard to arouse; the general epileptic convulsions had ceased, but the lesser fits were quadrupled in number. Withdrawal of the bromides restored her to her normal condition, which was usually rather intelligent. A nurse by mistake gave two epileptic children nearly one hundred grains of lithium bromide a day for mild epilepsy. In a few days both were brought into a condition of extraordinary feebleness of mind and body. Neither of them could walk; the left leg was more affected than the right. They were restored within two or three days after withdrawing the bromide.

Dr. Mitchell related equally striking cases of melancholia, with and without suicidal tendency, produced by large doses of bromides in some form. The enfeebling effect of bromides upon the muscular system and upon the mind, or irritation of the latter, was sometimes seen in alcoholics or those suffering from insomnia who had taken the bromine in the form of bromo-caffeine, bromide of sodium, etc. Habitual drunkards sometimes said they became more drunk on one side than on the other, oftenest on the left. A similar result was observed sometimes from excessive doses of the drug under discussion.

DR. E. G. JANEWAY, of New York, had seen three deaths result from excessive doses of bromide. Autopsy revealed no other cause. He knew of two other fatal cases through coroners. The amount used per day in the former cases had been one ounce, six drachms, and three drachms, continued some time. He had seen less serious results in other cases, in alcoholism, in typhoid fever, etc.

DR. HOBART A. HARE, of Philadelphia, said the studies of Ringer and some others had shown that potassium was the base of some of our more poisonous salts. He had known citrate of potassium given for several days produce alarming nervous depression in a child. In some of the cases related by the author some other bromide was used than potassium; yet he would suggest that physicians should use the bromide of potassium less than they were accustomed to do, and employ, say, sodium bromide.

DR. LYMAN corroborated the author's observations, and DR. W. H. THOMSON related three cases of temporary mental alienation due to large doses of bromides.

DR. C. L. DANA had not noticed that difference in the effects on the nervous system between potassium bromide and other bromides suggested by some writers. It was well known that iodide of potassium was often administered in very large daily doses, over three hundred grains, without much depression. Small doses of bromide of potassium, etc., often had the reverse effect of depression, causing a feeling of cheer, and it was his custom to begin with only four to six grains.

DR. MITCHELL said he had never been able to see more depressing effects from potassium salts than from other bromides.

Idiopathic Osteopsathyrosis in Infancy and Childhood.—DR. J. P. CROZER GRIFFITH, of Philadelphia. Osteopsathyrosis, or fragilitas ossium, is a comparatively rare condition at any time of life, or dependent upon any cause. It is far most frequent in advanced years, and is then due to an atrophy of the osseous

structure. At other periods of life it may be symptomatic of other affections, such especially as certain nervous diseases, osteomalacia, rickets, etc.

There are still a number of cases remaining which may be called idiopathic, since they can be traced to no recognizable cause, and as most of them are not associated with any atrophy or other visible pathological alteration of the bone. Some of these occur in youth and adult life, but the writer confined himself to those developed in early years and reported a case in point.

This was of a boy who had several fractures, occurring at or soon after birth, and who, up to the age of two years, had suffered in all seventeen or eighteen fractures. The slightest cause was sufficient to produce them, and it was necessary to keep the child upon a stretcher, so great was the fragility of the bones. The general health of the subject was good, and there was no constitutional affection in him or in his parents which accounted for the condition.

The writer then reviewed the cases of unusual fragility in infancy and childhood of an idiopathic nature, which have been reported in medical literature, and discussed the etiology, pathology, diagnosis, and treatment, so far as it is possible with the little light which the reports shed upon the subject. The cause is, as the title indicated, unknown. With regard to pathology and diagnosis, the writer discussed briefly the relation of the disease to rickets, to osteomalacia, and to imperfect osseous development. The latter is especially exemplified in some of the reported instances of multiple intra-uterine fractures. The disease may, and probably does, bear a certain relation to these pathological conditions, but it is distinct from them. Certainly, in his opinion, it is not at all of a rickety nature, although it may sometimes be combined with rickets.

DR. LYMAN, of Chicago, said he had once seen a man of twenty-five, who up to that age had sustained thirty-three fractures. There was also a tendency to bending of the bones, shown in the pelvis, tibia, etc. The tibia was translucent to a ray of light. General health good. No fractures for two years, or since age of twenty-three.

Painful Points in Gouty Compared with Rheumatic Arthritis.—DR. WILLIAM H. THOMSON, of New York. The differential diagnosis between gout and rheumatism was usually simple enough in typical cases, especially when of recent origin, but in many chronic cases, especially when the joint complication had become general, it was not easy, and one frequently found gouty patients treated for rheumatism. For many years he had found in the two classes of cases a difference in the location of the pain on manipulation of the joint. This was more especially noticeable in the knees, but also in considerable degree in the ankle and other articulations of the extremities. In gout the greatest pain was elicited by transverse pressure on the condyles. Not so in rheumatism. Here in the knee the typical points of tenderness were around the tendon of the quadriceps just above and below the patella, and posteriorly along the tendon of the hamstring muscle. It seemed natural to infer that gout affected the periosteum chiefly, while rheumatism involved more the synovial structures.

Habit Chorea.—DR. WHARTON SINKLER, of Philadelphia, had found one hundred and forty-three cases of habit chorea out of a total of ten hundred and fifty-nine cases of chorea appearing at the dispensary, and from a study of these and other cases he had come to the conclusion that this affection was a true chorea, not a form of spasm or tic, as believed by some writers, including Gowers, for the greatest proportion of cases occurred during the second decade, none after the fourth. There was a heart murmur in thirty-two of the one hundred and forty-three cases. Season appar-

ently exerted no influence. Among medicinal measures, arsenic to the point of toleration was most efficient.

DR. OSLER thought the author had taken a step backward. The French were right in separating habit spasms from choreas. Personally he thought they were entirely different.

DR. PUTNAM agreed with Dr. Osler. Habit spasm described by the author belonged to the degenerative type far more than did chorea.

DR. WEIR MITCHELL said he had never been much wedded to names, and he was indifferent whether the condition was called habit spasm or chorea, but he had certainly seen cases of chorea pass into habit spasm—if you like.

The President, DR. JACOB, had written upon the subject of facial spasms (which character most of Dr. Sinkler's cases showed) in 1886, and expressed the belief then, which experience had further confirmed, that the condition was due to irritation from nasal catarrh. Treatment of the catarrh was most productive of relief from the spasm habit.

A Method of Curing Tic Douloureux.—DR. CHARLES L. DANA, of New York, in this paper first referred to the rebelliousness of these cases to medicinal and even surgical treatment. One patient, who had had the Gasserian ganglion removed by a surgeon, suffered not only a recurrence of the pains but became insane. The method by which he and Dr. Elliot, of New York, had cured seven out of eight cases consisted in hypodermic injections of very large doses of sulphate of strychnine. Rest abed was enjoined during the treatment, and freedom from care. Strychnine injections were given once a day, beginning with, say, one-thirtieth of a grain and rapidly increased to one-fifth or one-fourth of a grain. Patients could not usually take more than one-fourth of a grain. The large doses had a peculiarly anodyne effect, quieting the patient for hours like morphine. Usually the injections were discontinued after five or six weeks, but might have to be renewed once or twice again. On discontinuing it he gave iodide of potassium, nitroglycerin, or other drugs. In a former paper he had impressed the importance of arterial sclerosis in neuralgic tics.

As this treatment had only been begun two years ago, he was hardly justified in speaking of the result as a cure, yet it had been in such contrast with that obtained by other methods that he wished to emphasize its value.

The Relation of Migraine to Neuralgias of the Fifth Nerve, Especially Supra-Orbital Neuralgia.—DR. J. J. PUTNAM, of Boston. It was of that form of neuralgia which came with intermittency that he spoke. The cases had been described, he said, under the head migraine, but as a matter of fact they differed in history, course, and treatment. Early writers had regarded it as malarial, but malaria was rarely the cause. True, cases occurred in groups, but this was due to season of the year. Occasionally it began in youth and continued at intervals for years. The pain was deep, sometimes over the entire area of the supra-orbital nerve; sometimes most at one spot, as on the brow; occasionally associated with pains in other parts of the head. Usually there was an attack in the morning, a lighter one in the afternoon, perhaps a light one at night. Some persons had two attacks every year, spring and autumn. In relation to catarrh, it usually came on when the latter had reached the frontal sinus, but sometimes it was quite independent of catarrh. Sometimes there was a family history of this or migrainous affection. Treatment: quinine in large dose four hours before attack, arsenic, attention to nasal passages.

DR. W. H. THOMSON referred to his paper on fluid extract of ergot in periodic neuralgias.

DRS. FUSSELL and JANEWAY thought the author's treatment was not against a malarial origin.

DR. S. W. MITCHELL said he had many years ago given some attention to the time of occurrence, of periodic neuralgias and their relation to the weather.

Virulence of the Diphtheria Bacilli Occasionally Found in the Throat in Cases Presenting the Clinical Features of Tonsillitis.—DR. H. M. BIGGS, of New York. Even to-day it was difficult for the profession to be convinced of the diagnosis of diphtheria without characteristic anatomical appearances. Studies by the health department demonstrated the following classes of cases: 1. Healthy throat in which diphtheria bacilli were present—almost always limited to persons who had been brought into close relation with diphtheria. 2. Simple anginas in which virulent diphtheria bacilli were found. From a sanitary point of view these cases must be regarded in the same sense as true diphtheria. 3. Cases of true diphtheria, presenting the ordinary clinical features of diphtheria with the bacillus. 4. Angina with membrane, no bacillus being found, could be regarded as diphtheria from some other organism than the Loeffler bacillus.

It was often asserted that by the result of bacteriological examination the total number of cases of diphtheria had been largely increased by the addition of cases of mild angina, which before such examinations had been regarded as simple angina. But it appeared from the studies of the health department that for a certain period one hundred and seven cases reported by physicians as diphtheria were excluded from diphtheria by result of bacteriological examinations, whereas during the same period only eighty cases had been pronounced true diphtheria on bacteriological examination which physicians had reported as false diphtheria.

The paper was intended particularly to emphasize the fact that all inflammations of the mucous membrane associated with the presence of the Klebs-Loeffler bacillus should be included under diphtheria, without reference to intensity or extent of process or character of exudate.

DR. WELCH, of Baltimore, said that in Baltimore bacteriological examination had confirmed the diagnosis of the physicians in over ninety per cent. of the cases when this had been of undoubted diphtheria.

Prognosis in Pneumonia.—DR. ANDREW H. SMITH, of New York (see p. 649).

DR. H. A. HARE, speaking of the comparative value of cold bath and coal-tar antipyretics, said the difference was that with the latter the oxidation processes were held in check and leucocytosis interfered with, while the reverse was true with the cold bath when there was indication for its use.

DR. WELCH thought it was not the local process in lobar pneumonia which gave rise to the severe symptoms, but rather the poison acting upon other vital parts of the body. Thus far the destructive influence of fever referred to by Dr. Hare rested upon ingenious theory rather than upon bacteriological basis.

The micrococcus lanceolatus of pneumonia stopped growing in a temperature above 41° C., but this did not occur in an ordinary case of pneumonia.

DR. A. H. SMITH thought too much attention was given to the treatment of the temperature in pneumonia. It was high too short a time to add much to the danger, and usually could be let alone. If one decided to use an antipyretic, cold water was appropriate.

Third Day—May 2d.

A Case of Oesophageal Hemorrhage with Cirrhosis of the Liver.—DR. G. M. GARLAND, of Boston, related the case. It occurred in a well-built man. The first hemorrhage was in 1888; recurrences followed up

to the fatal one in 1895. The loss of blood by vomiting and passage with the stools was great, amounting at times to more than two quarts. Toward the end particularly the blood came from the mouth almost constantly, without the act of vomiting. When he first saw the man in 1889 he and other physicians diagnosed ulcer of the stomach, and it was not until later that cirrhosis of the liver was discovered. At autopsy no source of hemorrhage was discovered except from the much dilated and very thin-walled veins at the lower end of the oesophagus. The histories of three other cases had been furnished him by Dr. Osler and physicians in Boston. The dilatation of the oesophageal veins leading up to hemorrhage depended upon obstruction to the portal circulation from cirrhosis of the liver.

DR. GRAHAM, of Toronto, mentioned a case reported by McKenzie, of fatal oesophageal hemorrhage from varicose veins in a boy of seventeen years whose liver was healthy.

DR. S. WEIR MITCHELL had also seen a case of fatal oesophageal hemorrhage in a child, in which autopsy revealed nothing but marked varicosity of veins in the lower part of oesophagus. The attending doctor exclaimed, "Oesophageal piles!"—which graphically described the appearance.

DR. JACOBI remarked that a close study of the structural changes in the oesophageal veins was desirable in order to explain why the hemorrhage should have been from these instead of from the more usual situation in the veins of the stomach, etc., in connection with cirrhosis of the liver. It was not improbable that those veins were atheromatous, for while atheroma was much more common in the arteries, it did sometimes occur in veins.

On Absorption in the Stomach.—DR. S. J. MELTZER, of New York, obtained the following results in some experiments relating to stomach absorption: Six to ten milligrams of strychnine, even on the full stomach of a rabbit, pylorus open, were sure to bring on tetanus in a short time. But where the pylorus was closed, even so large a dose as two hundred milligrams remained many hours in the stomach, producing no effect. It seemed, therefore, that the mucous membrane of the stomach did not absorb even the smallest fraction of strychnine. Next to the stomach, the mucous membrane of the oesophagus absorbed strychnine poorly, while the pharynx absorbed it rapidly, as did also the rectum—the latter even better than the small intestine. Prussic acid was absorbed very well from the stomach even when the pylorus was ligated and the stomach full. Perhaps this was due in part to its volatility, as gases were readily absorbed from the stomach, and in part to a hemorrhagic condition which it caused on the surface.

THE PRESIDENT had for over fifteen years administered five or six drops of Magendie's solution without the addition of water, for the relief of cough. Morphine in the stomach had no such effect—facts which tended to support Dr. Meltzer's conclusion, based on experiment, that absorption was more rapid from the mucous membrane of the pharynx than from that of the stomach.

Congress Memorialized.—DR. WELCH read the report of the committee of five and resolutions were adopted protesting against action by Congress looking to the prohibition of vivisection in the District of Columbia.

Increase of Pneumonia.—DR. J. J. PUTNAM, of Boston, presented charts showing death rates from pneumonia in Massachusetts, Glasgow, and England. The death rate from this disease in some thirty years had increased five hundred per cent. The charts showed that it was far more important than, for instance, typhoid fever.

Dispensaries and Their Use in Teaching.—DR. M. H. FUSSELL, of Philadelphia, in this paper described the method of utilizing dispensary cases in teaching medical students at the University of Pennsylvania. Formerly, as in most other dispensaries, the cases had been instructive only to the attending physician and his private students, if to anybody. Now the history of every case was recorded on a printed formula, students in different classes were required to again take the history and make a diagnosis and suggest treatment. An instructor pointed out their errors. Where there was scarcity of material the ward instructor went over the case before the whole class, but the superiority of the first plan was evident, since it brought the student face to face with the patient, as he would be compelled to be in actual practice.

Mescal Buttons.—DRS. D. W. PRENTISS and F. P. MORGAN, of Washington. An outline of the paper was given by Dr. Prentiss. They had been led to investigate the properties of the mescal button (*Anhalonium Lewinii*) by an account of its use among the Indians on the Rio Grande given them by Professor Mooney. The Indians ate the button during religious ceremonies, remained in a dreamy state over night, had hallucinations of color vision, and felt no depressing effects subsequently. It produced wakefulness rather than sleep. Medical students who had partaken of it testified to like effects. The authors suggested the following therapeutic uses: For general nervousness, nervous headache, irritable cough, colicky pain, hysterical manifestations, in mental depression, etc. Five or six beans were taken to produce the hallucinatory effects. One had relieved irritable cough in an asthmatic patient over night. The bean or button grew on a cactus of the name given.

Many other papers were read by title.

Officers Elected.—Dr. J. M. Da Costa, *President*; Dr. F. C. Shattuck, *Vice-President*; Dr. J. Minis Hays, *Recorder*; Dr. Henry Hun, *Secretary*; Dr. W. W. Johnston, *Treasurer*; Dr. J. E. Atkinson, *Councillor*.

A vote of thanks was extended to the retiring president for the services which had made this meeting perhaps the most successful one in the history of the association.

Chlorosis and Fever.—Dr. Guomi has recorded eleven cases of chlorosis accompanied by febrile symptoms. From his personal observations and a careful study of the literature of the subject he thinks he is justified in presenting the following conclusions, which have been published in the *Deutsche Medizinische Zeitung* of March 16, 1896: Although the true pathogenesis of chlorosis has not yet been definitely established, it is nevertheless apparent that this disease is an *anæmia sui generis*. It is a primary affection of the blood. The coloring matter of the blood is always much reduced, but this reduction is not strictly proportionate to the diminution of the number of the red blood corpuscles. Simple chlorosis is not accompanied by fever. Often, indeed, the temperature may be subnormal. When fever does occur some intercurrent disease or secondary action must be thought of. The most frequent disease producing a rise of temperature in connection with chlorosis is an apex trouble of the lungs, generally tuberculous in character. Next in frequency we find constipation. In the latter case free purgation speedily results in the disappearance of fever. In chlorosis slight ailments of a thoroughly benign nature may result in a rise of temperature. There is no distinct clinical type of febrile chlorosis. In animals in whom artificial blood changes have been engendered, a febrile movement is never observed. The urine in chlorosis often shows a diminution in the amount of urea excreted. The excretion of uric acid is also reduced.

AMERICAN MEDICAL ASSOCIATION.

Forty-Seventh Annual Meeting, Held at Atlanta, Ga., May 5, 6, 7, and 8, 1896.

R. BEVERLY COLE, M.D., PRESIDENT, IN THE CHAIR.

General Session. First Day—Tuesday, May 5th.

(By Telegram to MEDICAL RECORD.)

THE opening session of the forty-seventh annual meeting of the American Medical Association was called to order by the President, DR. R. BEVERLY COLE, of San Francisco, at 10:30 A.M. After a prayer by REV. DR. McDONALD, the address of welcome on behalf of the medical profession of Atlanta was delivered by DR. F. M. RIDLEY.

Address of Welcome.—He spoke not only for Atlanta, but also for the great commonwealth of Georgia, one of the thirteen original States which threw off the British yoke at Yorktown and proclaimed liberty to the world. An incidental allusion to the struggle of the patriots in Cuba was received with a burst of applause. The speaker referred to the former meeting of the association in Atlanta. This was not very many years ago, yet wonderful changes had come into the science of medicine since that time—greater perhaps than any that had been heralded in all the previous history of the healing art. We owed nearly all the progress which had ever been made to the labors of specialists. Galvani, Koch, Pasteur, Lister, and Georgia's own Crawford Long were all specialists, and indeed it is only by a division of labor that any great achievement can be accomplished. This meeting was a meeting of specialists who had come from all parts of the country to announce their own discoveries and to learn of those of others. It was with the expectation of great results from their deliberations that he had been commissioned by this happy, prosperous, proud old commonwealth to bid them thrice welcome.

Welcome by the Citizens.—An address of welcome on behalf of the citizens of Atlanta was then delivered by HON. JOHN TEMPLE GRAVES. He had enjoyed, he said, the address of Dr. Ridley, but he had also been greatly comforted by the prayer, for when a thousand doctors as determined looking as those he saw before him met together, a prayer was by no means amiss. He did not speak for the doctors, but simply as a citizen, and as such he thanked God the licenses of those before him had all expired by geographical limitation, for if his hearers should join forces with the doctors of Atlanta there would not be an appendix safe in the city to-night. Atlanta was so healthy that the doctors had perforce nothing to do but to chase the appendix. They were all rich, but had no patients, and would only occasionally, to keep their hand in, percuss a sound liver or feel the beats of a full and regular pulse. Atlanta was the city of conventions, and it was always happy to extend its hospitality to all, even politicians or commercial men, but it had never been so glad to welcome any as it was this great convention of America's representative physicians.

The report of the committee of arrangements was then read by DR. WESTMORELAND, after which came the president's address.

The President's Address.—The President, DR. R. BEVERLY COLE, then delivered his address. Eighteen years ago, he said, in this same city of Atlanta, he was elected to the office of first vice-president, his superior officer being then Prof. Lewis A. Sayre, of New York. He looked upon it as an interesting coincidence that it should be his privilege to return to this Athens of the South to round out his official connection with the American Medical Association. Af-

ter a few words in praise of the city and of its wonderful growth since the period referred to. Dr. Cole entered upon a discussion of some questions of importance to the profession.

A Lowering of the Standard of the Profession.

—The tendency of medical men of to-day is to depreciate the dignity of their profession and bring it to a commercial level. When the older members of the profession were yet young, to be a physician was considered the greatest of honors and the holiest of callings; the medical man was looked upon by those whose ailments he ministered to in a sense as a saint, and his word was law, to disobey which was a mortal offence. The doctor was a gentleman as well as a scholar, commanding the love and esteem of his patients and the community in which he lived. This was then the rule, but now it is the exception, certainly as to the scholarly attainments of the physician. The reason for this is undoubtedly to be found in the multiplicity of so-called medical schools with their bidding for patronage, the low standard of preliminary requirement, the limited curriculum pursued, and the superficial examinations. The ranks of the profession are overcrowded, and those who are in any manner qualified, together with many who are not, in order as speedily as possible to become prominent, resort either to the making of books while they are still without the least experience in the science of which they profess to treat, or organize medical schools and thus increase the evil of overcrowding. The only remedy for these growing evils is governmental interference and regulation of medical education, or at least of professional examination. In some of the States recent new departures in this direction have been made or attempted, giving evidence of a disposition to correct errors, but the orator questioned whether these new requirements and regulations were faithfully carried out. He feared the announced advance was not much more than a species of advertisement, intended to appease the anxiety and restless spirit of those who have been laboring assiduously to bring about a revolution in our system. New York, it is true, has taken through its board of regents a decided step forward, which if religiously carried into effect would meet and correct many defects, and the result would be highly satisfactory. Illinois also, and perhaps some other States, he said, are making efforts in the same direction, but the results of his observations were not such as to encourage him in the hope that the steps taken by these and some other States would be generally followed in the proper spirit.

Cut Rate Insurance Examinations.—Dr. Cole then referred to the cutting down of examiners' fees by two of the large life insurance companies. "No man qualified to make a thorough examination, if he be properly imbued with the value and importance of his service, will or can assume the responsibility attaching to his function as an examiner without an adequate return. Surely the fee of five dollars was small enough, and the offer of any sum less is simply an insult to an educated physician, and a bid for cheap, unscientific service, which can be had from the ranks of the unskilled and irresponsible. But these are not such services as a sound insurance corporation desires. Let every examiner plant his feet and decline employment without adequate compensation. Let it be published to the world that certain companies employ incompetent men, or, paying cut fees, receive cut services, and very soon will they discover their mistake and be brought to a realization of the fact that the best goods always command the best prices."

Foreign Practitioners in the United States.—Another question which the speaker thought the association should seriously ponder is that of reciprocity in medical practice between this and foreign countries.

In looking over the medical registers of the various countries, he said, it may be seen at once that the number of graduates of the medical schools is greatly in excess of the number of men engaged in the practice of their profession. If we seek the cause of this discrepancy we shall learn that from three-fourths to seven-eighths of those who do not remain at home come to America.

In Germany the examination for the doctorate is much less stringent than the "Staats-Examen," the former conferring no rights and the latter being indispensably necessary to entitle the candidate to the privilege to practise in the empire. Consequently the student who desires to emigrate may pass the required examination for the degree of doctor in medicine and then come to America and pose as a learned foreign doctor. Foreign governments, however, do not grant to Americans the right to practise in their countries. While these governments are to be commended for imposing a high standard of medical qualifications, yet it is a poor rule that does not work both ways. "I would not," Dr. Cole said, "have Canada, Great Britain, Germany, France, or any other country having these regulations and requirements recede one iota, but would rather encourage them to even higher aims; but I would have our own people adopt a similar system, through which foreigners coming here will be required to undergo a rigid examination before a national board of examiners, composed in part of the heads of the medical bureaus of the United States army and navy and partly of men appointed by the President or chief of the bureau of education, which board would have its headquarters at Washington."

The Moscow Congress.—The speaker then referred to the action of the committee of the Twelfth International Congress in excluding the English language, and said that this action was an insult to English-speaking people.

Clerical and Medical Bolstering of Quack Medicines.—The proneness of the clergyman to endorse every sort of proprietary and patent medicine should be overcome. The minister, whose duty it is to look after the soul, thinks he must take care of the body as well, and he not only presumes to prescribe for the sick man, but also to give his official endorsement to every nostrum put upon the market, without having the slightest knowledge of its composition or the nature of the disease for which he recommends it. If he conscientiously discharges the duties properly attaching to his own profession, he will have all he can do, leaving the investigation of disease and its treatment to those whose profession it is to deal with such matters. This pernicious practice is, however, not limited to the representative of the church, but extends to the ranks of our own profession. Medical men, particularly the younger, often attach their names to general recommendations and grant individual certificates setting forth the wonderful results of the employment of certain proprietary medicines. This is less excusable still, since such certificates carry with them the prestige of professional endorsement. It is in itself a gross violation of the code by which we profess to be governed. All such violations on the part of members of the association should be made punishable, the orator contended, at least to the extent of reprimand if not of expulsion.

Unjustifiable Operations.—In concluding, Dr. Cole deprecated the tendency to mutilate the human body without just cause and to cut off or out every offending part, instead of seeking to drive out the disease and save the part. It has been said that all there is of value in our science is in surgery, and even the laity are often eager for operation, as affording the speediest means of relief of their ills. Abdominal operations are sometimes not only justifiable but absolutely nec-

essary; nevertheless, it cannot be denied that they are performed too frequently. The mere fact that the improvements and advancements in surgical procedure make them relatively safe should not be accepted as an argument, and the speaker said that he looked with suspicion upon those who claim that, as no use can be assigned to the appendix vermiformis, it should be removed upon the slightest provocation or excuse.

On motion a committee was appointed to consider the suggestions contained in the address and report at a subsequent meeting.

Antivivisection Legislation.—A memorial was presented from the Medical Association of the District of Columbia, praying that the American Medical Association take action to prevent the passage of a bill now before Congress prohibiting vivisection in the district. If this passed it would close the biological laboratories in the district, including those of the army, navy, and marine hospitals service, and would prevent all serious medical research in Washington.

A committee was appointed to consider the memorial and recommend action of the association.

The Jenner Centenary.—DR. MARCY, of Boston, brought up the question of the Jenner centenary celebration, which it had been announced would occupy the whole of Thursday. Several gentlemen had prepared addresses, upon request of the committee appointed four years ago by this association, but upon arrival here the members had found no mention of the centenary in the official programme, and nobody seemed to know when the celebration would be held. Dr. Marcy moved, therefore, that the entire afternoon of Thursday be devoted to the delivery of the addresses prepared for the occasion. This was strenuously opposed by many who would hear of no interference with the work of the sections for which they had prepared papers to be read. After much discussion it was decided to hear the addresses after the general session on Thursday morning.

Pan-American Congress.—DR. READ, of Cincinnati, announced that the second Pan-American Medical Congress would be held in Mexico City in November next, and he moved that delegates be appointed by the association to attend the congress.

Election of the Secretary.—DR. LOVE, of St. Louis, asked what had become of a proposed amendment to the constitution, which he had offered in Baltimore, making the office of secretary one to be voted for each year. There was no notice of such amendment on the official programme. The secretary in reply read from the minutes of the Baltimore meeting to prove that the proposal of the amendment had not been acted upon and had therefore died. On motion the meeting was then adjourned.

Second Day—Wednesday, May 6th.

The session was called to order by THE PRESIDENT promptly at ten o'clock.

DR. WESTMORELAND reported in behalf of the committee of arrangements, and the secretary read the usual announcements. An invitation was received from the secretary of the Louisiana State Medical Society to the association to attend the annual meeting of the society in New Orleans on May 12th. It was accepted with the thanks of the association.

Early Publication of the Programme.—It was resolved that hereafter the programme of the annual meeting of the association be published in the journal two weeks before the date of the meeting.

The Permanent Secretary.—DR. LOVE, of St. Louis, brought up the question of the secretaryship at the Baltimore meeting. He said the nominating committee had recommended the election of a new secretary

of the association, but it was ruled that this was unconstitutional, and he called now for the reading of the section dealing with this matter. It was read and was found to provide that the permanent secretary should hold office until death, resignation, or removal by a two-thirds vote of the members present at an annual meeting. The speaker then said that he had introduced a proposed amendment to the constitution, providing for the annual election of the secretary. This proposed amendment was not ruled out, yet it was not printed in the programme to be acted upon at this meeting, and he called for the reading of the minutes of the Baltimore meeting for an explanation of the omission. Upon the suggestion of THE PRESIDENT the further discussion of this question was postponed until after the address on general medicine.

The Importance of Fevers in the South.—DR. WILLIAM OSLER, of Baltimore, delivered the address on medicine with this title. Referring to the fact that humanity has but three great enemies—fever, famine, and war—he mentioned the interesting circumstances that three of the greatest benefits conferred on mankind have been in connection with fevers—the introduction of cinchona, the discovery of vaccination, and the announcement of the principle of asepsis. He then discussed in a brief manner the way in which the continued fevers had been differentiated during the present century, and paid a tribute to the part which had been played in this work by the American students of Louis, the great French physician. The prevalence of typhoid fever in the United States was such as to make it to-day the fever of the country. He referred to its apparent increase in the smaller towns and in the country districts, and suggested that the profession in these parts should give very much more attention to local health matters. In the Southern States for many years typhoid fever was not supposed to be very prevalent, but of late physicians had begun to recognize that the increase was widespread.

He spoke of the necessity of knowing fully the complex and varied symptomatology of the disease, and of the unfailing accuracy with which it could now be differentiated from malaria. He then spoke of the contrast between the treatment of typhoid fever at the beginning and at the close of the century, and criticised strongly the so-called abortive and antiseptic plan of treatment which had been advocated in the journal of the association. He then discussed the importance of the study of malaria in the South from the new standpoint of Laveran's researches, and urged that the younger physicians should equip themselves thoroughly for this work, referring to a number of problems which yet awaited solution. Lastly, the speaker took up the question of the existence of a third type of fever in the South independent of both typhoid fever and of malaria. He held that the evidence was not conclusive as to its existence. On the contrary, the trend of opinion seemed strongly in favor of the view that it was typhoid fever, although he confessed that further work was needed before the problem could be declared settled.

On motion the thanks of the association were extended to DR. OSLER for his most suggestive address.

The Secretary Again.—The discussion of the alleged suppression of Dr. Love's amendment was then resumed. The speaker said that the matter was one which he would gladly not have taken up, but when once he had introduced a resolution he was not willing to have it suppressed, especially by the person whom it affected. The representatives of every State in the Union had declared that they wanted a more efficient secretary. One would suppose this would be sufficient to elicit a resignation from the undesired officer, but, as it was not, other measures must be taken.

DR. McLEAN, of Detroit, ex-president of the asso-

ciation, was asked if he had ruled the amendment out of order at the Baltimore meeting, but he said he had laid down all responsibilities at the close of that meeting and he refused to reassume them by answering this question now.

On motion of DR. QUIMBY, of Jersey City, the question was laid upon the table for one year.

Another Alleged Suppression.—DR. BURT ELLIS, of San Francisco, said that he also had introduced an amendment to the constitution at the Baltimore meeting, but there was no mention of this in the programme, and he called upon the secretary for an explanation. The secretary was about to read the amendment referred to, when a Philadelphia member objected strenuously. The objection was sustained. Then the reading of the minutes of the Baltimore meeting was called for, but was hardly begun when the hour for adjournment came. The adjournment was appointed for noon, in order to give the members an opportunity to attend an old-fashioned Georgia barbecue at Lithia Springs.

Third Day—Thursday, May 7th.

The session was called to order shortly before ten o'clock. A call was made for the reading of the minutes of the Baltimore meeting and this at once gave rise to a dispute as to what constituted the official record, whether the printed report in the journal of the association or the written minutes in the secretary's book. As the discussion threatened to consume the entire session, the whole matter was laid on the table and the members were left in doubt as to whether or not there were any authoritative records of the proceedings of former meetings in existence.

The Report of the Trustees.—DR. MONTGOMERY then read the annual report of the board of trustees. It covered a period of eight months ending December 31, 1895. There was at that time a balance in the treasury of \$10,084.98. The loss to the journal by the new policy as to advertisements, enforced upon the trustees at the Baltimore meeting, was estimated at over \$3,000. It was thought desirable that permanent quarters for the association be secured, and the trustees asked permission to establish a building-fund. They also suggested that members of the association who have been on the list for forty years and over should be entitled to be made honorary members and receive the journal free of cost. On motion this report was accepted, and the trustees were granted permission to establish a building-fund.

Rush Monument Committee.—DR. GEORGE H. ROHE presented a report of the committee of the monument fund, which stated that it had increased by \$776 during the year—\$550 from the new subscriptions and \$126 from investment of funds already in hand. The total amount is now \$3,787.

DR. HOLDEN, of Vermont, renewed his offer of last year to be one of twenty to give \$100 each to complete the amount named for the erection of the monument.

Restriction of Entertainments.—DR. McLEAN, of Detroit, said that while all the members were very appreciative of the hospitalities of the different cities visited by the association, he felt nevertheless that the entertainments were, and should remain, secondary to the scientific work, and therefore moved that future reception committees be instructed to provide for no entertainments which could in any way interfere with the work of either general sessions or sections. A resolution of similar import was read from the executive committee and was adopted, with the amendment that the secretary be instructed to have the resolution printed upon the programme of all future meetings.

A second resolution of the executive committee pro-

vided that no entertainments be given on the first evening of any annual meeting, so that the dinners of the sections might be given on that evening.

Next Annual Meeting.—The nominating committee made a partial report to the effect that the next annual meeting will be held in Philadelphia on the first Tuesday in June, 1897.

The officers nominated were Dr. Nicholas Senn, of Illinois, *President*; Dr. George M. Sternberg, U. S. Army, *First Vice-President*.

The "Address on Medicine" was assigned to Dr. Austin Flint, of New York; the "Address on Surgery," to Dr. W. W. Keen, of Pennsylvania; "State Medicine," to Dr. Jerome Cochrane, of Alabama.

Address on Surgery.—DR. N. SENN, of Chicago, selected for his subject, "Some of the Limits of the Art of Surgery." He said modern surgery has attained a degree of development which entitles it to the distinction of a science and an art. As a science surgery is of recent date, having been founded and perfected during the last half of the present century. As an art it has been practised for centuries by our ancestors with credit to themselves and benefit to the injured, the crippled, and the sick. When Boyer wrote the introduction to his classic work on surgery he expressed the conviction that surgery had reached perfection. How little did he dream of the great changes that would be wrought in the practice of his cherished profession by the progressive pathologists and surgeons of the next few generations! What a contrast between the standing of the surgeon of today in the community, in the profession, and from a scientific aspect, as compared with his colleagues of only a century ago!

Modern pathology and the new science of bacteriology have laid a permanent foundation for the steady and progressive advance of surgical thought and work. The inflammatory complications of wounds and the etiology of most of the chronic infective surgical diseases have been cleared up by bacteriologic investigations during the last twenty-five years, and the knowledge thus gained has enabled the surgeon to prevent in a large measure the former, and to treat intelligently and with increased success the latter. The wonderful development of operative surgery during the same time is one of the earliest and richest fruits reaped from the vast and fertile field sown and cultivated by bacteriologists of every civilized nation. Antiseptic and aseptic surgery has smoothed the rough and rugged pathway of the practical surgeon. The almost universal introduction of antiseptic and aseptic precautions in the treatment of wounds in private and hospital practice has nearly eradicated the three greatest enemies of the surgeon of old, namely, hospital gangrene, erysipelas, and secondary hemorrhage, and minimized the occurrence of suppuration and its manifold immediate and remote complications.

In considering special work, Dr. Senn said that the *furor operativus* manifested in special departments of surgery, and its obvious results, render the standing and legitimate scope of the general surgeon very uncertain and indefinite at the present time. Let the general surgeon turn to the right or to the left, advance or retreat, and he finds himself on reserved territory. As for the physician, he is expected to answer night calls, prescribe for diarrhoea and whooping cough, watch cases of typhoid fever, measles, scarlatina, and small-pox, and should complications arise and he fail to report to the proper authority he renders himself liable to censure. Much of this ill-applied energy in the surgical world has resulted in detriment to patients and in retarding actual surgical progress. Operative surgery has been carried to extremes.

The speaker next passed on to the consideration of antiseptics and asepsis, saying that the marvellous re-

duction in the mortality following injuries and operations which the present generation has witnessed is largely due to the prevention of wound complications by the employment of efficient antiseptic and aseptic precautions.

Phlegmonous Inflammation.—The employment of antiseptic and aseptic precautions in the treatment of intestinal and accidental wounds has greatly diminished the frequency of progressive phlegmonous inflammation and its often disastrous consequences. That such an occurrence cannot always be prevented, even by the most scrupulous care and attention to details, every surgeon of experience is willing to admit. In the most virulent forms of phlegmonous inflammation the most heroic and timely treatment, local and general, is often fruitless in averting speedy death. In the most desperate cases the surface lesion is often insignificant; the infection, following the lymphatic pathways, soon reaches the general circulation, resulting in death from acute sepsis before any decided gross pathologic lesions have appeared at the seat of infection or in any of the internal organs. How rapidly general infections may take place has been shown by the experiments of Schimmelbusch, who found micro-organisms in the spleen five to ten minutes after infection of a wound. Colin and Niessen demonstrated by their experimental work that amputation a few minutes after inoculation of the ears and limbs of rabbits with pure cultures of anthrax did not protect the animals against generalization of the disease. Such cases in the human being fortunately are seldom met with, but when they do occur the art of surgery is powerless in arresting the progress of the disease. Parenchymatous injections of solutions of carbolic acid or corrosive sublimate along the course of the inflamed lymphatics and the internal use of alcohol in heroic doses promise the most, but in the great majority of cases the extension of the infection continues and terminates speedily in death from general sepsis. In the treatment of diffuse phlegmonous processes it is now customary to make free incisions, establish free drainage, and disinfect the cavity by flushing it freely with a safe and yet efficient antiseptic solution, such as a saturated solution of acetate of aluminium, a three-per-cent. solution of carbolic acid, or a 1 to 5,000 solution of corrosive sublimate, and apply to the part hot compresses wrung out of the same solution.

Closely allied to phlegmonous inflammations of the soft tissues is acute suppurative osteomyelitis, as it is caused by the same kinds of microbes and results in more or less extensive destruction of tissue. The etiology and pathology of this disease are now well understood, and upon them is based the early operative treatment, which is generally indorsed by the profession at the present time. The early removal of the osteomyelitic product by operative interference, as a rule, relieves pain promptly, limits necrosis, guards against joint complications, and recognizes the danger from general sepsis. Immobilization of the affected limb in proper positions, and the exposure of the osteomyelitic focus by the use of the chisel or gouge as soon as a positive diagnosis can be made, are the modern resources which have succeeded in greatly reducing the mortality from this disease as well as its immediate complications and remote consequences.

Tuberculosis of Joints.—The speaker said that only a few years ago the surgeons who paid special attention to diseases of the joint were enthusiastic advocates of early resection or arthrectomy in cases of tuberculous joint affections. It was believed that such medical treatment would succeed in eliminating the local affection and in preventing the extension of it to distant organs by reinfection from the peripheral focus. Statistics prove that these hopes are unfounded, and conscientious surgeons have substituted largely in

place of operative treatment conservative measures. A change in practice has taken place, largely due to the beneficial effects obtained from intra-articular and parenchymatous injections of iodoform and glycerin. Dr. Senn has resorted to this treatment in hundreds of cases with the most satisfactory results. In about one-half or two-thirds of all cases of uncomplicated joint tuberculosis this treatment proves curative. It is of special value in the treatment of tuberculous abscess in communication with a tuberculous joint or bone. From one to three or four injections usually suffice in obliterating the abscess cavity.

Cancer.—Coming to the subject of malignant tumors, he said the essential cause of carcinoma and sarcoma remains to be discovered. The science of surgery must first divulge the true nature of tumors before we can expect a decided advance in their more successful treatment. The essential features of the modern treatment of malignant tumors he summed up very briefly as follows: Operate early and thoroughly. The treatment of inoperable sarcoma by injections of the sterilized toxins of the streptococcus of erysipelas and the bacillus prodigiosus has not equalled the expected results.

Brain Surgery.—In the orator's opinion, operative interference is absolutely indicated in fractures of the cranial vault under the following circumstances: (1) All open fractures, including gunshot and punctured fractures. (2) Depressed fractures attended by well-defined symptoms caused either by the depression or intra-cranial complications. (3) Rupture of the middle meningeal artery with or without fracture of the skull. The indiscriminate use of the chisel and the trephine in the hands of the inexperienced practitioner is fraught with danger and should not be encouraged by teachers and expert surgeons. Cerebral localization and aseptic surgery have made it possible to treat a few intracranial lesions successfully by direct operative interference.

Surgery of the Abdomen.—The abdominal cavity was largely a *terra incognita* to the surgeon of less than half a century ago. To-day it is the favorite battle-ground of the average surgeon and the select field of the so-called abdominal surgeon. Notwithstanding the wonderful improvements in the technique of operations upon the stomach, partial gastrectomy and pylorotomy have yielded anything but encouraging results. In nearly fifty per cent. of cases the patients subjected to radical treatment for malignant disease of the stomach succumbed to the immediate effects of the operation. Dr. Senn said he had opened the abdominal cavity for the surgical treatment of malignant disease of the stomach nineteen times, and in only one case did he find the disease limited to the organ first affected, and in this case the general health of the patient had been so broken down by the obstructive pyloric carcinoma as to contraindicate a radical operation. In all of the remaining cases a pylorotomy or partial gastrectomy was out of the question, as the carcinoma of the pylorus or stomach had extended to adjacent organs or had given rise to regional infections through the lymphatic glands sufficiently to contraindicate any attempts at radical removal of the disease.

The Generative Organs.—Dr. Senn next considered at length the organs of generation, saying that the greatest onslaught of modern surgery has been upon the organs of generation, male and female. The future historians who will record the work of many gynecologists belonging to the present generation will have reason to express their surprise at the disasters the art of surgery has produced when plied in cases far in advance of a scientific foundation. Here and there we hear a feeble voice protesting against the indiscriminate surgery upon the organs of generation of the opposite sex, but the mutilating work continues in

spite of such opposition and well-meant advice. Dr. Senn said that when he arraigned the gynecologists before such a representative body, composed of representative medical men of this country, for innumerable and inexcusable transgressions of the rules which ought to govern and control the art of surgery, he did not include the scientific, conscientious workers in that department of surgery, but his remarks applied to a class of routine operators which had recently grown to alarming dimensions, not only in this but in nearly every country which has been penetrated by the dim rays of so-called bold surgery. The new generation of doctors no longer finds satisfaction in practising in some rural district. Its members have their eyes on large cities and have heard of enticing fees paid to specialists for insignificant operations. Why buy a horse and saddlebags when a fortune awaits them in devoting themselves to a specialty, more particularly gynecology? The recent graduate or the man who has become disgusted with country practice seeks a much-employed gynecologist, follows his work for a month or two, and returns to his prospective field of labor a full-fledged specialist. He is now ready to extirpate the uterus, remove ovaries and fallopian tubes, sew imaginary lacerations of the cervix and perineum. Do you suppose that such an aspirant for gynecological fame ever examines a woman and finds her perfect? Is it not true that in nine out of ten cases he finds something to mend? In order to show that the speaker's views were real and not visionary, he related a few instances.

Laceration of the perineum is another subject of the amateur gynecologist. The extent of laceration and the symptoms caused by it are not always carefully considered in deciding upon the propriety of an operation. Dr. Senn said that to do an operation on the perineum in five or seven minutes still serves as an attraction for the lookers-on in many private hospitals and gynecological clinics. He fully appreciates the value of a well-performed perineorrhaphy in proper cases, but he was equally well satisfied that the operation has often been performed unnecessarily, and that it requires more than five or seven minutes to perform it properly.

The frequency with which women are being castrated is one of the most flagrant transgressions of the limits of the art of surgery. It is not unusual for one operator to exhibit from five to six normal ovaries as the result of half a day's work. All kinds of excuses are made for this kind of surgery. Dr. Senn asked the question: Where is this wholesale unsexing of our female population going to end? The beginning of the end has come. The army of women minus their essential organs of generation is beginning to raise its voice against such mutilating work. The number of women who willingly sacrificed their ovaries to restore their shattered health without securing the expected relief has increased to an alarming extent. This sad experience has made the gynecologists more desperate and bold. It is difficult to say where this rage for the removal of the female sexual organs will end, or what organ will be the next battle-ground for the aggressive gynecologists. The clitoris, the vagina, the cervix uteri, the ovaries, the fallopian tubes, the uterus and its ligaments have successively passed through a trying ordeal of operative furor. What the next fad will be is impossible to foretell.

He could not dismiss the subject of genital surgery without making a strong plea in favor of conservatism in the treatment of prostatic hypertrophy. Reference was made to the experiments of J. W. White on animals in this connection; also to the clinical experience of Ramm, whose results covered about the same ground as those of White, and who urged the utility of castration as a legitimate surgical procedure in the treat-

ment of non-malignant obstructive enlargements of the prostate. The reason the speaker alluded to this subject was this: he feared that when this operation on aged men for hypertrophy of the prostate becomes common property and is indorsed by surgeons of high standing, it would be misapplied in the same way, probably to a lesser extent than the removal of normal ovaries. Men will be castrated for stone in the bladder, chronic cystitis, and malignant disease of the bladder. It is not always easy or possible to make a positive differential diagnosis between simple hypertrophy of the prostate and some of the conditions which simulate it so closely. In doubtful cases it appears to him it would be advisable to make the diagnosis sure by a suprapubic cystotomy before resorting to a mutilating operation, rather than remove the testicles and later discover a bladder or encysted stone or malignant disease of the bladder or prostate. Castration is such an easy operation that every tyro in surgery will be tempted to perform it upon willing subjects suffering from obscure affections of the bladder complicating hypertrophy of the prostate gland. The Ramm-White operation deserves a fair trial at the hands of competent surgeons, in well-selected cases, but Dr. Senn apprehends evil in the future, not so much from the proper use as from the abuse of this procedure.

Finally, he had written and delivered his address with malice toward none, in the interest of the suffering portion of our population, for the true advancement of the science and art of surgery, and as a plea for recognition of the good work done by the great mass and backbone of our profession, the modest, toiling, inadequately remunerated general practitioner.

On motion the thanks of the association were extended to the author of the address.

Miscellaneous Business.—The report of the secretary was then read and accepted. That of the treasurer was not read, as this officer was absent.

Vivisection.—The report of the committee to consider the memorial of the Medical Association of the District of Columbia was presented. The committee presented a resolution that the association should protest earnestly against the adoption of Senate Bill 1,552, prohibiting experiments on animals in the biological laboratories in the district, and asked that an impartial investigation be made to determine whether charges of cruelty brought by the Humane Society, upon the strength of which the passage of this bill was urged, were true or false. DR. GARCELON, of Maine, opposed the resolution, but after an eloquent appeal by SURGEON-GENERAL STERNBERG it was unanimously adopted, and the secretary was instructed to send a copy of the resolutions at once to the commissioners of the District of Columbia.

The Cleveland Medical Society Outlawed.—The judicial council reported that no members of the Cleveland Medical Society should be admitted to membership in the association as delegates from that or any other society. A communication was received from the New York County Medical Association reaffirming its allegiance to the code of ethics of the American Medical Association.

The Jenner Centenary.—The programme of the Jenner centenary, to which it had originally been decided to give all of Thursday, was then read, and it was agreed that the rest of the day should be given to the addresses. The general session was then adjourned and the Jenner celebration was begun. The character of Dr. Jenner and the history of his discovery of the protective value of vaccination were the subjects of the first address. In the absence of its author, DR. N. S. DAVIS, the paper was read by DR. DIDAMA, of New York State. The paper recounted the well-known facts concerning the life of Jenner and the

manner of his great discovery, the story being told in an interesting way. DR. H. R. STORER, of Rhode Island, gave a list of the Jenner memorial medals, tablets, portraits, etc.

Scientific Researches Relating to the Specific Infectious Agent of Small-pox and the Production of Artificial Immunity from this Disease was the title of an address by GEORGE M. STERNBERG, M.D., LL.D., Surgeon-General U. S. Army.

The experimental evidence relating to the nature of the specific infectious agent of vaccine and of variola was reviewed; also that relating to the genetic relation of cow-pox, horse-pox, and small-pox; and that relating to the production of artificial immunity by subcutaneous inoculations with vaccine lymph and by subcutaneous or intravenous injections of blood serum from immune animals.

The following conclusions were stated:

I. Small-pox, cow-pox, and horse-pox are genetically related, being different manifestations of the same infectious disease in different genera of animals (*Man, Bos, Equus*).

II. The specific infectious agent of variola and of vaccinia has not been demonstrated. The extended experimental investigations which have been made indicate that it does not belong to the class of micro-organisms known as bacteria.

III. Various bacteria are commonly found in the lymph from vaccine vesicles, obtained either from bovine animals or from man. Among these are the well-known pus cocci, and these micrococci are probably largely responsible for the erysipelatos inflammation and other unpleasant complications which frequently result from vaccination with such lymph.

IV. Lymph preserved in glycerin after a time becomes sterile, so far as the presence of bacteria is concerned, without losing its specific virulence.

V. Immunity may be induced by subcutaneous inoculation of vaccine virus, without the development of a vaccine vesicle; and it is probable that the subcutaneous injection of lymph preserved in glycerin would give protection without any of the septic complications so common as a result of vaccination by the usual method.

IV. The blood serum of immune animals contains a substance in solution which destroys the specific virulence of vaccine virus when brought in contact with it.

VII. This substance is not present in sufficient amount to make the blood serum of immune animals available for the production of immunity in man (or for the treatment of variola). But it may perhaps be obtained in a concentrated form by chemical methods, and in that case would be likely to prove useful, and possibly specific, as a therapeutic agent in this disease.

VIII. The immunity resulting from the subcutaneous injection of vaccine lymph, like that resulting from vaccination in the usual manner, is gradually developed and is not complete until the eighth day,¹ depending, no doubt, upon a multiplication of the infectious agent in the body of the susceptible animal. On the other hand, the immunity resulting from the transfusion of a large amount of blood serum from an immune animal to a susceptible animal is an immediate result of such transfusion.

"The Propagation, Preservation, and Use of Vaccine Virus" was the title of an instructive address by DR. FRANCIS E. MARTIN, of Massachusetts. "The Statistical Evidence of the Value of Vaccination to the Human Race" was the title of the closing address by DR. EUGENE FOSTER, of Georgia. The celebration

was under the auspices of the American Medical Association and of the American Public Health Association.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A CENTRAL HOSPITAL BOARD—CHARITY ORGANIZATION SOCIETY—UNJUSTIFIABLE ARREST OF A DOCTOR—ARMY SURGEON'S GRIEVANCES—DR. FOWLER'S CASE—AN INDIAN CASE—DECIDUOMA MALIGNUM—CLINICAL SOCIETY—SARCOMA—SEROUS EXPLETORATION AFTER OR DURING PARACENTESIS.

LONDON, April 17, 1896.

A MEETING was held on Monday to consider the often-talked-of scheme for establishing a central hospital board for London. The meeting was called by the Charity Organization Society, a self-constituted body which has a certain number of supporters. At the same time this C. O. S., as it abbreviates itself, has inspired a good deal of distrust and here and there of opposition. It began work by offering to inquire into the antecedents and deserts of applicants to subscribers for pecuniary aid, so as to prevent undeserving mendicants from being assisted by several persons while more modest and more deserving sufferers were left unaided or inadequately helped. Out of this grew several modes of action, and the officers of the C. O. S. would like to subject all hospitals and charities to its influence or control. Of course this is sure to be resented, and many most generous persons refuse to have their charities directed by such machinery. It is not always easy to judge, but the C. O. S. certainly inspires no enthusiasm for its work, save in the breasts of its paid officers. I sometimes think its chief use is to provide them with nice berths. We have too many boards and societies, and to have one to report on the others has always appeared to me unnecessary. But to return to the proposal for a central hospital board. Such a plan was recommended by the Lords committee and is regarded with approval by some administrators, though probably on the ground that it would have no authority except to formulate its opinions or recommendations. Howbeit it was, at the meeting six hundred and fifty-eight general practitioners and one hundred and six consultants had filled up the form issued by the C. O. S. in favor of such a proposal. The actual scheme submitted to the meeting was for a board with one hundred and sixty-nine representatives of the medical charities, including five representatives of the general practitioners. What could such cumbrous machinery be expected to accomplish, unless to provide a better berth for the moving spirit of the C. O. S.? It was actually proposed to give representatives to the County Council and to the British Medical Association—the idea being apparently to popularize the notion by getting as many persons of as divergent views as possible to indulge in unlimited talk.

A gross blunder of the police is reported from Edinburgh. They arrested a medical man on a charge of murder by producing abortion. There was no evidence other than that the doctor had attended a woman with whom he had no acquaintance, and who told him she had been taking drugs to produce the miscarriage then going on. The authorities released him after a time, but it seems as if they had been culpably negligent of their primary duties. I fear there is no redress in such a case as this, but surely the procurator fiscal or sheriff ought to be called to an account. The dangers of a doctor's life seem ever increasing.

¹ Experiments of Bécère, Chambon, and Ménard (1896).

The secretary for war (Lord Lansdowne) has declined to reinstate Dr. Fowler, and his case will be brought before parliament. He was dismissed from the army in direct defiance of the regulations. So gross was the case that he was offered an appointment in the colonial service, but this cannot nearly compensate him for the loss of his commission, to say nothing of the unjust stigma. He entered a room and saw some unseemly conduct and remonstrated, with success. He did not report this incident, as the senior captain was present, whose duty it would be. Medical officers have no disciplinary authority outside their own department. A court of inquiry was held. What scapegoat could be found? Of course a doctor, who had no rights. He was accordingly condemned, in spite of the law that no officer or private can be condemned on statements made before such a court. Thus, to gratify the prejudices of combatant officers, a doctor is to be illegally ruined and the higher authorities refuse redress. No wonder vacancies in the army medical department cannot be filled up. It is whispered that Sir R. Buller is a determined enemy of the doctors. He is going to Egypt. If he happens to get wounded or sick he may change his notions as to the value of their services and the respect due to their calling.

Your readers may remember that it is not long ago since a surgeon-major in India was cashiered for asking a married lady when driving out for a kiss. Very improper doubtless, and the combatants concerned in dismissing him must be immaculate examples of British soldiers. Still I am sure that a combatant might have been more imprudent without risking expulsion from the army.

The Obstetrical Society has had a discussion on deciduoma malignum. One or two cases were reported, but they were not free from doubt. In fact, most of our authorities doubt the existence of such a condition. America and the continent supply all we know on the subject. It is thought by some of our ablest observers that a rapidly growing sarcoma is the true explanation of what has been observed. The normal foetal appendages are made up of rapidly growing elements, and this is the character of sarcomata. The microscopic appearances may, therefore, give rise to erroneous deductions. Great stress is laid on the metastases. Those and the primary disease may be malignant, but the question is whether the latter is really decidual. The preparations were referred to a committee for further investigation.

Before the Clinical Society of London on Friday last, Mr. Godlee gave some account of two cases of acute abscess of the liver operated on, both ending fatally.

A case of cranial cyst of sarcomatous origin, no recurrence two years after operation, was shown by Dr. Pitt and Mr. Lane. The patient, in 1891, first complained of a pain in the top of his head, where he found a soft swelling which when it bulged outward formed a tumor. On four occasions it became enlarged and painful, subsiding by the discharge of a considerable quantity of serum through an orifice which formed in the scalp. In November, 1892, the swelling measured about two and one-half by two inches. It fluctuated and also pulsed distinctly. A few days after its contents discharged themselves, about an ounce being collected and examined, when it was found to be simply serous. A depression three-fourths of an inch deep replaced the swelling and was bounded by a thin, irregular, bony margin, which in parts yielded slightly to pressure. In December, 1892, the scalp over this area was freely divided, when a space was exposed which extended some little way beneath the overlapping edge of bone. Covering the whole of the floor, being most abundant at its limits and destroying the overlapping bone, was a quantity

of some material sarcomatous in structure, as verified by subsequent examinations. As the growth was so soft and extensive it was not felt advisable to remove such a large area of bone and dura mater as would be required for its entire elimination, and the wound was closed. Since the operation, except for a temporary leakage of serum and a subsequent attack of erysipelas, the patient has enjoyed excellent health, and he had no return of the headache from which he suffered previous to the operation.

Mr. Makins recalled a case of a patient with a large tumor of the upper jaw, which had formed within a year and was attended by severe hemorrhage. He removed the upper jaw and scraped the base of the skull. It healed up by primary union and the patient left the hospital in a fortnight. He heard nothing more of the patient for between two and three years, when he came back with a large recurrence and an open ulcer with thick edges involving nearly the whole of the cheek. He was told nothing could be done for him and he returned home, where he resorted to some quack remedy. After a time the tumor underwent shrinkage, and in the course of five or six months it entirely cicatrized. The question arose whether or not it was a gumma, but a number of competent microscopists who had been shown the sections were strongly of opinion that the appearances were those of a sarcoma. He believed there were several other cases of the kind on record.

Dr. Samuel West drew attention to albuminous or serous expectoration after paracentesis for serous effusion, and related a case occurring just as forty ounces of fluid had been withdrawn by syphon. The cases of albuminous expectoration differ a good deal *inter se*. The attacks usually come on during paracentesis or immediately after it, sometimes as late as two hours after. They last for a short time, usually not more than an hour or two but occasionally longer. The quantity of fluid varies from a few ounces to even more than three pints. In character it is frothy, like that of acute bronchitis. It contains much mucin and little albumin. The physical signs are those of congestion of the lungs. There appears to be no necessary relation between the duration of the pleurisy prior to paracentesis and the liability to serous expectoration, but as a rule the cases have lasted some little time. It is not to be connected with the use of the aspirator, for some of the cases (as in this) occurred when the fluid was removed by the syphon only. The result is rarely fatal, and among the fatal cases some complication besides the effusion is generally found. The condition seems less common than it used to be twenty or thirty years ago, probably because of the earlier performance of paracentesis. Edema of the lung is the only satisfactory explanation. In the non-fatal cases this edema must be due to some transitory condition, and is probably in most cases to be connected with the sudden distention of the lung after it has been collapsed for some time. In the fatal cases some organic lesion is generally found in addition, which would account for the result.

Dr. Hale White related a case of a patient recently admitted, whose chest was full of fluid. As no improvement followed she was aspirated. Soon after she began expectorating this albuminous fluid, and it continued for four or five days in considerable quantities.

Dr. L. Benham said this phenomenon was not met with in edema from ordinary causes, and suggested as a more probable explanation thrombosis of the pulmonary vessels.

Dr. S. West admitted that in the recorded cases pulmonary thrombosis was very commonly observed, and it certainly looked as if it must be due to some complete obstruction of the vessels. In respect to Dr.

White's case, it was rare for a case to go on several days, forty-eight hours having hitherto been the longest period. Minor cases did not require any active treatment, and in the acuter cases there was no time to do anything.

DR. McARTNEY'S MEDICAL TREATMENT OF APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. McCartney's contribution to the subject of the medical treatment of appendicitis in the *MEDICAL RECORD* for May 2, 1896, is too important to be lightly considered by any of us, because it shows the earmarks of correct diagnosis and of unbiassed report in showing what opium will really do in real appendicitis. Too large a proportion of cases that are cured by medical treatment are like the European typhlitis cases, not appendicitis at all. Dr. McCartney has apparently diagnosed appendicitis correctly in twenty-four cases and has carried the patients through to an interval stage without a death. For physicians who are not in control of better resources for their patients this heroic opium treatment, like the sweet-oil treatment, certainly merits attention and a place of record in medical history. To be sure, the ground will have to be gone all over again with most of these cases within the next ten years and some of the patients will be lost eventually in their subsequent attacks. Tuberculosis of the appendix, large enteroliths, strangulating adhesion bands, portal embolism, and several other common fatal complications of appendicitis will not down; but, nevertheless, we must all remember what medical treatment did in twenty-four exacerbations of appendicitis. It is, of course, too late in the day to argue that medical treatment should often be substituted for surgical treatment in the cities, where the patient can have skilled surgical attention. Dr. McCartney probably did not mean that. The etiology and pathology of appendicitis are now fully understood and the surgical death rate in skilled hands has been reduced to a fraction of one per cent. in interval cases and in cases operated upon in advance of pus formation or of septic peritonitis, so that we must look to diabetes cases and dilated heart cases and things like that for the surgical death rate. In just such cases, however, I am likely to employ Dr. McCartney's plan in the city. In appendicitis discussions it is interesting sometimes to leave out the question of death rate altogether and talk only of the suffering rate. For instance, in one of Dr. McCartney's cases the abscess fortunately emptied through the bladder. In one of my patients, who had been under medical treatment, the pus fortunately escaped by way of the mouth and the vagina simultaneously, after perforating the lung, but I was obliged to remove the appendix after a subsequent attack, because the patient began to weary of fortunate evacuations of pus. In another one of my appendicitis patients, in whom the whole gangrenous cæcum sloughed off under medical treatment, the pus fortunately escaped through both buttocks, which it perforated after burrowing.

I am sure that if Dr. McCartney could spend the time and the money to acquire facility in operative work which would allow his patients to emerge safe and sound from timely operations, it would save him many a weary ride over the hills—but there's the rub. The general practitioner to-day must have so much information upon so many other things equally important with appendicitis that time is too short to cover the length of art. I much regret that Dr. McCartney in his contribution twice refers to the fee as a motive in surgical work. That idea lowers the caste of his whole article. I do not know a surgeon of importance

who ever thinks of the fee in the presence of life-saving work. We all go out in the stormiest midnight to places where we would not ask an assistant to go. We travel miles by railway to patients who probably cannot even pay our car fare. We all put our hands into our pockets to help some poor devil who cannot pay for hospital board. We all do in the city precisely what Dr. McCartney probably does in the country, but the most fortunate patient is the one who is situated where he can really have the best treatment, and the best treatment in appendicitis cases is not medical treatment of any sort.

ROBERT T. MORRIS, M.D.

49 WEST THIRTY-NINTH STREET, NEW YORK,
May 3, 1896.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a paper on "The Lesions of the Appendix Vermiformis and Cæcum Demanding Surgical Interference," which I read before the section on surgery of the New York Academy of Medicine, November 14, 1892, which, together with the discussion in which the medical and surgical sides of the question were ably represented, was printed in the *MEDICAL RECORD* of November 26, 1892, I said in closing the discussion "that cases should be selected with care, but usually for operation, and that if all of a thousand suspected cases were operated upon, the mortality would probably be fifty per cent. less than in another thousand cases which physicians now let pass without operation."

In the light of a further experience I now believe that if the error of operating upon every suspected case of appendicitis were made, and such operation were done by a surgeon who knows what practical asepsis and careful technique are, the death rate would not be five per cent. With all this, I do not believe that every case is an operative case or that an operation should be advised or permitted in every instance. I hold that a surgeon of ripe experience, or a physician of equal experience, can tell in the vast majority of instances when operation is indicated and the class of cases in which operation can be postponed under careful watching.

I am led to make this communication to the *MEDICAL RECORD* from reading an article by Dr. W. N. McCartney in the May 2d number of this journal, entitled "Appendicitis from a Medical Standpoint," in which the author does me the honor of quoting some of my contributions to this surgical subject. He says that in the *MEDICAL RECORD* of April 28, 1894, I insisted that "appendicitis should always be regarded as a surgical disease." The author further contradicts my statement that the great danger is peritonitis, by saying that "the safety lies in the peritonitis would be more proper, and there is no peritonitis in the fulminant cases," which is a most astonishing proposition. It will probably surprise the surgical profession to know that fulminating appendicitis, which is the most formidable kind, resulting from rapid death of the wall of the appendix, or perforation, in either of which conditions septic organisms pass through the diseased and non-resisting membrane or through an aperture into the peritoneal cavity, will not produce peritonitis.

Dr. McCartney adds that during the past six years he has seen twenty-four cases of appendicitis and that all recovered. I once heard a physician say at a meeting of the American Medical Association, when this subject was being discussed, that he had had seventy-five cases with equally phenomenal success.

I venture to say that Dr. McCartney with twenty-four recoveries in twenty-four cases of appendicitis without surgical interference stands alone in the history of

medicine. To those of us with whom hardly a week passes without seeing one or more deaths from neglected cases of this affection, it is incredible that any such result could ensue.

I have full confidence in the sincerity and candor of this physician, but I am sure he erred in his diagnosis, and that such teachings as he essays are fraught with danger.

It so happens that in the same number of the *MEDICAL RECORD* in which Dr. McArtney's paper appears there is published another paper on this subject by Dr. Samuel Lloyd, who presents the question chiefly from the medical aspect of this lesion in an examination of five hundred and fifty-eight cases with two hundred and sixty-three recoveries and two hundred and ninety-five deaths. Of this number two hundred and twenty-six were operated upon, with one hundred and ninety-two recoveries and thirty-one deaths—a mortality of 13.6 per cent. Two hundred and sixty-five were treated conservatively; sixty recovered and two hundred and five died—a mortality of seventy-seven per cent. The author closes by saying—what every reasoning man must appreciate—that this is a dismal showing for the conservative treatment of appendicitis. If those five hundred and fifty-eight had within the first twelve hours of the first symptoms of the attack been turned over to a competent and conscientious surgeon, does any sane man believe that any such mortality rate would have occurred, and can such believe that, had these patients been operated upon, of the five hundred and fifty-eight cases two hundred and ninety-five would have died? Under proper conditions not fifteen in the five hundred and fifty-eight should have perished.

If I may be permitted again to state my views, I would formulate them as follows:

1. Appendicitis is strictly a surgical lesion, and the cases which are permanently cured without operative interference are either mild in type, the process of infection being gradual and limited and of such character that it is rapidly hedged in and arrested by rich plastic exudate with adhesions, the canal of the tube being meanwhile restored, permitting drainage of the infected tube into the cæcum, the plastic exudate subsequently undergoing absorption; or the successful issue is the result of blind chance in the formation of adhesions which are strong enough to force the abscess to break either through the abdominal wall at some point or into the rectum, bladder, vagina, or intestinal tube, all of which conditions are fraught with great danger to life and subsequent usefulness, and all of which can be prevented by early operative interference.

2. There are cases which do not require operation. They belong to the group just mentioned, in which the septic process is mild and in the vast majority of cases readily recognized by the experienced clinician. None the less, these cases should be under surgical observation for operative interference should the symptoms of infection become pronounced. It is probable that the proportion of cases which recovers under so-called conservative management would number about fifteen in every hundred, which might be increased if it were permitted to include cases which recover from a single attack, but which are subject to repeated seizures (recurring appendicitis).

JOHN A. WYETH, M.D.

NEW YORK, May 7.

Deafness.—Any child whose hearing is defective or doubtful should be examined by a medical expert as to the state not only of the ears, but also of the tonsils and naso-pharynx.

Reviews and Notices.

THE DISEASES OF CHILDREN, MEDICAL AND SURGICAL. By HENRY ASHBY, M. D. Lond., F.R.C.P., and G. A. WRIGHT, B.A., M.B. Oxon., etc. Third Edition. Edited for American Students by WILLIAM PERRY NORTHRUP, A.M., M.D. New York: Longmans, Green & Co. 1896.

THIS book comprises the detailed management of the surgical and medical diseases in children.

It is divided into thirty-seven chapters and contains about two hundred illustrations, many of which are superfluous.

A great many points have been added in this new edition and a great many articles have been omitted. So, for example, we find a small article on gonorrheal ophthalmia. Page 53 has a new style of nursing-bottle, with a few remarks. We notice that bromoform is not even mentioned in therapeutics of pertussis.

The author omits many new drugs, and it is proper to note that to-day, when antitoxin is considered a specific for diphtheria, that we find the space on page 293 devoted to some device of an American physician to give hypodermic injections of an antiseptic liquid by a many-pointed syringe. In the appendix, page 771, the author gives considerable space to antitoxin. The treatment of diphtheria is gone over, and the author quotes Dr. Welch extensively, whose strongest remark is that it is the duty of every physician to use antidiphtheric serum, and that beyond doubt antidiphtheric serum is a specific curative agent for diphtheria, surpassing in its efficacy all other known methods of treatment. The name of Dr. Louis Fischer is not mentioned. Why?

Again, it is noticeable that while a sterilizer was illustrated and endorsed on page 739, edition of 1893, in this third edition, on page 798, Freeman's Pasteurizing apparatus is shown and endorsed.

The remarks on matters relating to hysteria are interesting.

The book has evidently not been entirely rewritten, for most chapters begin and end exactly as did its predecessor.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS, WITH ESPECIAL REFERENCE TO THE CLINICAL APPLICATION OF DRUGS. By JOHN V. SHOEMAKER, M.D., LL.D. Third Edition. Thoroughly Revised. F. A. Davis Company, Publishers, Philadelphia. 1895.

THIS elaborate work has been compiled into one volume of over 1,100 pages, instead of two volumes as heretofore. The author has kept the work in accord with the United States Pharmacopœia of 1890. A great many new drugs have been added, amongst them being tolusal, tolypyrin, salocoll, salacetol, chlorphenol, bromphenol, formalin, dulcin, tannigen. Animal extracts and immunized serum, or antitoxins, have been added, giving this new book a very modern appearance.

The type is clear. It is full of very practical recipes, making it valuable for the average practitioner. It certainly deserves recommendation and endorsement.

THE MEDICAL MUSE, GRAVE AND GAY. A Collection of Rhymes Up-to-date, by the Doctor, for the Doctor, and against the Doctor. Collected and Arranged by JOHN F. B. LILLARD. New York: J. E. Booth. 1896.

THERE are a few poems in this selection. The other things are the veriest doggerel, that would be a discredit even to the new poet laureate. If the compiler had used more discrimination, the book might have passed as affording amusement to the doctor and his young children, but some of the verses admitted are simply nasty and unfit for any but professional eyes. The typography of the book is in keeping with its contents.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. In Photo-Lithochromes, from Models in the Museum of the St. Louis Hospital, Paris, with Explanatory Woodcuts and Text. Edited and Annotated by J. J. PRINGLE, M.B., F.R.C.P. Philadelphia: W. B. Saunders. 1895. Part II.

THE second fasciculus of this set of striking pictures tends to strengthen the favorable impression made by the first.

The reproductions of the museum casts, while impres-

sively natural, cannot be said to be exactly lifelike, and the layman usually exclaims on seeing one of these lithochromes, "Was that taken from a dead man?"—the eye being of necessity closed when the impression for the model was taken. There are four face pictures and one of the hand in this number, besides several woodcuts.

In one the erythematofollicular variety of lupus erythematosus is shown; in a second hypertrophic or elephantiasis rosacea; in a third is most beautifully depicted a circinate papulo-squamous syphilide showing peculiar cockade figures; and following it is a two-figured plate of xanthoma planum et tuberosum.

Nothing further need be said of the descriptive text than that the articles are respectively from the pens of Hallopeau, Besnier, Thibierge, and Darier.

EPITHELIOMA PRIMITIF DE L'URÈTRE. By MELVILLE WASSERMAN, Laureat de l'Institut (Académie des Sciences); Docteur des Facultés de Médecine de Paris et de Heidelberg; Ancien Assistant de la Clinique Chirurgicale de Heidelberg.

AT the surgical congress held at Lyons in 1894 Professor Albartan read a paper on primary epithelioma of the urethra, with a report of a case upon which he had operated that year.

The specimen was examined microscopically by Dr. Wasserman, and his interest in this rare affection was so great that he determined to collect, if possible, all the cases which had been reported. The results of his labor have been published in the above monograph.

The author was able to find records of forty-seven cases, covering a period from 1831 to 1894.

From an analysis of these cases the conclusions arrived at are as follows: Primary epithelioma of the urethra is a rare disease, and occurs with about equal frequency in the male and female. It has no special predilection for any portion of the canal. Histologically, the tumor consists of pavement epithelium. Recurrent gonorrhœa and traumatism favor its development. In the male it is generally complicated by urinary fistulae. The diagnosis is at the present time rendered easy by means of the endoscope. The most probable source of error is cancer of Cowper's glands, but the situation and symptoms are different. The prognosis is grave. Resection of the urethra may give a good result in the very early stage. When the disease has reached considerable development, amputation of the penis or removal of all the genital organs is the only treatment. In the female, if more than one-half of the canal is involved, the utility of an operation is doubtful. Where the disease is so far advanced as to render a radical operation impossible, suprapubic cystotomy, or, in the female, the formation of a vesicovaginal fistula may be employed as palliative measures. The work is illustrated by some excellent plates.

AN ATLAS OF THE NORMAL AND PATHOLOGICAL NERVOUS SYSTEMS, TOGETHER WITH A SKETCH OF THE ANATOMY, PATHOLOGY AND THERAPY OF THE SAME. By DR. CHRISTFRIED JAKOB, Practising Physician in Bamberg, formerly First Assistant in the Medical Clinic at Erlangen; with An Introduction by PROF. DR. AD. V. STRÜMPPELL. Translated and Edited (authorized) by JOSEPH COLLINS, M.D., Instructor of Nervous and Mental Diseases, New York Post-Graduate Medical School, Visiting Physician to the Hospital for Nervous Diseases; Attending Physician to St. Mark's Hospital. Pp. 230. Published by William Wood and Company, New York. 1896.

THIS work is the second of the series of hand atlases which have been announced to be published by this house. The publishers have departed from the usual form of atlases, abandoning the large and cumbersome quartos for the small octavo, which can conveniently be held in the hand.

Every year witnesses an advance in the illustrative method of presenting the facts of science to its students. In this book the acme has been reached. Every device of ingenious illustration has been employed—the photographic, the schematic, and the diagrammatic; color sketches and folding plates displaying regional sections. The reproductions of microscopical appearances with the staining are very perfect. As new stains are continually being used which bring out fresh facts in regard to the histology of the nervous system, the publication of this work is very timely, for it will bring the student and the practitioner up to date in these interest-

ing and important particulars. To the student it will be especially useful as an aid in that intricate and bewildering labyrinth of facts to be acquired in order to understand the brain and nerves, as well as their development. To the physician not versed in nervous diseases, the chapters on pathology and therapeutics, while not elaborate, form a brief compendium, which will be useful in suggesting a diagnosis in puzzling cases in which the question of brain or nerve lesions arise.

The translator's task has been no easy one, but it has been performed in such a conscientious manner as to contribute to the success of the work.

ATLAS OF NERVE CELLS. By M. ALLEN STARR, M.D., Professor of the Diseases of the Mind and Nervous System, College of Physicians and Surgeons, Medical Department of Columbia College; Consulting Neurologist to the Presbyterian and Orthopaedic Hospitals and the New York Eye and Ear Infirmary; with the co-operation of OLIVER S. STRONG, A.M., Ph.D., Tutor in Biology, Columbia College, and EDWARD LEAMING, M.D., F.R.P.S., Instructor in Photography, College of Physicians and Surgeons. With 53 Plates and 13 Diagrams. Published for the Columbia University Press by Macmillan & Company, New York and London. 1896.

THE paper, typography, and beautifully reproduced plates of this quarto atlas give it the appearance of an *édition de luxe*.

The histological technique is discussed by Dr. Strong, who did the staining and made the sections for the photographic plates, which Dr. Leaming produced. This chapter cannot fail to be of interest and service to those who are studying the histology of nerve tissues by Golgi's or the impregnation methods, that of precipitating metallic salts in and around the nerve elements. It is this method, as Dr. Starr says, which "has revealed many facts hitherto unknown and and has given a conception of the nerve structures and the connection of the nerve cells both novel and important."

In addition to the demonstrations of the nerve cells of the spinal cord, cerebellum, and brain cortex which have been studied by Golgi and others, the writer has presented original work in the studies of the corpora quadrigemini, optic thalamus, and lenticular and caudate nuclei.

The explanation of the plates and the exposition of the subject display the clear, concise, and comprehensive style characteristic of Dr. Starr.

The photographic plates have been done in the most careful manner, and their reproductions are most artistic, but, with a few exceptions, they fail of lucidly expressing what the writer desires, and serve as a most excellent illustration of the impossibility of using photography to express scientific facts, except where plane surfaces alone are to be represented. The diagrams which are given to show the relations of the parts and the courses of nerve fibre are excellent. If, side by side with the photographic plates, diagrammatic representations of the cells had been given, it would have helped the reader very much.

HINTS AND SUGGESTIONS AS AIDS IN THE CARE AND PRESERVATION OF THE TEETH AND THE RELATION OF THE DENTAL ORGANS TO OUR HEALTH. By CHARLES G. PEASE, M.D., D.D.S. Published for the benefit of the laity.

WHILE this book contains some advice which might be followed with profit in the care of the teeth, its principal object seems to be to advertise the author and inform the public how many distinguished titles he possesses, and how many papers he has read before various societies.

The homœopathic therapeutics and materia medica at the end of the book are calculated to excite laughter in this day of rational and scientific medicine.

METATARSALGIA. (Morton's Painful Affection of the Foot). Its Causes, Symptoms and Treatment, with Illustrative Cases and Bibliography. By THOMAS S. K. MORTON, Professor of Surgery in the Philadelphia Polyclinic, etc. Reprinted from the Transactions of the Philadelphia Academy of Surgery, Meeting of March 6, 1893. Second Edition. Enlarged and Revised. Philadelphia: 1895.

THE affection of which this little brochure treats is not a very uncommon one, and the suffering which it produces is frequently so great that the author has done well in bringing the subject again before the profession.

The cases cited seem to have been of the severest type and

chiefly those in which the trouble had existed for a long time without treatment, and based upon these cases the only plan of treatment advocated is amputation of the offending toe. But there are many cases presenting somewhat milder symptoms, yet suffering from considerable pain and disability which are due to a shortened tendo Achillis and the consequent imperfect flexion at the ankle. These cases are promptly and permanently relieved by thoroughly stretching the contracted tendon and the plantar fascia.

HANDBOOK FOR HOSPITALS. By ABBY HOWLAND WOOLSEY. Third Edition. G. P. Putnam's Sons.

A THIRD edition of this valuable little work has made its appearance in a very handsome dress. The chapter on "Air Supply and Heating" should furnish useful suggestions to superintendents of many an overcrowded and poorly ventilated hospital.

STUDENTS' AID IN OPHTHALMOLOGY. By GERTRUDE A. WALKER, A.B., M.D., Clinical Instructor in Diseases of the Eye at the Woman's Medical College of Pennsylvania. With forty illustrations and colored plate. Philadelphia: P. Blakiston, Son & Co.

THIS small publication, consisting of one hundred and eighty pages, designed for the use of students is a fair example of its class. The necessarily brief exposition of the subject is excellent in the consideration of ophthalmoscopy, refraction, and allied topics, but is weak in the consideration of the diseases of the eye, particularly regarding etiology and pathological anatomy. A glossary of derivations is added which is of value to students and will be appreciated by them.

There is an absence of technical terms that will render the perusal of this work an easy task to the undergraduate in medicine.

EPIDEMIC OPHTHALMIA, ITS SYMPTOMS, DIAGNOSIS, AND MANAGEMENT, WITH PAPERS UPON ALLIED SUBJECTS. By SYDNEY STEPHENSON, M.D., F.R.C.S. Ed., Surgeon to the Ophthalmic School, Hanwell, W. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co. 1896.

THIS volume of two hundred and seventy-eight pages is well printed on heavy paper, contains twenty-five illustrations, and is of convenient size. There is one colored plate illustrating the known specific micro-organisms found in the conjunctival sac in the course of conjunctival affections. The contents of the volume are divided into five parts, four chapters and an appendix. The first part treats of "Epidemic Ophthalmia, Its Symptoms, Diagnosis and Management"; the second of "A Clinical Enquiry into the Prevalence and Significance of the Follicular Granulation of the Conjunctiva"; the third of "The Treatment of Trachoma and Its Complications"; the fourth of "The Treatment of Follicular Conjunctivitis." The appendix deals with "Lavatory Arrangements." The four forms of epidemic ophthalmia, *i.e.*, acute contagious conjunctivitis (catarrhal conjunctivitis), purulent conjunctivitis, trachoma, and diphtheritic conjunctivitis, are exhaustively discussed. Their causes, symptoms, prevalence, course, results, and treatment—preventive and immediate, medicinal and surgical—plans for isolation, etc., are treated of in the fullest manner. The evidence of wide observation which the work affords and the numerous references to literature on the subject entitle the opinions of the author to the highest respect. The directions and suggestions regarding the construction of lavatories, use and care of towels, and the general conduct of the washing of children and adults in order to prevent the contraction and spread of contagious eye disease, are admirable and are directly applicable to residential schools, asylums, penal institutions, etc.

The volume is one that should be in the hands of every physician, as its application to sanitary requirements and preventive medicine is general.

AN AMERICAN TEXT-BOOK OF OBSTETRICS FOR PRACTITIONERS AND STUDENTS. By JAMES C. CAMERON, M.D., etc. RICHARD C. NORRIS, M.D., Editor; ROBERT L. DICKINSON, M.D., Art Editor. With nearly nine hundred colored and half-tone illustrations. Pp. 1,009. Philadelphia: W. B. Saunders. 1896.

THE introductory chapter on "Anatomy" by Piersol and the section on the "Physiology of Pregnancy" by the same

author, comprising one hundred and forty-four pages, are exhaustive. Palmer contributes several valuable sections on the "Diagnosis of Pregnancy," among which we note as especially interesting the portion devoted to the breast signs and changes in the uterus.

The important chapter on "The Pathology of Pregnancy" contains sections by Davis, Etheridge, and Kelly, with one on "Diseases of the Fœtus" by the lamented Dr. Earle (completed by Mergler). Those on accidents and surgical operations and on extrauterine pregnancy are of great practical value. The chapter on "The Physiology of Labor" by Dickinson is enriched by numerous original illustrations from the pencil of that accomplished artist, while the monograph on the "Conduct of Normal Labor" by Jewett, in regard to both the text and the illustrations, is beyond criticism.

Reynolds contributes upward of one hundred pages on the mechanism of labor, presenting the subject with his well-known accuracy and attention to detail. The chapter on "Dystocia," by Hirst is exhaustive, presenting an elaborate study of contracted pelvis. The "Physiology of the Puerperium" by Jewett and the pathology of that state by Garrigues and Norris, include about one hundred and fifty pages with a copious bibliography.

The chapter on "Obstetric Surgery," is so full and so richly illustrated that it seems more like a new monograph than the presentation of a familiar theme. The minute directions for performing the various operations will be extremely valuable to the general practitioner. Jewett's section on "Symphyseotomy" is the best that has yet appeared in English. A short practical section by Hirst on "Celiotomy for Puerperal Sepsis" concludes a volume to which it is impossible to do justice in a short review.

ELECTRICITY IN ELECTRO-THERAPEUTICS. By EDWIN J. HOUSTON, Ph. D., and A. E. KENNELLY, Sc. D. New York: The W. J. Johnston Co., 253 Broadway.

THE time is near at hand when every medical school in the land will be obliged to make electro-physics and electro-physiology a part of its curriculum.

It means much to the medical profession, therefore, when men of the highest standing among physicists take thought and time to write a book on electricity in electro-therapeutics.

Physicians, save the favored few, are handicapped by their lack of knowledge of the fundamental principles of electro-physics, a knowledge which is absolutely necessary to an intelligent appreciation of the value of electricity in medicine.

Either they must take time for the works devoted to electricity and magnetism in their broadest aspect, or else be content with such out-of-date handling of the subject as is contained in the books devoted to electro-therapeutics.

Here, however, is a book up to date, written for and adapted to the physician's needs. It is impossible to conceive of a simpler and a more scientific presentation of the subject. One great charm of the book is its absolute freedom from all historical data, theories, and expressions of controverted ideas.

The medical student or physician who thoroughly masters its contents is in a position to undertake the study of electro-therapeutics intelligently.

It seems invidious to distinguish when all is good, but the chapters on "Frictional and Influence Machines" and "High Frequency Discharges" are unique in their treatment, and to one in the habit of handling such machines and currents most suggestive and helpful.

COLOR VISION AND COLOR BLINDNESS. A Practical Manual for Railroad Surgeons. By J. ELLIS JENNINGS, M.D., St. Louis, Mo., Formerly Clinical Assistant, Royal London Ophthalmic Hospital, etc. With illustrations. Philadelphia: F. A. Davis Co. 1896.

IN this volume of one hundred and fifteen pages the subject of color blindness is concisely and briefly treated. After a short historical sketch the finer structure of the retina is discussed, the writer apparently accepting the views regarding the histology of the layer of rods and cones, advanced by Norris and Wallace. These views have not yet been substantiated by the researches of others. The physics of light and color are treated in a simple, clear manner, and rendered quite attractive. The various theories of color perception and color blindness are referred to briefly, after which follow chapters devoted to an analysis of the various forms of color

blindness and to the detection of the defect. Special tests are mentioned. Acquired color blindness is considered. The book is of convenient size, is well printed, and is admirably suited for any medical man who does not desire more than a practical knowledge of the subject.

VOICE BUILDING AND TONE PLACING. By H. HOLBROOK CURTIS, M.D. New York: D. Appleton & Co.

THIS really excellent little book was written, we rather imagine, to give a setting to the chapter entitled, "Tone Placing," in which Dr. Curtis gives "his method of relieving injured vocal chords by tone exercises."

Dr. Curtis has been subjected, in our opinion, to much unjust criticism on account of his methods of procedure in treating the singing voice.

We are compelled to say, however, that this is partially his own fault, for, in a paper setting forth the principles laid down in Chapter VII. of this book and read by him several years ago, he put the subject in an unfortunate manner and did himself and his method injustice. This is not the case in this present treatise, in which the whole matter is clearly, tersely, and scientifically expounded.

Speaking generally of throat practice, the treatment of the vocal cords, strained or in a state of inflammation from whatever cause, is, both in this country and in Europe, a reproach to our throat specialists. In making this charge we know whereof we speak, from a more or less intimate acquaintance with the prominent laryngologists in both Europe and America.

In the practice of most men that delicate and beautiful piece of our anatomy, the vocal cords, is sorely abused; what with eternal sprays and applications of zinc, nitrate of silver, tannin, and heaven knows what other astringents, with now and again the cautery for the removal (sic) of singer's nodules, no wonder so many voices are permanently injured. And much credit is due to Dr. Curtis for having been the first to perfect a rational and scientific method of treating injured vocal cords by natural means.

The steps by which Dr. Curtis arrived at his method are very interesting. Briefly, he noticed in certain cases that on phonation the slit of the glottis was concave and the cords farther apart than usual, with a consequent loss of tension, weakness of attack, and inability to "hold" the note.

In another class of cases he found that though the patients had precisely the same symptoms the slit of the glottis was convex, the vocal cords touching each other at a certain point, where, from constant attrition, a nodule had developed.

On inquiry he found that in the first class the singers practised exclusively with the sound of long O and with no attention to respiration, and that the second class used the sounds Ah and long E, in their exercises, with the explosive attack known as "coup de glotte."

It occurred to the author to have the first class exercise with Ah and E, the second with O, with the exceedingly interesting result that the inflamed cords rapidly rehabilitated themselves, or, as he puts it: "To our utter surprise we found both pupils absolutely cured of the symptoms of which they complained, at the end of a very few lessons, and each roundly denounced the method and the teacher who had led them into such error."

It goes without saying that in either case, while the change in the exercises temporarily relieved the pathological condition, constant practice would simply have changed one condition for another.

Dr. Curtis, therefore, was led to seek some exercise and method of attack in which the vocal cords should be to all intents and purposes parallel in the emission of all notes, and the glottic aperture neither convex nor concave.

The exercises by which this end is accomplished are fully described in the work. It only remains for us to say that of our own knowledge a number of singers have adopted the same, not only to the temporary relief of their inflamed vocal cords, but to the permanent preservation of their voice.

We cannot too heartily recommend this excellent though simple method to those who have the care of the speaking or singing voice, and we hope that the laryngologists will throw aside all prejudice in the matter and make a trial of what Dr. Curtis recommends, on its own merits.

We have devoted considerable space to this particular chapter, but the whole book is well done and suggestive, written in a scientific spirit, and contains much that is new, especially the chapters on respiration and the registers.

THE TOXIC AMBLYOPIAS: THEIR CLASSIFICATION, HISTORY, SYMPTOMS, PATHOLOGY, AND TREATMENT. Being an Essay to which was awarded the Alvarenga Prize of the College of Physicians of Philadelphia, October, 1894. By G. E. DE SCHWEINITZ, A.M., M.D., Professor of Ophthalmology in the Philadelphia Polyclinic, Clinical Professor of Ophthalmology in the Jefferson Medical College. Philadelphia: Lea Brothers and Co.

THIS volume, consisting of two hundred and thirty-eight pages, is excellently printed in large type on good paper and is well bound. Section I. is devoted to the consideration of the classification of toxic amblyopias: quite an elaborate form of classification is adopted, based on the effect of the different agents on the eye, on the central and peripheral nerve tissue, and on the system at large. Section II. takes up the consideration of amblyopia from alcohol and tobacco and considers it exhaustively. Points for the differential diagnosis between the amblyopia from alcohol and tobacco and those from non-toxic retro-bulbar neuritis, disseminated sclerosis, locomotor ataxia and "scotomatous atrophy of optic disc" are given. The toxic effect produced by alcohol and tobacco, bisulphide of carbon, iodoform, nitrobenzol, coal-tar products, arsenic, lead, mercury, ergot, the anæsthetics, opium, cannabis indica, quinine, salicylic acid, filix mas, and many other less important substances are discussed. The extensive bibliography appended to each division of the subject and the reports of original research indicate the exhaustive nature of the author's inquiry. Prolixity in the wording of the text is avoided without impairing the clearness with which the facts and theories are presented. It is little to say that the work reflects great credit on its author: it affords a comprehensive exposition of the subject up to date and is of value to the general practitioner as well as to the specialist.

THE FUNCTIONAL EXAMINATION OF THE EYE. By JOHN HERBERT CLAIBORNE, JR., M.D., Adjunct Professor of Ophthalmology, New York Polyclinic. With twenty-one illustrations. Philadelphia: Edwards and Docker Co., 1895.

THIS volume, consisting of ninety-six pages, is well printed from good-sized type. Aside from the printer's art the volume has nothing to commend it. Under the title "The Functional Examination of the Eye" the subjective examination of the refraction only is considered, a very small part of the work indicated by the title. This might be condoned if the topics treated of were well presented; as it is, the style leaves much to be desired. The statements made exhibit a lamentable degree of inaccuracy in many instances. Instead of being concise and lucid, many of the passages are verbose and difficult to understand. The chapter on mydriatics is probably the best one in the book, but it fails to mention the danger of exciting acute glaucoma in elderly individuals by the use of such drugs as atropine and duboisine. There is no index.

A Loud Heart Murmur.—Dr. F. R. Gibbs reports a curious case in *The Lancet* of April 4, 1896: The patient, a bright and intelligent schoolgirl, aged fifteen years, belongs to a family many members of which suffer either from phthisis or cardiac disease. Her personal history is good. She has never suffered from any serious ailment and has always enjoyed fair health. The cardiac mischief causes no other symptom than the fact that she easily gets "out of breath." The heart is not enlarged or dilated, there is a good first sound, followed immediately by a murmur and a low second sound. The murmur is mitral, and this is the interesting feature of the case, for it can be heard when the patient is fully dressed at a distance of twelve feet or more. It can also be heard when with the chest exposed she is placed three feet away from a closed door and the listener is at the same distance on the other side in the hall. As might be expected, the murmur varies somewhat in intensity from day to day, but it is only very rarely that it cannot be heard a foot away from the chest without the stethoscope.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 25, 1896:

	Cases.	Deaths.
Tuberculosis.....	242	124
Typhus fever.....	1	0
Typhoid fever.....	5	2
Scarlet fever.....	86	10
Cerebro-spinal meningitis.....	4	5
Measles.....	453	20
Diphtheria.....	283	38

Dr. Jones (*N. W. Lancet*) lays down the broad rule that no examination of the heart can be considered completed when one has neglected to examine the patient in both the upright and recumbent postures.

Koch's Circuit.—To prove that a microbe is the cause of disease it must fulfil Koch's circuit. It must always be found associated with the disease; it must be capable of forming pure cultures outside of the body; these cultures must be capable of producing the disease; and the microbe must again be found associated with the morbid process.—*DA COSTA (Manual of Modern Surgery, 1895).*

Heart Pain.—Taking consecutively a hundred cases of coarse and decided forms of disease of the heart which have been under his own immediate care, the author has found that in just half the number there was no complaint whatever of pain in any part of the chest. Seventeen referred the pain generally to the front of the chest; fifteen to the back (especially between the shoulders); twelve suffered pain at the epigastrium; eleven suffered pains on the left side of the chest; while two referred their suffering to the right side. Those who localized the pains to the exact area of the heart were but eight, and of these two complained of it only after exertion. One described it as a sense of extreme soreness at the apex, while in another it partook of the character of neuralgia about the left breast. Only eight per cent. complained of pain directly referred to the situation of the organ diseased.—*A. ERNEST SANSON, M.D., F.R.C.P. Lond., "The Diagnosis of Diseases of the Heart and Thoracic Aorta."*

Induced Labor in a Case of Previous Cæsarean Section.—*Dr. Schlaepfer* records the case of a woman, twenty-seven years old, who was delivered by Cæsarean section of a dead child at the termination of her first pregnancy. Conceiving again a year and a half later, and desirous of having a child, and presenting a simple flat pelvis of the first degree, it was concluded to induce premature labor during the ninth month. This was with some difficulty effected after the introduction of a bougie and subsequently of a water-bag, the child being delivered after version. The infant was asphyxiated, but was resuscitated after some manipulation. The placenta came away after expression; the uterus contracted well and presented a depression upon its anterior surface, supposedly corresponding with the cicatrix of the previous section. This depression had not before been appreciable, nor was it so subsequently.—*Centralblatt für Gynäkologie.*

Hours of Sleep.—A healthy infant sleeps most of the time during the first few weeks, and in the early years people are disposed to let children sleep as they will. But from six or seven years old, when school begins, this sensible policy comes to an end, and

sleep is put off persistently through all the years up to manhood and womanhood. At the age of ten or eleven the child is allowed to sleep only eight or nine hours, when its parents should insist on its having what it absolutely needs, which is ten or eleven at least. Up to twenty a youth needs nine hours' sleep, and an adult should have eight. Insufficient sleep is one of the crying evils of the day. The want of proper rest and normal conditions of the nervous system, and especially of the brain, produces a lamentable condition, deterioration in both body and mind, and exhaustion, excitability, and intellectual disorders are gradually taking the place of the love of work, general well-being, and the spirit of initiative.—*The New York State Medical Journal.*

How Long Should the Treatment of Syphilis be Kept up?—*Kaposi (Wien. Med. Wochenschrift)* questions the effectiveness of the method of continuous treatment which *Fournier* praises and which consists in treating the disease for years, alternating between mercury and iodide of potassium. With a single course of treatment of several months, or two or three courses in two years, *Kaposi* has seen his patients get well and bring healthy children into the world. He considers it both useless and dangerous to prolong treatment beyond limit. He also thinks it quite possible that the great frequency of affections of the nerve centres, usually considered as due to syphilis, may be caused by a too prolonged treatment. The initial treatment should be continued for some time and carefully watched. The first treatment should not be repeated unless one is confronted by some unexpected accident. Occasionally syphilitics who are healthy in appearance and feeling may receive a second course of treatment during the first year. *Kaposi* considers syphilis a curable disease.

Physiology as She is Taught.—A twelve-year old boy wrote the following composition on "breath": "Breath is made of air. We always breathe with our lungs, and sometimes with our livers, except at night, when our breath keeps life going through our noses while we are asleep. If it wasn't for our breath, we should die whenever we slept. Boys that stay in a room all day should not breathe; they should wait till they get outdoors. For a lot of boys staying in a room make carbonic oxide, and carbonic oxide is more poisonous than mad dogs; though not just the same way. It does not bite; but that does not matter as long as it kills you."—*Bristol Medical Journal.*

Rampant Protectionism for French Physicians.—The *New York Times* is informed that French medical students are angrily complaining that they are crowded out of their own schools by youths from abroad, and French doctors are even more indignant because these foreigners, instead of going home after acquiring a knowledge of physics and surgery, settle down in France and compete with the native practitioners. Of the six thousand students in the Paris Medical School, it seems that one thousand are aliens, and the proportion is almost as large in provincial institutions, notably at Montpellier, where the students have just held a mass meeting and adopted resolutions in which they declare that "the invasion of foreigners constitutes an obstacle to our studies and a threat for the future." To prove the latter assertion, they point to the fact that already, of every five doctors in France, one is foreign born. As a remedy for these evils, *Dr. Brouardel*, the senior member of the Paris Medical Faculty, has seriously advised the Minister of Public Instruction to create a new and special medical diploma, which shall not confer upon its owner the right to practise as a doctor in France. This is certainly a most curious condition of affairs. Unfortunately, the statistics at hand do not reveal how many of these interlopers are American.

THE CLINICAL DIAGNOSIS OF VASCULAR LESION IN THE PONTO-BULBAR REGION, WITH ILLUSTRATIVE CASES.

By JOSEPH COLLINS, M.D.,

NEUROLOGIST TO THE CITY HOSPITAL, PHYSICIAN TO ST. MARK'S HOSPITAL,
NEW YORK.

ALTHOUGH the pons and the oblongata represent the crossing and close juxtaposition of many sensory and motor pathways, in addition to being the seat of origin of practically all the cranial nerves, yet so definite is our knowledge of these very intricate segments of the nervous system that from a viewpoint of semeiology and diagnosis we are able to localize a lesion in them with more accuracy than in many other parts of the nervous system which anatomically are much less complex. Diagnoses made clinically have received in many instances such accurate post-mortem corroboration that positive statements seem justifiable concerning the seat and confines of the lesion in such cases as I am about to report. The occurrence of vascular lesion, and by such I mean the lesion of hemorrhage, embolus, and thrombus, in this locality is not frequent, and when it does occur death, and that not long delayed, is the usual result. The cases reported herewith may be considered uncommon.

The following case of alternate hemianalgesia has a clinical history which points with accuracy to a definitely localizable lesion in the pons:

M. G—, male, thirty-nine years old; born in Sweden; married; by occupation a salesman. Sixteen years ago he had the initial lesion of syphilis, which was treated for five weeks until the primary manifestations disappeared. Since then he has had no anti-syphilitic treatment. A few months after infection he had the common cutaneous and mucous-membrane manifestations of syphilis. He has not been a very hard worker nor is he given to excesses of any kind. He has not suffered from rheumatism, gout, or any infectious disease, and, in fact, except for a tendency to constipation, he has been very well. On July 17, 1894, he ate excessively of beef, pork, cabbage, and pastry. After dinner he returned to his work, and soon complained of great pain and distress in the head and stomach. As his bowels had not moved for several days he attributed these symptoms to constipation, and for their relief he took a large dose of castor oil. He then complained of vertigo, was very much nauseated, and vomited severely. When he tried to stand his legs would not support him; the left side of the body seemed powerless. Although he could move the arm and leg he did not seem to have any strength in them. There was no loss of consciousness. On the way to the hospital he noticed that he saw everything double, and that speech had become thick. The next day he had trouble in swallowing; things went down very slowly and water and other liquids frequently regurgitated through the nose. Inability to articulate became more pronounced, and it was with difficulty that he could make people

understand. The inability to speak was not at all of the nature of aphasia, but a dysarthria rather, almost anarthria. There was continual twitching of the lower lid and of the portion of the face just below it. A short time after he was taken to the hospital he noticed a numb sensation in the left side of the face and the right side of the body, although he could feel a touch in these parts. He remained in the hospital six weeks, and during this time the diplopia had begun to disappear and speech had become somewhat more intelligible. Hiccough was a very troublesome symptom during two weeks of his stay in the hospital. The vertigo and unsteadiness still continued, and when he left the hospital, although he had the use of his extremities, he was so uncertain in gait that he had to be steadied.

On September 25, 1894, he entered Prof. C. L. Dana's clinic. The patient, a tall man, appeared well nourished. He walked without trace of paralysis, but with an uncertainty of gait which reminded one of a drunken person. When he stood it was with the feet wide apart; when he walked he was obliged to steady, not sustain, himself with a stick, and the feet were widely separated to give him a broad base of support. The right side of the body was stronger than the left, and the knee jerk on the left side was livelier than on the right. If the patient was balanced he could support the weight on either leg. The left upper extremity was weaker than the right. Examination for sensory defects revealed the presence of analgesia and thermo-anæsthesia of the right side of the body from the middle of the neck downward, and of the left side of the face and head. The following diagram gives a graphic representation of the sensory defect (Fig. 1).

FIG. 1.

Sensibility to touch, as well as the muscular sense, was preserved. The strongest spark from a static machine applied to the right side of the body did not cause a wince, and on the right side of the body and the left side of the face the patient could not discriminate between a test tube containing hot water and one containing water ice cold. Examination of the eyes showed paresis of the external rectus of the left eye, homonymous diplopia at all distances, paresis of the superior rectus of the same eye, the false image above the true one. A prism of 9° base up fused the images. Analgesia of the cornea of the left eye, redness, and continual lachrymation; and, in addition, a congestion of the optic disc of the left eye and a fulness of the veins of the fundus. Right eye normal. Slight evi-

dences of defective innervation of the seventh nerve, particularly in the lower part of the face of the left side. Voice nasal and whining, but no dysarthria.

Examination, February 3, 1895: Station and gait were improved, but he stood and walked with widely separated feet. No evidence of motor hemiplegia. Tongue deviated slightly to the left, although this was more apparent than real, as the left side of the mouth was not drawn back as far as the right. The soft palate and upper portion of the vault of the pharynx were raised higher on the right side than on the left. No pharyngeal anaesthesia. The left eye was red and continually irritated. Persistent treatment was necessary to check ulceration of the cornea, which began some months before. There was evidence of vasomotor paresis, and a continual redness of the left ear. Sensory examination revealed practically the same condition as when the patient was last seen. A pin could still be jabbed into the flesh of any part of the right half of the body to the distance of half an inch without causing any pain. The cornea of the left eye was so anæsthetic that the blunt end of a pencil could be rubbed across it. Pulse, 80; respiration normal, but labored on exercise. There was some difficulty in swallowing water; it seemed to stick in the throat, but did not regurgitate. Speech was somewhat nasal and whining. There was a great deal of frontal headache, occipital dullness and heaviness, and vertigo. The legs tired very easily and the right side particularly, but he was able to do some work if he remained seated. He was easily excited and made nervous. Ocular conditions were the same as before, but he said he used the right eye to see with and consequently did not have diplopia.

Examination, July 15, 1895 (one year after onset of disease): He complained of feeling bad in the head and of a continual staggering feeling. He said that if any one called him or he was interrupted suddenly, or if he attempted to get out of the way of anything, such as a vehicle or a car, he became all mixed, all turned around, could not quite appreciate his surroundings, and was unable for some time to orientate himself properly. The right leg felt weaker than the left, and he had a tendency to walk, to stagger, and to fall toward the left. He could walk all right if he steadied himself with a stick, and he did not tire very easily. He had no trouble in swallowing anything except cold drinks. If he took a drink of water the first one or two swallows went down all right; then the next seemed to stop in his throat, and he "had to push it down." Fluids did not regurgitate. He could whistle and cough, and in the latter gave a good tone; but he could not sneeze. He felt worst on arising in the morning; his legs were stiff and he had heavy, dizzy sensations in the head. It did not make his face tired to chew food or to talk. Noise distressed him more than anything else. It gave him a confused, restless, disturbed feeling in the head, particularly in the left parieto-temporal region. When one touched, rubbed, squeezed, or applied electricity to the outside of the right arm, the patient felt a pulling sensation in the left side of the head. His gait was that of a drunken man, with a tendency to fall to the left. Knee jerks equal on both sides. Dynamometer: right, 95; left, 80. Relatively there was the same strength in both legs. Tests for sensibility: Patient felt the slightest touch of cotton on the right side as well as on the left; the area of analgesia was the same as before, but the intensity of it was much less; although he did not feel the prick of a pin, it did hurt if it was jabbed in, and the strong sparks of a static machine were uncomfortable; there was still thermo-anæsthesia, but compared with that present on the first examination it was much less. Muscular sense was preserved. There was less anæsthesia of the left eye than formerly, the touch of

the blunt end of a pencil or of cotton causing him to wink. There was evidence of previous trophic changes in the left cornea and also haziness. After first coming under treatment the patient gained between thirty and forty pounds, and became obese and unwieldy. This increase he was now rid of. He was again able to work at his former occupation, but earned only something more than one-half of his former wages.

December 28, 1895: The right side of body and the left side of face were less analgesic than on previous examinations, but lack of pain sensibility was yet well marked. Tactile sensibility in all parts of the body was exquisitely preserved. There was distinct perversion of thermal sensibility on the right half of body and left side of face. Cold was almost always felt as hot, and in certain places, such as the right side of the abdomen, it caused a "burning" sensation. It is to be remarked, however, that this perversion of temperature sense was not so much a thermal anæsthesia as it was a latency of thermal recognition. Thus, he said that he often burned the right hand and did not know it till after it was done. There existed a persistent association of cephalic sensation and impressionability of the right upper extremity to irritation. For instance, if the right hand was put in cold water, he complained of a tingling, tense, pulling sensation in the left side of the head—not in the epicranial structure but deep down "in the brain." These sensations were in that part of the head where the motor areas are located. Muscular and articulatory senses normal. Slight ataxia of the left upper and lower extremity. Slight tendency to fall to the left. Knee jerks normal.

To recapitulate briefly the symptoms in this case in the order of their occurrence:

1. Vertigo of sudden onset and great severity.
2. A feeling of loss of strength in the left side of the body.
3. Diplopia, homonymous, due to paresis of left external rectus.
4. Dysarthria.
5. Dysphagia.
6. Irritation symptom: persistent twitching of the left lower lid and of the part of the face below it.
7. Crossed hemianalgesia and thermo-anæsthesia.
8. Involvement of lower portion of left facial.
9. Ataxic paresis of the right half of the body, more of the upper than the lower extremity.
10. Paresis of the superior rectus and analgesia of the cornea of the left eye.
11. Gait unsteady, tendency to fall toward the left.
12. Difficulty in quick physical orientation.
13. Diminution of sense of hearing in the left ear.

The treatment to which he was subjected consisted of the persistent administration of iodide of potassium in moderate doses and the vigorous use of tonics, graduated exercise, electricity, massage, etc.

Let me now refer briefly to the nature of the lesion in this case before speaking of its localization. The fact that this patient had syphilis which received no treatment save local applications, and the fact that the attack came on suddenly and that it had not been heralded by premonitory symptoms, speak in favor of rupture of a blood-vessel rather than a blocking-up of its calibre, as does likewise the persistence of the symptoms and their slow amelioration. The influence of syphilis in determining rupture of blood-vessels in the brain has not received the emphasis and recognition which the statistical frequency with which it is an antecedent of hemorrhage warrants. This fact is well brought out by Dana in a recent contribution to the cerebral apoplexies.¹ The influence of severe indigestion in precipitating an apoplexy has often been alluded to. Syphilis is a most important causation of

¹ MEDICAL RECORD, February 23, 1895.

thrombosis of the blood-vessels in general, but suddenness of the attack, absence of premonitory symptoms, and slight amelioration of the symptoms are not suggestive of thrombosis. The intactness of the valvular apparatus of the heart and the absence of any source from which it might arise bear evidence that the disease was not the result of an embolus. Yet withal, rupture of one of the vessels of the pons is an extremely rare occurrence, and the diagnosis of hemorrhage is at best but problematical, while the comparative frequency of thrombosis makes the latter probable. If the original lesion was hemorrhagic, the focus must have been very small and the ruptured vessel very slight. Hemorrhage into the pons is survived very exceptionally. Its occurrence is attended by loss of consciousness, which almost always is the precursor of dissolution. Repeated attacks of general convulsions which often occur bespeak the same issue. A lesion in the pons which will produce convulsions must either be of considerable extent and severity, or it must be in the immediate vicinity of the motor tracts, as the convulsions are caused by irritation of the latter. On the other hand, if the lesion were a thrombosis of specific origin, it is probable that the area of softening which would result, or a recurrence of the thrombosis, would have caused other symptoms before now. If it were a hemorrhage and a very small one, there would have occurred in a few days after the attack a coagulation of the blood, which would become softened and resorbed, and then a fibrinous wall about the little cyst would form, which, contracting, would leave only a small cicatrix. The slight destruction of tissue about this and the secondary degeneration would account for the course of the disease since then and the surviving symptoms.

A retrospect of the findings on examination of this case shows that there was defective action of the external rectus, which is supplied by the sixth nerve; analgesia of the left side of the face and left eye in the territory of the sensory distribution of the fifth nerve. The fact that the patient had no difficulty in chewing and that this exercise, likewise talking, did not make the face tired, shows that the motor division of the fifth nerve was intact. Immobility of the mimic muscles in the lower part of the face showed the involvement of part of the seventh nerve or some of the cells forming its nuclei. Analgesia and thermo-anæsthesia of one-half of the body and of the opposite side of the face and head indicate a disturbance in the tract of the sensory pathways which conduct pain and heat sensations at a location brainward to their complete decussation. The striking disturbance of gait and orientation which the patient presented are considered typical of cerebellar disturbance. The disturbance of hearing in the left ear which the patient noticed shortly after the onset of his disease, and the continuance of it to the present time, and particularly the distress in mind and body produced by noises, bespeak some involvement of the pontine eighth nerve, *its* nucleus, or, barely possible, the nucleus of Deiter. It is now well established that such disturbance of equilibrium may be explained by the involvement of those fibres of the auditory nerve in the pons which convey equilibrium sensations to the cerebellum. The distressing vertigo from which the patient suffered and from which he yet suffers is a frequent symptom of pons lesion, when the lesion involves the lateral portion or when the fibres of the middle and inferior cerebellar peduncles are involved. It may also be the result of involvement of the intra-pontal portion of the auditory nerve. The anarthria and dysphagia, the latter due to involvement of the motor glosso-pharyngeal, are common symptoms of disease of the pons, and are often referred to as cerebral pseudo-bulbar symptoms. The very slight ataxic paresis of the right side may

indicate an involvement of the tract of muscular sense, which in the pons is known as the fillet or lemniscus. The fact that there was never any motor hemiplegia in the literal interpretation of such designation, and the fact that there are not now nor has there been any evidences of secondary degeneration in the motor pathways, such as spasticity, exaggerated reflexes, clonus, etc., which would necessarily have followed if the continuity of any motor conducting-paths had been interrupted, goes to show that the lesion did not implicate those tracts. That the only focus of disease that will produce such a grouping of symptoms must be located in the posterior or dorsal portion of the pons, and in its middle third, is very apparent. A lesion which produces alternate hemianalgesia, thermo-anæsthesia, slight ataxic paresis, and involvement of the fourth, fifth, sixth, seventh, and eighth nerves, must be in the reticular formation of the pons on the side opposite to which the analgesia is in the extremities, and on the same side as the facial involvement. It must involve some of the fibres of the fillet or lemniscus in order to cause the ataxic paresis. It must encroach upon the nuclei or emerging root fibres of the sixth, seventh, and eighth nerves in order to account for the homonymous diplopia, the lower facial palsy, and the disturbance of hearing. The cerebellar gait, or, better, the disturbance of equilibration, the mental confusion so readily produced by auditory impressions, and the tendency to fall toward the left, may also be explained by involvement of the intra-pontal portion of the latter nerve, or at least that part of it which conveys impulses to the cerebellum. To account for the paresis of the superior oblique muscle on the left, it is necessary that the lesion interfere with the conductivity of the left fourth nerve fibres after its crossing between the two superior cerebral peduncles and behind the upper part of the fourth ventricle in the superior medullary velum—that is, the issuing root of the opposite fourth nerve as it passes through the ventral part of the pons. The fact that there was no paralysis of the extremities indicates the integrity of the pyramids, and, moreover, it shows that the lesion was not sufficiently anterior in the pons to interfere with any of those fibres. The integrity of motion of the parts supplied by the fifth nerve shows that the lesion did not extend very far laterally. It is worthy of notice that the patient avers that he has had a tendency to fall toward the left—the side on which fibres going to the cerebellum, auditory or other, must be involved. Although much significance is not attached to the symptom to which side the patient tends to fall, yet the common opinion is that such a tendency is toward the side opposite to which the disease is located.

There are a few cases similar to this in the literature, some of which are accompanied by post-mortem details, while others are clinical studies. A case reported by Weir Mitchell¹ resembles it somewhat. Starr² has recently reported a case in which the symptoms correspond very closely to those of this one, except in his case the sixth and eighth nerves were not permanently affected.

In a case reported by Senator³ a fifty-six-year-old man awakened one morning and complained of vertigo, difficulty in walking, tendency to fall to the left, disturbance of speech and of swallowing, and a sensation of cold in the left half of the face. Examination showed no disturbance of consciousness, tachycardia, tendency to fall to the left on standing and walking. On lying down there was no ataxia, and the performance of movements was unimpaired. There was no paralysis of the tongue or palate, simply difficulty in swallowing and hoarseness, which was due to in-

¹ Transactions of the Association of American Physicians, 1892.

³ Archiv f. Psychiat., vol. 11, p. 713.

complete apposition of the vocal cords. Sensibility in the left half of the face and on the right half of the body was completely lost. The left half of the tongue, the left cornea, conjunctiva, and nasal mucous membrane were also anæsthetic. Skin reflex normal, patellar reflex lost on both sides. Hearing and taste normal. The autopsy showed a thrombosis in the course of the left vertebral artery and an area of softening in the outer inferior portion of the left half of the medulla. The thrombus was situated at the point of exit of the anterior spinal and the posterior inferior cerebellar. The area of softening extended above as far as a cross-section of the crus pontis, and below almost to the apex of the calamus scriptorius, turning inward to the raphe and reaching apparently as far as the vagus nucleus. Externally and laterally it seemed to project further brainward into the pons. Microscopically it was seen that the focus involved the left restiform body, the neighboring portion of the funiculus cuneatus, and the lateral column, as well as the ascending root of the trigeminus and a portion of the vagus nucleus. The fact that in this case of Senator's there was no involvement of the sixth, seventh, and eighth nuclei, shows wherein it differs from my case. This is explained by the fact that in the latter the lesion was in relatively the same plane but at a different level; that is, it extended further brainward. Otherwise the cases are very similar.

In my case, therefore, the localization of the lesion is as follows: It is situated in the pons at the level of its middle third below the point where the ascending and descending roots of the fifth nerve unite. The structure known as the *formatio reticularis* is the part chiefly involved. On account of absence of paralysis the lesion must be dorsal of the pyramids. It has some extent in the dorso-ventral plane—sufficiently far to involve some fibres of the lemniscus, thereby causing ataxia of the anæsthetic limbs. It must extend some distance in the cephalo-caudad plane—caudad sufficient to produce involvement of the sixth, the eighth, and possibly the ninth, but not sufficiently cephalad to involve the third nucleus. Laterally it involves the seventh, and mesially it extends to the eighth.

CASE II.—Bulbar thrombosis. C. J. R.—, single, thirty-two years old, occupation detective. Father died of tabes, mother of nephritis. There is nothing in his personal history bearing on the present illness. A few years ago he had a cough and occasional slight hæmoptysis, from which he recovered. He has been a moderate but steady drinker, rather intemperate sexually and in the use of tobacco. He denies rheumatism, syphilis, and infectious disease. His present trouble began in the spring of 1893. Previous to the attack which we are about to describe, he had had a great deal of frontal and occipital headache, which he attributed to "biliousness," and for some days immediately antecedent to the attack he felt depressed, nervous, and easily agitated. One Sunday morning in the spring of 1893, while riding down-town in a horse-car, he remarked that he could not control the face, that it would twitch, particularly on the right side. This was disagreeably apparent to him when he found himself smiling at a person whom he did not know and whom he had no desire to greet. Later he noticed that his speech was not so distinct as usual and that articulation had a tendency to be stumbling and incoherent, quite like that of a drunken person. He does not recollect that it had a nasal twang. He could not handle properly the right side of the face; that is, it would not obey his wishes. On eating, food would get between the gums and the cheek and would have to be dislodged with the finger. While asleep saliva would dribble from the right side of the mouth. There was no trouble in swallowing, at least

his attention was not attracted to it. At this time there was some weakness of the left side of the body, of both arm and leg, and although the right side of the body was not parietic, it was nervous and trembling. He could not write very well with right hand, not because it was weak, but because he could not control it properly. The strength of the left side of the body was more impaired when he felt cold. He remembers that it was impossible to whistle at this time nor could he wink the right eye. He remained at work and continued to smoke, but noticed that his cigar would go out continually while smoking it. These symptoms lasted about six weeks and gradually passed off. During the following summer he considered himself quite well, except that two drinks of whiskey would go to his head and make him feel drowsy, weak, and queer; previous to the attack he could take from eight to twelve drinks a day without any disagreeable manifestations. He noticed also that he was extremely nervous and prostrated after coitus. Smoking would affect him very much the same way as whiskey. During the summer he had considerable headache, tired easily, was irritable and impatient, lost confidence in himself, and had cramps in the legs frequently. In the beginning he took rheumatic medicine for a few days, but aside from this he had no treatment.

The second attack was on November 22, 1893. He was on duty in the depot of a neighboring city where he had an assignment. While waiting he noticed that his speech was getting thick and indistinct; he talked as if he were extremely drunk. Speech continued to grow worse during the day, and the next morning he noticed that it had a peculiar nasal twang. Previous to this time his voice had no nasal intonation. The morning of the day following the attack there was lack of mobility in the use of the face and lips, and three days later there was great trouble in swallowing. It was hard work to get anything down; water would choke him, but would not regurgitate through the nose. Solids went down with more readiness than liquids, but very slowly. On the second day after the attack he remarked that the left half of the body was very weak, the arm weaker than the leg. It was very difficult to lift the arm above the head and the left leg dragged, particularly when he got nervous or excited. He remarked also that the lower lid of the left eye was hanging, that he could not close this eye, and that the left side of the face would not respond to the will. Later, on attempting to shave, he could not make tense the skin over the left side of mouth by endeavoring to compress the lips. When he laughed the corner of the mouth would pull to the right side. Bladder, bowels, vision, hearing, and taste seemed normal. Cardiac palpitation was troublesome, and he was very much frightened. Emotionally he was easily upset and was particularly prone to tears without assignable cause. There were no pain, paræsthesiæ, or objective sensory symptoms, so he states. After several weeks the symptoms began to abate, the difficulty in swallowing being the first to improve, then the weakness of the left extremities.

Examination February 20, 1894, three months after second attack: General appearance that of a moderately well-nourished young man. Immobile, staring expression of countenance. Ocular aperture equal on both sides; pupils contracted to light and accommodation; range of mobility of eyeballs limited; visual and color field unchanged; optic nerve normal in appearance: vision $\frac{20}{30}$, both eyes. Ears, R. H. D., $\frac{9}{14}$ with watch; L. H. D., $\frac{14}{14}$. Tuning-fork heard, right, twelve seconds; on mastoid, six seconds. Left, heard ten seconds; on mastoid, six seconds. No change after inflation. Membrana tympani dull and in-drawn. Sense of smell and taste normal. No noticeable asymmetry

of facial innervation; on smiling the aperture of the mouth was slightly greater on the left side; he could puff out both cheeks equally. No defect of sensibility in the area of distribution of the trigeminus. Tongue somewhat immobile, more unwieldy in movements toward the left. Anæsthesia of the fauces, tonsils, and pharynx. The palate was raised sluggishly on intonation. He had difficulty in puckering and compressing the lips and could not whistle. Speech drawing; voice had marked nasal twang, especially with such letters as b, d, j, p, q, u, v, etc. When asked to repeat the alphabet he became mixed toward the last. Station good; gait natural. No static or sensory ataxia of upper extremities. Knee jerk increased on right, normal on left. Same with elbow reflex. Grip of right hand nearly double that of left; similar disproportion in strength of legs. No apparent muscular atrophy. Tremor of both hands, more of the right than of the left. Pulse, 96. He frequently felt faint, especially when excited or nervous. Face readily became blanched or suffused. Slight trouble in swallowing. Larynx: abduction of vocal cords normal; anæsthesia could not be made out. Efforts at coughing were toneless. He complained of being very nervous and was exhausted easily, especially in the afternoon; he had a sensation as if something was holding him down, pushing him down by the head, a sinking sensation. It fatigued him to talk and to eat. Sleep was not refreshing; he felt stiff and cumbersome in the morning. He was emotional and had crying-spells. Noises and excitement had a very bad effect on him.

It is unnecessary to give in detail the results of careful and repeated electrical examinations that were made, other than to say that the facial nerve and the muscles supplied by it responded to the faradic and galvanic currents on both sides. Although the records show individual variations at different times, they were not constantly in favor of either side and reaction of degeneration was never present.

Examination six months later, September 24, 1894, revealed practically the same conditions, except that there was slight diminution in size of the left upper and lower extremities, particularly manifest in the shoulder and thigh. The left half of the body was weaker than the right, and myotatic irritability, manifested by increased elbow and knee jerks and ankle clonus, was greater on the left side. There were no sensory disturbances except the loss of sensibility in the fauces and pharynx and absence of the palatal reflex. The tongue was less unwieldy, did not get caught between the teeth, and substances that he swallowed had no tendency to get into the larynx. He had gained eight pounds in weight, was not so emotional, had no syncopal attacks, could read a long sentence without stopping to breathe, and he did not become fatigued so easily. He had a stiff neck very often and a heavy dull feeling in the back of the head. Faradic contractility on both sides of the face was equal, the cheeks, lips, and muscles supplied by the fifth and seventh nerves all responding. The tongue felt flabby and showed sluggish electrical irritability.

Examination, July 2, 1895: He complained of general weakness, backache and headache in the morning, which wore off after he had been up for a time. There was considerable pain in the back of the head and in the eyes, particularly if he became tired. Fermentative dyspepsia continued, a symptom which had been troublesome from the beginning. When the head bothered him he had a weak, faint sensation in the stomach; when he became nervous, the contents of the stomach soured, and he felt a fluttering sensation in the abdomen and had an evacuation of the bowels. He had better control of himself generally and more confidence; speech was better until he became tired; then it was nasal, squeaky, and drawing. He com-

plained of a dry sensation in the throat; when nervous he had a tense drawing sensation in the lips and mouth, as if a rubber band were stretched across it, could not raise his voice, and felt that it was held by something at the pomum Adami. Fluids did not regurgitate except in gargling, when if he happened to throw the head back fluids would come through the nose. He had no feeling, he said, in the back part of the mouth and throat, and noticed that when he went in bathing he had to be very careful that water did not get into the air passages. Bladder, bowels, and sexual functions normal. He had seminal emissions when fatigued. Circulation good. All the symptoms were greatly accentuated when he was tired; at such times he could not keep his eyes fixed on an object and had a feeling that some one was stuffing cotton in the eyes and in the left ear. Taste, touch, and smell normal. He could make a whistling noise, but not a tune; cough was nearly toneless. He swallowed fluids and solids equally well, but had to be careful, for if he attempted to swallow rapidly he choked. Occasionally the tongue would get in the way of the teeth, especially if he was excited or tried to hurry; he was unable to draw the tongue down on the right side. Partial paralysis of the soft palate, palato-glossus, and palato-pharyngeus muscles. Anæsthesia of the soft palate and of the back of the pharynx. Paresis was shown by the inability to draw the muscles of the soft palate upward. No anæsthesia of the epiglottis or of the larynx. The epiglottis seemed to close properly when the patient had singultus. In the larynx a partial paralysis of the arytenoides caused incomplete closure of the cartilaginous glottis. The imperfect tension of the vocal cords signified imperfect innervation of the crico-thyroid. Abductor muscles normal. The palato-pharyngeal reflex was slow and when a bit of cotton was carried into the palato-pharyngeal vault it was keenly felt. The patient was able to stand easily on either foot; the tendon jerks were exaggerated on the left side; the superficial reflexes were normal. Dynamometer: right hand, 95; left hand, 75. There was no ataxia of station or of locomotion. When he tried to shut the eyes an involuntary grimace resulted. An extremely annoying symptom to the patient was involuntary and uncontrollable smiling. These outbursts might be the result of some excitation by no means humorous. For instance, when riding in a car or sitting in church or theatre, if he happened to meet a woman's eye, his face would break into a smile or broad grin. The upper lid of the left eye and the left side of the face were not so expressive and were less mobile than the right side. Voice about as formerly, bulbar. With some amelioration of the symptoms, and a moderately good condition of his general health and strength, which allowed him to earn a living by a light occupation, this represents his condition to-day, now more than two years after the original trouble.

A brief recapitulation of the symptoms shown in first attack:

1. Premonitory symptoms of some weeks' duration; then twitching of the right side of the face.
2. Gradually increasing dysarthria.
3. Immobility of the right side of the face. Inability to wink right eye.
4. Some weakness of left half of the body.

These symptoms gradually abated, but he remained very nervous and very susceptible to all sorts of excitation.

Several months later a second attack of sudden onset occurred.

1. Dysarthria, rapidly increased, nasal twang.
2. Dysphagia.
3. Weakness of the left side of the body, slight hemiplegia.
4. Left side of face immobile.

5. Examination some time later showed no cutaneous sensory disturbance.

6. Hemiparesis of the left side.

7. Exaggerated tendon reflexes on the left side.

8. Tongue somewhat immobile; some anæsthesia of the fauces, tonsils, and pharynx; difficulty in puckering the lips; inability to whistle; speech drawling and nasal; dysarthria; some tachycardia.

9. Partial paralysis of the arytenoideus, imperfect innervation of the crico-thyroid.

10. Involuntary smiling and grinning, uncontrollable.

11. Some atrophy of the musculature of the tongue and slight wasting of the left upper and lower extremities.

12. General bulbar symptoms, vasomotor, tremor of hands, emotionalism, band sensation around lips, nervousness, amyosthenia, etc.

First, as to the nature of the lesion. The age of the patient is against hemorrhage; the absence of a syphilitic, rheumatic, or diathetic history against thrombus; and the integrity of the valvular apparatus of the heart against embolism. Nevertheless, the premonitory symptoms, extending over a considerable time and varying from day to day dependent upon the condition of the patient's vitality and the inroads being made on his stock of vital resistance; the gradual onset of the disease; the severity of the first attack, reaching its height only after several hours, and then the slow amelioration after the symptoms had persisted for a time, bespeak unequivocally, the absence of diathesis or previous syphilis notwithstanding, in favor of thrombosis. The occurrence of a second attack, although not in the same blood-vessel or locality, bears testimony, I believe, to the correctness of this view. We are assisted in the localization of the lesion in this case not alone by a consideration of the symptoms briefly recapitulated above, but by a consideration of the symptoms that are absent. In the first place, integrity of the third, fourth, fifth, sixth, seventh, and eighth nerves; the absence of sensory disturbances, tactile, thermal, pain, and muscular in the face as well as on the body; and the absence of equilibrium disturbance exclude a pons lesion. (We have taken it for granted that the symptom complex is either pontal or bulbar.) The twitching of the face and the succeeding immobility are irritative symptoms of the seventh nerve or nucleus involvement. The fact that there was no diminution of faradic irritability or a more susceptible response to the positive than to the negative pole, that is, reaction of degeneration in the seventh nerve and its musculature, shows that the involvement of the seventh was of sufficient severity to produce irritation but not to produce paralysis. Dysphagia and anæsthesia of the soft palate and back of the pharynx point to involvement of the glosso-pharyngeal; tachycardia and paresis of some of the intrinsic muscles of the larynx to the pneumogastric. The integrity of the spinal portion of the eleventh is shown by the equality of the shoulders and normal appearance and activity of the trapezius and sterno-cleido-mastoid muscles of one side as compared with the other. Involvement of that portion of the eleventh which comes from the medulla is shown by paresis of the vocal cords and velum palati. The involvement of the twelfth nerve is shown by the dysarthria, by the diminution of the mobility of the tongue, by the ease with which it becomes fatigued, and above all by the diminution in volume which the tongue has undergone.

Thus it will be seen that the lesion must have involved the ninth, tenth, and twelfth nerve nuclei. In addition there was motor paresis of the left side, which, although now considerably less than in the beginning, is still apparent on examination. There are also to be elicited on this side of the body physical

signs, such as increased myotatic irritability, exaggerated triceps and patellar reflex and ankle clonus, for the occurrence of which we may positively postulate a lesion somewhere in the motor tract which has caused a secondary degeneration to go on from the level where the focus is situated to the end of the fibres whose continuity it severs. That is, starting from the lesion, there has formed in the pyramidal tracts extending downward a pathway of connective tissue. It is to the presence of this newly formed tissue in the place of the normal neuraxons that we attribute the weakness of the left side of the body and the increased myotatic irritability. The cranial nerve involvement points to a certain level in the medulla. It is natural to infer that the involvement of the motor tract is at the same level, and as this level is above, or brainward to the decussation of the motor tracts, the lesion must be on the side of the medulla opposite to the hemiplegia, viz., on the right side. We may say, therefore, that the lesion in this case is on the right side of the medulla, extending above from the nucleus of the ninth (the glosso-pharyngeal emerging immediately below the facial) down to near the beginning of the motor decussation. The severity of the lesion has been expended principally in a ventro-dorsal direction and not laterally, as the absence of sensory disturbances, of ataxia, and of incoordination indicate. The intensity of the anatomical lesion was probably from below upward, as the slight involvement of the facial indicates. The symptoms now resemble those of an ordinary case of bulbar paralysis, except that they are more unilateral and less progressive. In fact, in this case the symptoms are not progressive, they are retrogressive. In the usual case of bulbar palsy of two years' duration it would be very unusual if the patient were able to return to work. It is probable that the anatomical condition at the bottom of not a few cases of bulbar palsy is primarily thrombotic in the beginning. But in most of these cases the process of thrombosis is a slow one, and occurs coincidentally in more than one small vessel, so that the secondary process is a slow but progressive one, and partakes more of the nature of a slow degeneration depending upon insufficient blood supply than it does of a sudden inhibition of function due to cutting off a considerable blood supply and a partial restoration when vascularity has become readjusted. In this case the artery that was thrombosed was the right anterior spinal, a branch given off from the vertebral immediately after the posterior inferior cerebellar. The median branch of this artery passes dorsally in the raphe and divides in the median portion beneath the nuclei situated near the floor of the fourth ventricle. The pyramids are supplied either from this artery or directly from the vertebrals. It is well to remember that the artery on the right side, the side in which the lesion is situated in this case, is very much smaller than the left.

Of the symptoms that have been enumerated, one or two deserve especial mention. The attacks of involuntary laughter or grimacing of which the patient complained are interesting. These manifestations in the emotional muscles, aside or divorced from any psychical accompaniment of the emotional state, have been noticed in other focal diseases of the brain, particularly in capsular lesion (Bechterew), in lesion of the basal ganglia (Brissaud), in lesion of the bulb (Collins), and in multiple sclerosis. They are to be explained on the supposition that the reflex centres in charge of the physical or mechanical side of the emotional display are, by reason of disease in themselves or on their connection, disassociated in part from the higher centres which preside over the psychical side of the emotions. In such case the normal relationship existing between the psychical areas and the

purely reflex is perverted, and cognizance of the former to a pleasurable impression may be manifested by tears, or *vice versa*. In a similar way may be explained the absence of inhibition of which these patients complain. An impulse coming down from the psychical areas is not given the usual reception by the reflex centres, on account of their disease, and the result is that the efforts at inhibition or control go askew.

CASE III.—E. M.—, thirty-one years old, by occupation a painter, entered the hospital for nervous diseases in September, 1894. He is married and the father of three healthy children. In March, 1894, he had a severe diarrhoea which lasted for some weeks; cause unknown; eight to ten stools a day. Present illness began in May. The onset was sudden. He was all right the evening previous to the onset of his illness. The first symptom was a severe prolonged chill, followed by violent vomiting—hæmatemesis. Shortly afterward he became delirious. He was treated in Roosevelt Hospital for pneumonia. After he had been in the hospital about two weeks it was noticed that he could not talk plainly; speech became stumbling and nasal; fluids came through the nose; finally articulation became so imperfect that his wife was quite unable to understand him, and he had trouble in swallowing.

Examination, February 27, 1895: Face expressionless and staring; mouth open; lower lip hanging; he looked as if about to cry. Body not emaciated; circulation fairly good; pulse rapid and weak. He was unable to whistle, but could puff out the cheeks. There was no dribbling of saliva. The tongue could be protruded and turned from side to side; there was slight unwieldiness when he carried it to the roof of the mouth. There was no atrophy of tongue; it did not get in the way and get bitten. Speech was marked by dysarthria, almost complete anarthria, and was very nasal. He could not cough and efforts at coughing were toneless. Pharynx sensitive, although not completely normal. The patient found it quite impossible to speak a word distinctly; he slurred the vowels and was unable to pronounce consonants. Knee jerk marked by exaggeration. Trapezius reflex lively; triceps reflex increased. Slight ankle clonus. No atrophy; muscular strength good; surprisingly strong grip. Moderate hyperalgesia, particularly of the lower extremities. Some ataxia of upper extremities. Pupils contracted to light and distance; no ocular palsies. Bowels and bladder were normal; he had had no trouble with them. When he stood his body was flexed on the pelvis and he could not walk without holding on to something. The head was bent forward. Psychically, memory was good and apparently unimpaired; he was easily moved to tears and easily depressed. He showed a tendency to fall forward when standing or attempting to walk, although when he was made to stand up erect, with feet together and eyes closed, he did not sway. Pulse easily excited, about 100. Apparently he had no difficulty in swallowing. No evidence of atrophy in tongue or palate, extremities, lips, etc. Electrical examination showed that the faradic current produced contraction in the muscles supplied by the fifth and seventh nerves, in the tongue and soft palate, and all the muscles of the extremities.

November 13, 1895: Mobility of eyeballs intact. No nystagmus. Functions of third nerve normal; pupils contracted to light and accommodation. Mobility of forehead and eyelids fairly good, but movements slow. Muscles of expression seemed to be in a state of persistent relaxation, but were slow in psychical response. He could blow out both cheeks equally, could pucker the lips, but was unable to whistle. Sensibility of both sides of the face preserved and acute. Jaw clonus very marked. No drooling.

Movements of tongue free and dexterous. The uvula raised itself promptly and vigorously when he said "ah!" Palatal reflex intact. No anæsthesia of pharynx or uvula. In the lips, face, and tongue faradic irritability was preserved. The reflex for swallowing situated on the front of the throat above the pomum Adami was easily stimulated by the faradic current. Sense of taste was normal. There was almost complete anarthria. The act of swallowing was performed rapidly and apparently with ease. On account of the loss of prehensibility of the lips there was some apparent disturbance in taking food and fluids into the mouth, but when they were once in he disposed of them easily. The eighth nerve was intact. Pulse weak and feeble in character, about 90 per minute, and easily accelerated; arterial tone sluggish. Knee jerks lively and exaggerated; slight patellar clonus on both sides; no ankle clonus. There was some apparent spasticity, but it could be overcome without difficulty. There was no ataxia of the lower extremities. The superficial reflexes, plantar, abdominal, and testicular, were normal. Sensibility seemed to be entirely intact. Dynamometer: right hand, 80; second trial, 60; left, first trial, 60; second trial, 50. There was considerable ataxia of the upper extremities. A peculiar kind of a tremor was to be seen in the index finger and thumb of the right hand when he made efforts of prehension. It was manifested when the patient tried to pick up in succession a number of small coins. When he succeeded in getting the second one between the fingers, which he did with a great deal of clumsiness, the fingers and thumb took on a movement very similar to the pill-rolling movement of paralysis agitans. This was the only purposive movement by which the tremor could be detected. It was more marked in the right than in the left hand. There was considerable spasticity of the upper extremities, more passive than active. The elbow reflexes were exaggerated. Myotatic irritability of the upper extremities and of the shoulders was abnormally lively. There was no muscular atrophy. The patient held himself in a flexed, rigid position, with the head bent forward; the thorax was fixed, and he was unable to furrow between the shoulders. The posture of the patient reminded one forcibly of paralysis agitans. The patient was barely able to stand alone with the feet wide apart and was not able to stand with the feet together. When he walked it was with the same rigid fixation of the body, and he reminded one of a stilt walker. There was more spasticity of the upper than of the lower extremities, and there was likewise greater incoordination and diminished dexterity of the upper extremities. Although he had really great strength in the hands and arms, he could not handle a knife and fork; meat had to be cut for him. It should be emphasized, however, that real ataxia was not very marked.

January 1, 1896: Tactile, temperature, and pain sensibility exquisitely preserved. All these were preserved with noticeable acuity in the face as well as on the surface of the body. Muscular and articulatory senses normal. Palatal sensibility and palatal reflex preserved. Corneal reflex prompt and active.

The clinical history of this patient is not an easy one to construe. The most important points in its development are that it came on during an acute infectious illness, true lobar pneumonia or grippal pneumonia. The striking clinical features of the disease were difficulty in swallowing, difficulty in phonation and articulation, regurgitation of fluids through the nose, and a positive loss of definite association between muscular strength, which was always quite well preserved, and ability to use this strength. At the present time there is no way of determining from the course of the disease what the actual lesion in the medulla was. That it was in the medulla, I

think there can be no doubt, as the one extra-medullary disease with which it might be confounded, associated neuritis of the bulbar nerves, can be excluded by the course of the disease.

The diagnosis in this case must be between poliomyelitis bulbi, acute inflammation in the substance of the medulla analogous to anterior poliomyelitis, and thrombosis of one of the bulbar arteries. The first disease, as is well known, is a very uncommon one. Yet a sufficiently large number of cases which have been carefully studied clinically and anatomically to have firmly established its reality have been reported. It occurs, like its analogue, anterior poliomyelitis, in the wake of acute infectious diseases, such as pneumonia and influenza. From its clinical history it cannot positively be differentiated from thrombosis and hemorrhage of the medulla. Its occurrence, however, may be conjectured mainly by the onset and course of the disease. In the former the symptoms unfold themselves with less brusqueness than in the latter. In the beginning of the former disease many groups of ganglionic cells or nuclei of the medulla may apparently have been seriously affected, on account of more or less complete inhibition of function, but after the acute manifestations, those corresponding to the exudative stage, have subsided, it will be seen that only a part of a nucleus or of more than one nucleus may have suffered any permanent damage. The course of the disease from this time onward is of more diagnostic significance. In poliomyelitis bulbi the disease will make no progress. That is, there will be no symptoms corresponding to those which may occur after thrombosis and which are dependent upon softening or other nutritive disturbances. Likewise there will be no considerable improvement, except in a general way and except that which can be explained by predicated assumption of function in part by those cells of a nucleus that have escaped serious injury.

In this case the symptoms have remained stationary for nearly two years. The patient presents in no manner the syndrome of chronic degenerative bulbar paralysis, except that the *facies* remind one of the latter. The functions of the tongue, which were first impaired, are intact and point to integrity of the hypoglossal nerve. It is only the nuclei of the glosso-pharyngeal and pneumogastric that would seem to be affected in conjunction with affection of the central motorial neuron projection, the pyramidal tracts. Further than this it does not seem justifiable to make a pathological diagnosis.

As was said in the beginning, the object of this paper is to utilize clinically for the benefit of our patients knowledge gained by the study of similar cases on the post-mortem table and in the laboratory, that it may guide us in our therapy.

47 WEST THIRTY-FIFTH STREET.

Tabes Dorsalis and Syphilis.—Dr. Storbeck (*Zeitschrift für klin. Med.*, Bd. 29, p. 141) gives the following statistics derived from the histories of one hundred and eight cases of tabes in the hospital and private practice of Professor Leyden. Twenty-two of these were syphilitic; twenty-three had doubtful histories and in sixty-three syphilis could be excluded. If one-half the doubtful cases were really syphilitic the result would be 30.6 per cent., which Storbeck, from the frequency of syphilis, thinks is not higher than could be expected, so that the relation of the two diseases does not seem to him established. The value of the article is augmented by the fact that it contains short clinical histories of the one hundred and eight cases and a table showing the percentage of syphilitic cases in tabes according to forty-eight authors, from the ninety-seven per cent. of Déjérine to the zero of Mayer.

A SINGULAR CASE OF PATENCY OF A GÄRTNER'S DUCT.

By ALEX. J. C. SKENE, M.D.,

BROOKLYN, N. Y.

THE patient was nearly fifteen years of age, very large, well-developed, and in perfect health of body and mind, but all her life had been greatly annoyed by a constant watery discharge from the urethra. The exact amount of the discharge could not be estimated. That it was considerable may be inferred from the fact that it kept her underclothing wet all day and saturated a protecting napkin at night.

She retained her urine the normal length of time; urinated freely and without pain or discomfort. The discharge from the urethra was not modified in quantity by the erect or recumbent position, nor by the empty or distended condition of the bladder. The most careful examination of all the pelvic organs revealed nothing abnormal, excepting a slight ridge or fold of mucous membrane in the vagina on the right side anteriorly. This elevation or ridge ran from the upper third of the urethra upward to the junction of the vagina and cervix uteri.

Its presence attracted my attention but did not impress me as anything of importance. The urethra was rather short but normal in every way, and the urethral ducts also; and I presumed that the muscular tissue might be defective at the neck of the bladder, and hence there might be a slight incontinence. This, however, was not sustained by the clinical history. The patient was admitted to my sanatorium, where I was able to investigate the case thoroughly.

Under the observations of a skilled nurse it was determined that the discharge came from the urethra and that there was no leaking from the bladder. I then suspected that there might be an irregular implantation of one ureter. A cystoscopic examination was made and both ureters were found in their normal position and were performing their function all right. Double bladder was thought of, with a communication between the one into which the ureters entered and the other. This idea was abandoned, because no known derangement of development could eventuate in such a malformation. Being unable to find any cause for this discharge in any lesion of the bladder, I examined the fluid and found that it contained a very few epithelial cells and a trace of albumin, but none of the constituents of urine. It was not urine at all, as had been supposed. A number of endoscopic examinations of the urethra were made at different times in the hope of finding the opening into the urethra, with most discouraging results. Finally, on one occasion, after making a prolonged exploration (with a fine probe used through the endoscope) of the upper part, I withdrew the instrument a very little way and observed a jet, as fine as a hair, of clear fluid. The discharge had been stopped by the pressure of the endoscope, and on the removal of the pressure the discharge came with force enough to make it visible. I then tried to introduce a probe into the opening, but that was impossible, owing to its small size. The opening, I observed, was at the place where the small ridge in the vagina joined or disappeared in the wall of the urethra. I at once concluded that this ridge contained a patent Gärtner's duct that was the source of the discharge. Several other careful and prolonged efforts were made to probe the duct in order to confirm the diagnosis, but without success.

Though much gratified with having discovered with reasonable certainty the nature of the trouble, I was perplexed about the treatment, but finally determined to close the entrance of the duct into the urethra. This was accomplished by passing a ligature round that portion of the vaginal wall (close to the urethra)

which was presumed to contain the duct. The ligature was tied quite tight, and to my great satisfaction the discharge was promptly and completely stopped. The following day the ridge in the vagina was enlarged considerably, most at the upper portion. This confirmed the diagnosis of a patent Gärtner's duct. I then divided the ridge or fold of the vagina just above the ligature, and about a drachm or two of clear fluid escaped. I then cut away the whole of the ridge of the vagina. In the portion thus removed I found the duct, which was very small at the lower part but large enough at the upper part to admit a pocket-case probe.

There was some bleeding, which was arrested with a tampon. The vaginal wound healed readily, leaving the end of the duct open through which the probe could be passed up to the parovarium. A clear discharge, in diminished quantity, continued. Tincture of iodine with five per cent. of carbolic acid was injected into the duct. After this there was pain and some rise of temperature, which subsided in about thirty-six hours. Several days after this there was a slightly colored discharge, very small in quantity, which subsided completely, and there was an end to the trouble. Apparently the portion of the duct left became obliterated. All examinations were made and the treatment employed without anaesthesia, which shows that my patient possessed remarkable self-control and was quite heroic.

This is the first case of patency of Gärtner's duct opening into the urethra that I have ever seen; neither have I found any such case recorded in the literature on the subject. The case must be of special interest to the profession on account of its being unique, the difficulties of diagnosis, and the special treatment required, which proved successful. The subject is of personal interest because it confirms the opinion that I have always held, that Gärtner's ducts are quite distinct from the ducts of the urethral glands, which I described years ago.

This whole subject has been treated in an original and masterly way by Amand Routh, M.D., B.S., M.R.C.P., in vol. xxxvi. of the Transactions of the Obstetrical Society of London. In this valuable contribution, entitled "On Cases of Associated Parovarian and Vaginal Cysts Formed from a Distended Gärtner's Duct," he gives the history of cases occurring in his own practice and that of others. He also relates two cases in which the persistent Gärtner's duct opened into the vagina. One is by Mr. Milton, of Cairo, Egypt, and the other by Lawson Tait. The following gives Dr. Routh's views on this question:

"Details of three cases of the above are given, and also of two analogous cases of patency of the whole length of the duct, with an anterior opening allowing free discharge, and thus preventing distention of the duct along its course.

"Comparison is drawn between such cases and those of distended but imperforate Müller's ducts.

"Evidence adduced from these cases is thought to establish, or at least to render plausible, the following propositions:

"1. That Gärtner's duct can be traced in some cases in the adult female from the parovarium to the vestibulum vulvæ, ending just beneath and slightly to one side of the urethral orifice.

"2. Homology tends to show that Max Schüller's glands are diverticula of Gärtner's ducts, just as the vesiculæ seminales are diverticula of the vasa deferentia. Some evidence is given that Skene's ducts are not necessarily identical with the anterior termination of Gärtner's ducts (as most of those who have traced Gärtner's duct to the vestibule have thought), but that Skene's ducts lead directly and solely from Max Schüller's urethral glands, Gärtner's ducts being continued

to the vestibule, behind but parallel to Skene's ducts.

"3. That Gärtner's duct, if patent, may become distended at any part of its course, constituting a variety of parovarian cyst if the distention be in the broad-ligament portion, and a vaginal cyst if the distention be in the vaginal portion. The cases described are instances of the association of both of these cysts, owing to simultaneous patency and distention of both portions of the duct.

"4. Attention is drawn to these cases as affording explanations of some obscure cases of profuse watery discharge from the vagina, not coming from the uterus or bladder.

"5. The question of treatment is also approached, and the opinion is expressed that where the whole duct is distended the vaginal part of the cyst may be laid open as far as the base of the broad ligament, and the broad-ligament portion encouraged to contract and close up.

"A very valuable work on The Duct of Gärtner, by Bland Sutton, was published in 1886, giving his results of examinations of seventy cows; and Mr. Alban Doran, in his review of this work, points out that as Gärtner's ducts are generally admitted to be the homologues of the vasa deferentia, and as the vesiculæ seminales are diverticula of the vasa, close to their termination on the floor of the prostatic urethra, it follows that the Max Schüller's glands of the female urethra are the homologues of the vesiculæ seminales, and he agrees with Bland Sutton in thinking that in woman, as in *Bos*, Skene's tubes represent the anterior termination of Gärtner's ducts. This latter conclusion is not, I think, correct.

"When this view was expressed in 1886, no cases had been published of a persistent Gärtner's duct opening at the base of the vestibule; but the cases now given, and other cases of cysts formed out of the vaginal portion of Gärtner's ducts, show that the opening of Skene's ducts and the opening of Gärtner's ducts are not necessarily identical in situation."

I am glad to add this case in further evidence of the ground taken in my first studies in this department.

CASE OF TUBERCULOUS ORCHITIS SUCCESSFULLY TREATED BY THE GALVANIC CURRENT—PERMANENT CURE.

By HALSTED BOYLAND, M.D.,

OF THE FACULTY OF MEDICINE OF PARIS; FORMERLY PROFESSOR IN THE BALTIMORE MEDICAL COLLEGE, ETC.

THREE years have passed since this case was treated, and as there has been no relapse the result obtained may be regarded as a permanent cure.

Mr. H—, when seen by myself for the first time in November, 1892, was suffering from what he supposed was a swelled testicle combined with irritability of the bladder. He had been a dyspeptic for some years past, gradually losing in weight, and presented at this time a slightly cachectic appearance; both lungs were perfectly normal, however, and the heart's action was good. There was no albumin nor sugar in the urine, but some engorgement of the liver existed. All these symptoms yielded to the treatment instituted, namely, four grains of benzoate of lithia in a glass of vichy water morning and evening and a pill at night composed of rhubarb, blue mass, taraxacum, and quinine—one grain each. The cachectic symptoms rapidly disappeared, having been entirely due to the liver. The restless nights of which the patient had complained were more quiet and there was a general improvement at the end of a week, except as regards the testicle; this had increased a little in circumference, the enlargement being on the right

side and about the size of a very large hen's egg. The question of general tuberculosis was now solved and put aside, while local tuberculosis became more and more probable. The absence of any syphilitic taint, past or present, excluded the diagnosis of syphilitic orchitis; then the slow and insidious development of syphilitic testicle was wanting. In this case the increase in volume had been only moderately rapid, and there had at no time been lancinating pains nor was there any hereditary taint either of syphilitic or cancerous nature; the diagnosis of malignant tumor of the testicle was therefore excluded. A small opening established itself a few days later, from which a thick, whitish, caseous matter could be pressed. The testicle on being squeezed was not particularly painful nor had it been all along. The lancinating pains so characteristic of cancer had always been absent. A microscopical examination of this matter revealed the bacillus of Koch. There was, therefore, no longer any doubt regarding the diagnosis—the case was evidently one of tuberculous orchitis. Here, then, we had a case of tuberculous orchitis absolutely circumscribed and no tuberculous deposit in any other organ, it being the second case of this kind that has happened in the writer's experience and controverting entirely the received opinion that when local tuberculosis exists there are always tuberculous deposits in other organs, notably in the lungs. A microscopical examination of the sputa resulting from a slight morning cough showed no bacillus of Koch and the physical signs of the lungs were normal.

It was now decided to have recourse to galvanism in the form of the constant current, in accordance with which daily applications were begun by placing the electrode of the positive pole directly on the testicle and that of the negative pole on the spermatic cord. The duration of each application was ten minutes, the strength of current being ten milliamperes, the first application being made on November 6, 1892. The effect of the current was almost instantaneous. At the end of each application the testicle was undoubtedly smaller than at the beginning and drawn up to the superior region of the scrotum. Each day there was perceptible diminution in its size, observable also before applying the current. The secretion through the opening, however, did not keep pace with the diminution in size; on the contrary it became more abundant and thinner, but did not at any time assume the character of pus. The testicle was now washed out internally with lukewarm water and a solution of camphorated naphthol and olive oil, two drachms to the ounce, injected through the opening in the scrotum directly into the tuberculous mass, the testicle having been well pressed and all detritus and caseous matter thoroughly gotten out beforehand. The quantity injected each time was two drachms. The electrical application was then made and the wound subsequently pressed with camphorated naphthol. The discharge began to diminish and to thicken somewhat, the caseous character changing to a fluid of a smooth, whitish consistency, which in two weeks more became serous, very scanty, and a few days later ceased altogether. The testicle was now reduced to four-fifths of its volume at the beginning of the treatment, and the general health of the patient was satisfactory. In order to be sure that no pockets nor secondary deposits had been made and left in the testicle, a small incision was made followed by a thorough examination. Nothing was obtained beyond a few drops of blood. The testicle presented a consistency similar to the normal one, although there was, as a matter of course, some obliteration of the epididymis, which formed a thick mass with the testicle and spermatic cord. The wound healed in twenty-four hours by first intention, when the electrical treatment was resumed. This was on December 28th, or just

one month and two days from the time when the case was first taken in hand. There had been from December 18th a slight return of the old irritability of the bladder, doubtless sympathetic, for it was confined to the trigonum, and there was no prostatic disease nor enlargement of any kind, as digital examination proved. When the discharge had disappeared and the testicle had become so much reduced in size, the vesical irritability entirely ceased and never returned again, removing with itself all doubts as to its origin.

The daily galvanic applications were continued until January 13, 1893, when the testicle was reduced to the normal size and there was a *restitutio ad integrum*, the only difference between the right and left sides being a scarcely perceptible feeling of thickening of the epididymis at its junction with the cord, all the parts being now perfectly and easily recognizable by palpation. There had naturally been considerable obliteration of the afferent and deferent vessels, also of the seminal ducts, followed, however, by a reconstructive metamorphosis, and although the question of impregnation from the testicle that had been diseased might be open to some doubt, it really made no difference practically, as that on the other side had remained perfectly normal. During the ten days in which there was a slight return of the vesical irritability a current of the same strength, ten milliamperes, was passed through the bladder for five minutes immediately after treating the testicle; the positive electrode being placed on the perineum, the negative just over the pubis, avoiding of course the bone, which being a non-conductor would have seriously interfered with the current, although it would not have stopped it altogether, as we know by our experience of sending a current from one mastoid process to the other. The only other change made in the treatment was to increase the strength of the camphorated naphthol solution from that of two drachms to the ounce or one-quarter used in the beginning, first to four drachms to the ounce or half strength, then to six drachms to the ounce or three-quarters strength. Each of these solutions was used for a few days progressively, when the naphthol camphré was used pure until the wound healed entirely.

The patient, who had been confined to his bedroom for some weeks, dating from the 26th of November, was able to go out for carriage exercise the latter part of December and to come to me for treatment on and after January 1st, the testicle being treated at his apartment in the morning in the usual way. I gave him static electricity as a general tonic in the afternoon. My dielectric machine is one of Carré's, No. 4, the largest size constructed, with an ebonite disc sixty centimetres in diameter and capable of giving sparks twenty-seven centimetres in length. The electromotor force of these machines is reckoned by the rheostat voltmeter at about ten thousand volts, static volts differing considerably in force from those of the continued galvanic or alternating currents. The patient is placed on the isolator in direct communication with the machine by holding in his hand the metallic conducting-rod, and for fifteen minutes is subjected to the effluvia of ozone alternating with static sparks; this was done daily for thirteen days, at the end of which time he left me entirely cured, having recovered his normal weight and color. He wrote to me some months subsequently and after his return to America, saying that he has had no return of his old trouble. He came back to Paris about two years from the time he ceased treatment and was then still in good health. In this paper the term orchitis is used in its general sense, although the main seat of the disease was the epididymis, the body of the testis being only in part indirectly affected, the thickening of the tunics giving

as usual in the different varieties of orchitis the appearance of one solid voluminous inflammation—hence the generic term orchitis. There are undoubtedly cases in which the testis proper is primarily affected, the epididymis remaining intact, but these are rare, and even then the immunity of the epididymis is not absolute, there being almost always some participation in the pathological process, whether sympathetic or direct. In passing the current through the bladder, care should be taken to have the electrode to be placed on the perineum made oblong and narrow to fit the parts, that placed above the pubis being about two inches in diameter. The ascending current is preferable. Although the question in which direction the current should be passed, up or down, in general is still in discussion, the author would say after an experience with electricity of many years that he has found the ascending current detergent, decongestive, and dispersive; the descending current, on the contrary, sthenic, reconstituent, cumulative. The action of the galvanic current on the tissues is purely chemical by cataphoresis and it is for this reason that it is destined to render still greater successes than any yet achieved in medicine or surgery.

How came this testicle to be tuberculous, there being no tuberculous deposit in any other organ nor any tuberculous history in the family for several generations back? As it is well known that the bacillus of Koch is carried in the mucous membranes of the mouth in health, it must be, according to the evidence furnished in this case, that the same bacillus is stored away in other membranes and organs, where it remains latent and innocuous until the bactericide condition is overcome by general weakness and a *porte d'entrée* is found always in the *locus minoris resistentia*. The etiology and semeiology of circumscribed tuberculosis would carry us too far beyond the limits of this paper, which is essentially a clinical one.

PSEUDO-MALARIA.

By REG. A. FERGUSSON, M.D., L.R.C.P. EDIN.,

BAKERSFIELD, CAL.

"THE term malaria should be limited to a definite disease in which we know there is a specific infectious origin" (Rotch).

My proposition is, that in the genus of diseases called malaria there are two species:

- (a) A true malaria due to earth-bred protozoa, and
- (b) A pseudo-malaria due to the presence in the system of toxic metabolites or of ptomaines.

For fourteen years it has been my fortune to have under observation the endemic diseases prevalent during the agricultural development of a new country and the growing up of a community. Bakersfield is the county town of Kern County. Kern Valley is the southern portion of the great San Joaquin Valley of California.

In a given locality the peculiar conditions of climate, of soil, and of water, the drainage and general sanitation, the manner of living of the inhabitants, and the presence or absence of malaria are the initial factors in the production of the diseases endemic in that locality.

The climate of Kern Valley is subtropical, continental, and dry, and, as in all districts away from large bodies of water, the tendency is to cool winters and hot summers. The rainfall averages five inches a year and occurs during the winter and spring. The mean winter temperature is about 52° F. The mean summer temperature is about 83° F. The annual range is from about 28° F. in December or January to 110° F. in July or August. The variation during the twenty-four

hours is from 25° F. to 50° F. The soil is principally a richly fertilized, deep alluvium, annually watered by the waters of Kern River and other mountain streams. The inhabitants are agriculturists or of the usual occupations of a small town, and are mostly immigrants from maritime and temperate continental climates.

Previous to the last fifteen years the rich soil had not been brought under cultivation and its energies were not expended in the growth of cultivated crops, but in rank vegetation; the land was intersected by sloughs and lakes and sluggish streams overflowing in the spring and drying up in the summer and autumn; the inhabitants obtained their drinking-water from these sloughs and streams or surface wells, and lived as only the inhabitants of a newly settled agricultural country may live. Under those conditions the most evident endemic disease of the country was due to an earth-born poison which invaded the body by the intermediate agency of the damp miasm and the drinking-water. Clinically this disease presented all the types of intermittent and remittent fevers called malarial. It also occurred as a pernicious, rapidly fatal intoxication, and as a chronic cachexia with degeneration of the blood and tissues, but most frequently it presented itself as a continued remittent fever. This latter type had a most unenviable notoriety throughout California and was known as "Bakersfield" or "Kern Island" fever. It was a remittent fever of severe type, with disintegration of the red blood corpuscles, and was variously complicated by every morbid condition that may arise from active or passive congestions of any of the internal organs. The most fatal complication was pneumonia. These diseases were due to hamatozoa. In their treatment quinine was the only medicine that could be relied upon.

Since 1884 there has been a rapid disappearance of these protozoic diseases. During the past fifteen years there has been a radical change in the physical conditions of the country. The soil, naturally well drained by substrata of sand and gravel, has been brought under cultivation and its energies expended in the growth and sustenance of cultivated crops; particularly in the production of vast fields of alfalfa (lucerne). This plant, like unto the eucalyptus, sends down tremendous roots into the soil, acting as living drains, and offers an immense area of green foliage to the air. The swamp lands have been reclaimed, the waters dammed off from the lakes, and sloughs and their beds turned into cultivated ranches. The waters of Kern River are diverted into irrigating ditches free from rank vegetation and filled with running waters. The water supply for drinking-purposes has ceased to be from surface wells and sluggish streams. It is now obtained from deep wells and artesian fountains, of which the source is the everlasting snows of the high Sierras and the course of which is through underground gravel strata deeply hidden from protozoic infection. Under these conditions of soil and water-supply malaria due to hamatozoa has ceased to be endemic in Kern Valley. "Bakersfield fever" is an exorcised spectre.

The species of malaria which I have been led, by clinical observation and the results of treatment, to regard as pseudo-malaria is still prevalent. It is a comparatively mild disease.

The symptoms of this disease vary from those of a mild indisposition or "bilious attack" to those of a more severe toxæmia. Instead of the unconscious feeling of well-being that accompanies good health there is a depressed feeling, with a sense of being tired and listless, and a strong disinclination to bodily or mental exertion. With this are associated general aches through the body and limbs, markedly under the shoulder-blades and around the waist; dull head-

ache, giddiness, and disturbed and dreamful sleep; foul tongue and bad taste, especially on awakening; anorexia; stomachal cough and foul breath; the functions of the alimentary organs are sluggish and irregular; liver dulness is sometimes slightly increased, with some tenderness of the capsule. The skin is usually dry and harsh, sometimes has a soft velvety feel; the sudoriparous glands are irregularly super-active and the perspiration is somewhat disagreeable; the conjunctivæ are muddy. The urine is highly colored and offensive. The spleen shows no morbid physical signs. There may be a slight tenderness over the splenic region, but it appears to be due to disturbance in the colon. There is always chilliness, sometimes there are mild rigors, and moderate irregular pyrexia. Patients with a history of previous protozoic toxæmia often show marked paroxysms and periodicity in the symptoms, and sometimes increased splenic dulness and skin pigmentation; it is in these cases that quinine medication is liable to be abused.

The above symptoms are due to some intoxicating element coursing with the blood and permeating the tissues. In the cases I have had under clinical observation I strongly doubt that an invading protozoon is a factor. The causes of this disease are errors in the adaptation of the manner of living to the habitat, and to errors in alimentation. These errors produce disturbances in the chemical and physical forces by which the cell protoplasm is transformed into simpler chemical elements unfitted either for the economic functions of the system or for excretion, and they interfere with the process by which the living cells take up and convert into their own proper substance the nutritive material brought to them by the blood. Hence toxic metabolites are produced in the system. These errors also bring about putrefaction of various kinds of albuminous matter in the alimentary canal and thus produce ptomaines.

These errors occur most markedly where a people have changed their habitat and not their habits, and where their modes of sustaining and protecting their bodies have no regard for their special conditions and special needs. This pseudo-malaria, as a result of these errors, is more prevalent when a change is made from a climate where the strain on the organism is on the lungs and kidneys to one in which the strain falls on the liver and skin, as from a maritime to a dry, hot climate.

If alimentation errs from excess, from insufficiency, from poor quality of ingesta, in cookery, in non-adaptation to the locality and climate in which the subject lives, or if the living tissues and cells fail in the proper construction of the digestive ferments or in the proper destruction of effete material so as to fit it for elimination by the excretory organs, or if the excretory functions be vitiated in their action, there accumulate little by little in the liquids and organs of the economy various products, more or less toxic, which impress on the organism a vital depreciation with this pseudo-malaria as a common consequent.

The most frequent complications of this disease are functional derangements of and eventually chronic organic changes in the liver and other alimentary organs, and chronic dermatoses.

The indications for treatment are to remove the faults of the environment and of the daily habits of life, to correct the habits of food consumption, to set right the nature and composition and the cookery of the available foodstuffs, to protect the skin, and by so doing the nervous system from strain, especially the strain of sudden changes of temperature; to cleanse the alimentary canal, to increase the functional activity of the liver and intestinal glands, to stimulate metabolism, and to increase elimination by the skin, kidneys, and lungs.

Quinine is not a specific in this disease, and is possibly beneficial only in so far as it may stimulate metabolic action.

Progress of Medical Science.

Division of the Vas Deferens in Prostatic Hypertrophy.—Dr. Reginald Harrison recently delivered an address on this subject,¹ from which we gather the following: In 1893 Dr. W. White, of Philadelphia, suggested that castration might be tried as a remedy for troubles connected with certain forms of prostatic hypertrophy, with the result that this practice has now been adopted in numerous instances with some amount of success. It is interesting to notice, now that attention has been called to the possibility of its practical application, how often the fact has been stated in surgical literature that interference with portions of the genito-urinary tract is followed by atrophy of the prostate. If we turn to records of injuries to the vas deferens it will be found that Birkett, Hilton, and others have shown that atrophy of the testis is a sequence in the human male of rupture or section of this duct. If this is so, why should we not take advantage of it, and in this way induce prostatic atrophy without resorting to castration? It is probable that in a certain number of prostatic cases the amount of shrinkage of the gland necessary to make all the difference between a life of misery and one of comfort is comparatively slight. This is a conclusion which may fairly be drawn from the observation that, although prostatic enlargement is common, only a small number of males thus affected can be said to suffer from it. Dr. Harrison's method is described by him as follows: After trying several plans for dividing the vas after passing through the external abdominal ring, subcutaneous and otherwise, the following appears to be the best: The scrotum having been shaved and prepared antiseptically, the tube is carefully sought for as it enters the scrotum. It being held subcutaneously in position between the finger and the thumb, a vertical incision through the skin is made over it to the extent of an inch or so. The spermatic cord having been recognized, the vas is separated from the other constituents by the finger and forceps by merely carefully tearing away the connective tissue about it. In doing this care should be taken not to drag on the testicle too much, but to support it while a loop of vas is detached, so that the connections of the former may not be loosened. The vas should be well cleared of all other textures, and then a loop of it is gently drawn out through the wound with a blunt hook. The loop is then encircled below the hook with a silk ligature not too thick, which is tightly knotted. The ligature is cut off short, the extraneous portion of vas removed by scissors, and the pedicle dropped into its place. The wound is closed with a catgut suture or two, and fitted with a small drainage tube. There is no bleeding worth mentioning if the operation is done in this way, and the wound usually heals in the course of a few days. He has reasons for believing that in a short time the vas, thus treated, becomes converted into a fibrous cord, which eventually, with the corresponding testicle, undergoes atrophy. If the vas, before the ligature is applied, is carefully cleared of other tissues, pain is not usually complained of, as is often the case when the whole thickness of the spermatic cord is included in a ligature, as is sometimes done in cases of castration. Both vasa may be so treated simultaneously, but he prefers doing one

¹ "Clinical Remarks on Division of the Vas Deferens in Cases of Obstructive Prostatic Hypertrophy," by Reginald Harrison, F.R.C.S. Eng. Reprinted from *The Lancet*, February 22, 1896.

at a time. In the opinion he has formed as to the utility and propriety of dividing the vas in cases coming under this category he does not stand alone, and unless mistaken he anticipates that further evidence in support of it will soon be forthcoming. The literature, however, will already be found to confirm some of the conclusions he has thus ventured to formulate. Too much importance must not be attached to some experiments on animals which have been made in connection with this subject. The moral influence of certain conditions and the material changes they give rise to, in their relation to the genital function in the human male, find no counterpart in the animal species. In offering these remarks on this aspect of a most important subject, he does so in the belief that the case as he has endeavored to put it, though not fully proven, has been sufficiently made out by direct and indirect investigation as to warrant a fair trial being made of it before we adopt castration as a remedy for prostatic hypertrophy and certain of the troubles arising out of it. In a paper read since these remarks were made Professor Guyon, of Paris, has added important testimony in favor of this proceeding. He publishes the particulars of two cases of bilateral division of the vasa in men seventy years of age or thereabout, in which the benefits obtained were prompt and conspicuous, and in correspondence with effects already noted.

Lung Surgery.—Dr. Péan, of Paris, has made a special study of pulmonary surgery and announces the following conclusions: 1. The surgery of the lung, like that of the viscera, has of late made much progress, thanks to the perfection of our anatomical knowledge and to the improvement in operative procedures for the arrest of hemorrhage. 2. Equally favorable conditions for surgical intervention do not occur in all affections of the lungs. 3. Wounds caused by contusing bodies, by stabbing and cutting instruments, and by gunshot projectiles of small and medium calibre usually heal well without causing supuration or troublesome reaction. 4. The danger which results from such injuries is due, not to the injury of the lung structure itself, but rather to the multiplicity and extent of the wounds and to the lesions of important neighboring parts. 5. The surgeon should not intervene too hastily in these injuries, either by making a simple exploration or by attempting to extract a projectile which can be seen near the surface. 6. Large projectiles, such as fragments of shell, give rise, especially on the field of battle, to disorders which in a large majority of instances are so severe that it is impossible for the surgeon to ward off danger even by suturing the visceral and parietal layers of the pleura. 7. A certain number of spontaneous affections of the lung may be successfully dealt with if the surgeon be careful to make a study of symptoms and indications, and a proper selection of his operative measures. 8. Simple and gangrenous abscesses, when they are of limited extent, show no tendency to cure, and threaten life, are amenable to surgical treatment. 9. In such cases the results are almost always favorable. 10. It is advisable to open, scrape, drain, and even cauterize tuberculous abscesses of the lung, when these cause severe pain or have resulted in fistula, or contracted extensive adhesions with the pleura. 11. It is often useful in these cases to associate with such treatment partial resection of the ribs. 12. No benefit is likely to result from excision of fragments of the lung surrounding the tuberculous cavities, as the tubercle bacilli have already spread beyond the apparent limit of the disease. 13. It is advisable to open hydatid cysts of the lung, the surgeon taking advantage of adhesions when such exist, and establishing still further adhesions when those existing are not of

sufficient extent, in order to be able to wash out the cavity with antiseptic solutions. 14. Solid tumors of the lung should be extirpated when superficial; the occasions, however, for this treatment must be rare, as such growths are almost always secondary.—*La Presse Médicale*.

Primary Cancer of the Lung.—Dr. Wolf has published a record of thirty-one cases of primary carcinoma of the lung which have been met with in the Dresden City Hospital since 1885. The percentage of occurrence was .428. Twenty-seven cases occurred in men, four in women, and the ages ranged between thirty-six years and seventy years, the majority being past fifty years. The right lung was five times the seat of the tumor, the left lung three times. Thirteen times the right bronchus was affected, eight times the left bronchus, and twice both bronchi were primarily involved. In five cases the bronchial carcinoma extended to the trachea. Thirteen cases were complicated with tuberculosis, and in several instances the tuberculosis is asserted to be the cause of the later developing carcinoma. In one case miliary tuberculosis was observed, in another miliary carcinosis; in another both miliary tuberculosis and miliary carcinosis. The course of the affection is very various, and there is no distinctive clinical indication of the disease. The diagnosis is easier in a case of lung carcinoma, especially when the tumor is situated near the pleura, than in a case of bronchial carcinoma. In the former instance a circumscribed dulness in conjunction with great wasting, and catarrhal sputum free of bacilli but occasionally bloody, may suggest the affection. Pain is occasionally present, but naturally dyspnoeic symptoms are more common to bronchial carcinoma than to lung carcinoma. Implication of the bronchial glands often manifests itself by dyspnoea or recurrent paralysis. Metastasis is more apt to occur with bronchial than with the proper lung carcinoma, as in the former instance the affection of the bronchial glands favors implication of the great vessels. The presence in the sputum of particles of the tumor is rare, as it was observed in only one of the thirty-one cases.—*Fortschritte der Medicin*.

The Treatment of Acute Gout.—Dr. Jaccoud, of Paris, divides this subject into three parts, according as one has to deal with the acute attack proper, the subacute attack, or the recurrent disease. In the first case he does nothing during the first five days except to promote diuresis by the most simple means, such as the administration of a litre or so of Evian or Vittel water daily, with perhaps the addition of a little acetate of potash; he does not even give milk, preferring that the power of the disease shall be expended on the organic tissues themselves. He applies anodyne embrocations to the joints and covers up the parts with a thick coat of wadding. At the end of this time, if the fever and pains have subsided, the attack is nearing its end and no further treatment is necessary; milk should now always be given. If no improvement has taken place Jaccoud gives a grain and a half of hydrobromide of quinine with three-fourths of a grain of digitalis powder in four pills, five, or six times a day; this usually produces the desired effect within two days. If, however, the pains are worse on the fifth day than at the onset salicylate of sodium in thirty to forty grain doses should be given, provided that the urine is free from albumin; after the second dose the urine is to be tested with ferric chloride, and if the salicylate reaction is feeble or wanting the drug must be stopped. In the subacute form of the disease, which is characterized mainly by its prolonged duration, if this treatment, though it diminishes the pains, does not cut short the attack on the ninth or tenth day, recourse must be had to colchicum.

This the author prefers to give in the form of pills; he recommends Becquerel's formula, each pill containing 0.3 grain of extract of digitalis, 2.25 grain of sulphate (or preferably hydrobromide) of quinine, and 0.75 grain of colchicum seeds. Not more than two pills should be given a day, to avoid the risk of excessive purgation. No special medication is to be employed between the attacks. The treatment of recurrent gout resembles that of the subacute form. In visceral gout unassociated with articular symptoms, a late complication only coming on after years of typical gout, if there is no joint affection within twenty-four hours, colchicum is to be given at once.—*La Semaine Médicale*.

Floating Bodies in Joints.—Dr. A. Houston has grouped the various conditions with their causes; and although but little which is new is brought out, the present knowledge is well stated in a brief article (*The Boston Medical and Surgical Journal*). He uses Volkmann's general classification in dividing these bodies into (1) those that are found in otherwise healthy joints and (2) those that are found in diseased joints. Those of the first class are of purely traumatic origin, and consist of either cartilage alone, bone, or bone and cartilage. These usually result from a severe trauma, and can be hardly regarded as a common variety. To confirm diagnosis of this type, we must have sufficient violence to have broken off a piece of the articular end of the bone; there must be found a loose body immediately after injury; these bodies must correspond in size and contour to gaps in the bone; and microscopic examination must show it to be made up of normal cartilage and bone, or cartilage alone. (a) Others of traumatic origin in healthy joints may be grouped as: Those loose bodies which are composed of pieces of cartilage or bone not broken off at the time of injury, such as have been studied by König, as osteochondritis desiccans. (b) Loose bodies which originated from hemorrhage into a sound joint as a result of trauma; they are rare, usually follow injury, and present symptoms for a time possibly extending over some years. (c) Loose bodies which are caused by drawing into a joint some foreign bodies in the capsule; as, for instance, bullets, which have been found in the centre of a cartilaginous body. Under the second class, or those occurring in diseased joints, he gives four varieties: (1) The most common, the so-called corpora oryzoidea, such as are found after tuberculous hydrops. As a rule, the symptoms in these conditions are not severe, partly because the bodies are small, and partly because the condition of the joint obscures symptoms occasioned by loose bodies. (2) Bodies that originate from cartilaginous metamorphosis, such as have been carefully studied by Gurlt. (3) Those resulting from changes occurring in the normal joint villi, which became subsequently detached. These have been studied by Rokitsansky, who was inclined to believe that all cartilaginous bodies and joints were formed in this way. (4) Loose bodies that occur in arthritis deformans; these are not common. He gives the following conclusions: (1) That the etiology of some of these bodies is not yet fully understood; but that the condition described by König, under the name of osteochondritis desiccans, explains the most of those that are found in otherwise normal joints. This deserves further investigation. (2) That few, if any, are the direct result of violence. (3) That the most pronounced symptom is the sudden onset of severe pain in the joint with locking of the joint, usually in a nearly extended position, this being followed by acute inflammatory process in the joint involved. (4) That lengthening of the femur (in movable bodies in knee) may occur as a result of irritation produced by the pressure of these bodies. (5) That the only treatment

for this condition is the removal by direct incision, preferably under cocaine anæsthesia, as soon as the diagnosis is made.

Coronillin.—In 1884 MM. Schlagdenhauffen and Reeb published an account of their researches in the chemistry of coronilla scorpioides. They found a glucoside $C_{12}H_{22}O_{11}$, to which they gave the name coronillin. It is found also in other species of coronilla, e.g., *C. varia*, *glauca*, *junceae*, *pentaphylla*. In subsequent papers, we are informed by the *Medical Chronicle*, March, 1896, the same workers published an account of the chemical, physical, and physiological properties of coronillin. They found that administered hypodermically or by the mouth to frogs it caused paralysis and rapid death. Rabbits and guinea-pigs died in convulsions. Pigeons and dogs, after frequent vomitings, lay down on their sides and struggled till death put an end to their sufferings. Kobert made a series of experiments for MM. Schlagdenhauffen and Reeb by Williams' apparatus on the frog's heart. Finally, cardiographic tracings from dogs and rabbits were obtained, and the authors published a large number of these. Those experiments show that coronillin acts exactly like digitalin, and may be classed in the digitalis group. Professors Spillmann and Haushalter undertook the research on the therapeutic action of coronilla scorpioides, using the watery alcoholic extract of the seeds and the active principle, coronillin. Their conclusions are: (1) Coronillin may be considered a cardiac drug, capable of favorably modifying some of the symptoms resulting from defective energy of the myocardium. (2) The good effects produced follow quickly the administration of the drug, but cease in great measure as soon as the drug is stopped. (3) The effects consist in an increased amplitude of the pulse, increased flow of urine, diminution of œdema, improvement in dyspnoea. (4) Coronillin also fails where digitalis is ineffectual; that is, when the cardiac muscle is profoundly degenerated. The useful therapeutic effect could be obtained with ten centigrams of coronillin administered six times a day (three-tenths of a gram taken in one dose produced itching of the limbs). Dr. V. Poulet has added observations on the effects of an alcoholic tincture of coronilla varia. According to this author, coronilla succeeded where digitalis failed; it may be employed in high doses for a long time without cumulative effects. It stimulates the digestive functions and acts as a tonic, never causing vomiting or diarrhoea, as digitalis does. It slowed the pulse and the heart beats in tachycardia. It also cut short attacks of cardiac and bronchial asthma very rapidly. Its diuretic action was very marked. Still more recently Dr. Hochhalt, of Budapest, has published a number of cases favoring the therapeutic use of coronillin. He has noticed in cases of phthisis with continued fever, along with increase of arterial pressure and steadying of the heart's action, a certain lowering of temperature. After summing up the work of previous observers, Professor Prevost proceeds to give a detailed account of his own researches. For his experiments on frogs, Professor Prevost used two varieties, *rana esculenta* and *rana temporaria*. As with other heart poisons of the digitalis group, the latter shows itself more sensitive, and is poisoned with approximately half the dose. Frogs of the variety *R. esculenta* die with doses above 0.001 to 0.0015 gram per hundred grams body weight. For *R. temporaria* the dose is about half. The action on the heart is like that produced by digitalis. After a phase of "peristalsis" of the heart, which appears earlier or later according to the dose, the heart stops in systole of the ventricle and diastole of the auricles, the auricles beating some time after the arrest of the ventricle. By means of Williams' apparatus, Professor Prevost obtained re-

sults similar to those of Kobert. The general symptoms observed in the frog after poisoning by coronillin are like those produced by other heart poisons. The frog becomes weaker. The nerves and the muscles remain excitable for a certain time, but the excitability seems lost sooner than in a frog whose heart has been simply removed. When the dose has been insufficient to cause death of the heart, the frog often showed, even for several days, a general weakness with paralysis of the muscles. The nerves and the muscles are scarcely or not at all excitable, while the heart shows slow beats, arrhythmic and peristaltic. Guinea-pigs show great sensitiveness to coronillin as to other heart poisons. The lethal dose is a little above 0.0002 gram per hundred grams body weight. Coronillin seems to be rapidly eliminated, and it is possible that it is not cumulative like digitalis. Diuresis was constant after the serious symptoms had improved, and the cardiac arrhythmia had ceased. This is analogous to a phenomenon often observed with digitalis, when diuresis comes on only after the administration of the drug is suspended. White rats showed a great resistance to the effects of coronillin, as to all heart poisons. Even young rats have borne doses of 0.02 gram per hundred grams body weight. More or less diuresis occurs in all cases. The author was not able to ascertain the toxic dose, for he never reached it, nor has he observed in rats those curious nervous symptoms that he has noticed after the administration of large doses of digitalin. The difference in susceptibility of different animals is a very interesting question. It is observed with many poisons and is closely related to that of idiosyncrasy. The substances which vary in the relative dose per kilogram of animals are also those to which men show a different individual susceptibility. Digitalin and the poisons of this group produce a notable rise of arterial pressure, which Traube considers the principal cause of the diuretic effects. Professor Prevost corroborates the observations of MM. Schlagdenhauffen and Reeb that coronillin acts similarly in markedly raising the blood pressure. Summing up, the author gives a table of the toxic doses of coronillin administered hypodermically for different animals. These doses are approximately half those which he has found for Homolle's digitalin, and correspond closely to those for Nativelle's digitalin. Coronillin then, by hypodermic injection, proves to be a powerful heart poison. The clinical experiments of MM. Spillmann and Haushalter fix the effective dose of coronillin administered by the mouth at from 0.20 to 0.30 gram and up to 0.60 gram per diem in divided doses. These doses seem large compared to the experimental toxic doses, probably owing to the difference in the method of administration, the drug being much more powerfully toxic given hypodermically than by the mouth.

Enlarged Bursæ about the Knee.—Dr. Roncali describes seven cases of enlarged bursæ about the knee, six of which were operated upon with complete success. One of the patients, a man aged twenty-five, fell on his left knee in January, 1893. Eight days after this the knee became swollen, and remained so for five months, then the swelling entirely disappeared. In August of the same year he noticed a swelling in the popliteal space, which was rapidly increasing, causing a sense of weight and weakness in the limb but no pain or fever. The popliteal artery could be felt beating over the tumor; the swelling was seen to be divided into an upper section as large as an eight months' fetal head, and a lower one about the size of an orange. Pressure on the tumor caused no diminution in its size or alteration in the form of the joints. An incision was made over the tumor, and the bursa with three crypts firmly adherent to the posterior surface of the capsule

of the joint was removed. There was no communication with the joint. The patient was able to leave the hospital two months after, with perfect freedom of movement and completely cured.—*Archivo di Ortopedia*.

Some Practical Points in Connection with Rupture of the Female Perineum.—Dr. Spanton states in the *Provincial Medical Journal* that he has operated on women of all ages between sixteen and seventy-three, and has found that age makes very little difference in the result of the operation. He thinks that elderly women should share the benefits which this safe procedure affords. With reference to the legal aspect in a case of laceration of the perineum left to itself, a case is cited in which the physician neglected to repair the laceration immediately after its occurrence, and septicæmia followed. An action was entered against the surgeon for damages, which resulted in the payment of the sum claimed by the patient, under the advice of the medical man's solicitor. He says that the legal point is perfectly clear, that when in the ordinary course of treating a patient a mishap does occur, the surgeon will not be held liable provided he takes the necessary steps to put it right; but, on the other hand, the neglect to do this, whether from oversight or from a sense that it is unnecessary, renders him liable for any after-trouble, loss of time, and so on, to which the patient may be in consequence subjected. The mode of operation adopted by the author is as follows: The patient is prepared by clearing the bowels several days before the operation, and an enema is administered a few hours previous, not just before the operation. The patient is kept in bed a day or two before the operation. The time referred is just following a menstrual period. The surface is shaved and cleansed with carbolic soap and chloroform. The amount of denudation necessary will depend upon the extent of the tear. Usually the line between the labia minora and labia majora is a good guide, and a rounded incision is made across the septum formed by the remains of the perineum, and extending on each side far enough forward to form a broad surface, of which the sides are to be brought into apposition. The flap is dissected up by a so-called splitting process, keeping as nearly as may be equidistant from vagina and rectum. This flap of vaginal mucous membrane and skin is drawn forward and brought together and held there until the deep sutures have been inserted. A full-curved needle is passed from one side of the raw surface to the other, commencing about one-third of an inch outside the skin margin and emerging on the opposite side at a corresponding point. The silkworm gut sutures are placed about three-eighths of an inch apart, are drawn up, not too tight, and secured. Catgut sutures are then placed in the anterior vaginal margin and cut off short. If the rectum is involved a flap similar to the anterior one is made, commencing at the anterior anal margin. This flap is turned back, and with a sharply curved, thin Hagedorn needle a fine catgut suture is carried first through one side and then through the opposite, from the raw surface into the rectum, leaving the ends hanging out. These are inserted about one-sixth inch apart, and are then tied from above downward, each knot being left in the rectum. An additional suture is placed at the point which is to represent the posterior edge of the new perineum, which helps to secure a rounded surface when all heals up.

Polyneuritic Psychosis.—Dr. R. Collello reports thirty-three cases of multiple neuritis, eight of which are described thoroughly. All the cases have in common the combination of mental disturbances with the symptoms of multiple neuritis; sometimes the latter symptoms predominate, sometimes the former;

only in a few were both equally strongly pronounced. The first neuritic symptom noticed is an ataxic and high-stepping gait, frequently followed by a paresis or paralysis of muscles, more especially of the lower extremities. Lesions of the facial nerve and of the nerves of the soft palate, larynx, and of other cerebral nerves may occur. The electrical reaction of muscles and nerves is more or less affected, in many cases amounting to an actual reaction of degeneration. The sensory disturbances belong to the late symptoms of the disease, such as pain in the atrophied muscles, tenderness to pressure along the course of the nerves, hyperæsthesias, hyperalgesias, etc. The thermic sensibility is as a rule unimpaired, though sometimes diminished or perverted. The reflexes are usually diminished, especially the tendon-reflexes. Vasomotor and trophic disturbances are frequent, as glossy, squamous skin, transversely striped and brittle nails, swelling of joints, bedsores, etc. General symptoms are not infrequently met with, such as dyspeptic symptoms, obstinate vomiting, diminished secretion of urine, lessened sexual desire, menstrual disturbances, tachycardia, etc. The functions of bladder and rectum are nearly always normal. Amnesia is the most characteristic mental symptom. This is general and profound, and may be entirely confined to the most recent events; at the same time the patient will answer questions with great precision and reason logically. During convalescence there is a gradual return of the memory. The amnesia develops in conformity with the laws regarding retrogression of memory; the most recent impressions disappear first, the older ones later; the intellectual abilities disappear more slowly than the intellectual processes, while the acquisitions which have become almost entirely organic are preserved. The amnesia is often accompanied by disturbances of consciousness, incoherence and narrowing of the field of thought, or symptoms of exaggerated irritability of the psychomotor sphere predominate. These are manifested by extreme excitement, frequently developing into attacks of mania. At the beginning of the disease disturbed sleep interrupted by frightful dreams, visual hallucinations (visions of serpents, mice, cats), and attacks of fear (fear of brigands, apparitions of blood-like color) occur. The prognosis is influenced by the rapidity of the course of the disease (best in chronic cases), by the general condition of the patient, by the possibility of removing the cause (alcoholism, arsenic or lead poisoning, etc.), and by the gravity of the complications (pneumonia, decubitus). The latter are often fatal.—*Journal of Nervous and Mental Disease*.

The Typhoid State.—The diseases in which the "typhoid state" most frequently occurs are for the most part as follows: (1) typhus fever (Rouillon) and the "typhus traumatique" of Ollivier; (2) yellow fever, "bilious typhoid" (Hilton Fagge); (3) enteric fever (the term "typhoid fever" should be discontinued); (4) certain "pernicious" malarial fevers; (5) the "malignant" type of scarlet fever; (6) variola (Hilton Fagge), especially in the third week; (7) in the first stage of the plague, "after the appearance of intense pyrexia and subsequent violent delirium"; (8) in cholera-typhoid and in cholera (Hilton Fagge); (9) in diphtheria, where the characters of an "infective" fever with febrile albuminuria and other "typhoid" symptoms are evident; (10) in "adynamic" remittent fever and in the so-called "typho-malarial fever" of the United States; (11) in "malignant" and "intestinal" anthrax—in this condition, however, the temperature is not always high; (12) in "infectious pneumonia" of an epidemic nature, and "croupous" or "fibrinous" in type (Whitelegge)—this occurs both in fatal and in non-fatal cases which are severe and protracted; (13)

in chronic starvation and general wasting (Whitelegge); (14) in phlebitis (Hodgson, Breschet, Blaudin) and in "la phlébite utérine" (phlegmasia dolens); and (15) in experimental injection of septic substances into the veins (Gaspard, Laurent, and Dupuis).—FORBES in *North Carolina Medical Journal*.

The Sputum in Malignant Tumors of the Lung.—While the morbid anatomy of sarcoma and carcinoma of the lung is a subject on which literature is copiously supplied, yet there are but few cases recorded in which the diagnosis of such primary growths has been made during life. Dr. Betschart had an opportunity of observing a case in which the diagnosis of primary diffuse cancer of the lung was made several weeks previous to death, this conclusion being reached through an examination of the expectoration. After dilating on the varied characters of sputum in pulmonary diseases, Betschart shows how little reliance can be placed on the color, consistence, or form of the sputum in the diagnosis of pulmonary neoplasms. When, however, particles of a new growth in the lung find their way into one of the bronchi and are thus admitted into the sputum, as may occur when circumscribed nodules exist in the lung, then sections of these masses would make a diagnosis easy. Sometimes, however, one may get a diffuse carcinoma of the whole organ, and the writer asserts that a diagnosis may then be made from the presence of characteristic cells or groups of cells in the sputum, and such an instance is the basis of his paper. Two cases of sarcoma of the lung are also noted in which a correct diagnosis during life was arrived at by section of tumor particles found in the sputum, in each instance small-round-cell masses being discovered. Only one case had hitherto been recorded of a diagnosis of cancer of the lung by this method. Hampeler found in gelatinous globular masses of sputum certain large polygonal cells with granular protoplasm, the diameter of the cells being from .002 to .025 mm., and that of their nuclei from .012 to .0125. Dr. Betschart assures us that these alone are sufficient to justify a diagnosis of cancer of the lung and describes in detail his own case. A patient had been admitted to the Zürich clinic with a diagnosis of pulmonary phthisis with encapsulated tuberculous pleurisy. The signs pointed to a rapidly advancing consolidation of one lung, and the sputum on examination presented microscopically what he considered characteristic features, viz., little gelatinous masses, some yellowish and translucent, others more opaque and brownish. Minute examination showed very large epithelial cells similar to those described by Hampeler, and in consequence cancer of the lung was diagnosed. A report of the autopsy is given, and the lung as described would not appear to differ in any essential from a condition of fibrosis of the lung, while plates of the sections show nothing further than large epithelial cells surrounded by thickened septa, such as might be expected in a chronic catarrhal pneumonia with much desquamation of the epithelium. That a diagnosis of cancer of the lung is possible in this way is a subject on which much might be said. Conditions of fibroid phthisis with secondary gangrene of the lung would possibly lead to a similar expectoration, while sections of the lungs would show quite as characteristic appearances as those submitted in Betschart's plates. Wherever, too, there is considerable interstitial pneumonia it would seem quite possible that the alveoli with their altered epithelial cells would be much contracted, giving to the microscopic sections the appearance of an irregular growth with epithelial cells lying amid a fibrous stroma, so that the difficulty in satisfactorily understanding its true nature would often be great. All in all, it seems that there is scarcely sufficient ground for Betschart to inform his readers of the absolute certainty of his diagnosis.—*Montreal Medical Journal*.

New York, May 16, 1896.

ARE NERVOUS DISEASES INCREASING?

WE have become so accustomed to the idea that the present age is particularly characterized by nervous diseases that we seldom question the truth of this impression. It is with pleasure that we read Philip Coombs Knapp's article in the May *Century*. He throws a little light upon the dark picture of our nervous degeneration and permits us to hope that our nervous systems are not in danger of the complete collapse that seems to threaten them.

The author says that the cause of the supposed increase in nervous disease is increased demand made by the conditions of modern life upon the brain. Everything is done in a hurry. We talk across a continent, telegraph across an ocean, take a trip to Chicago for an hour's talk. Business methods are such that a fortune may be made or lost in an hour. The conditions of a democracy are such as fill the people with unrest, each one striving to better his condition. We take even our pleasures sadly and make a task of our play. We must not only take an active part in all local affairs, but must sympathize with the dwellers in the uttermost parts of the earth. What wonder if the pressure is almost more than our nerves can bear.

The question arises as to whether these conditions are worse than those that have prevailed in the past. Human life and liberty are more secure than ever before. The civilized world suffers less and less from epidemics. Plague, small-pox, and cholera have almost entirely disappeared. Infectious diseases are becoming less deadly. The dangers of war and oppression are less. We no longer have the Inquisition, the stake, or the Bastille. Property is no longer taken from us without due process of law. A man can take a journey without fear of highwaymen. The farmer can plough his field without a dread of the red man's arrow. The material comforts of life have increased. We know nothing of the horrors of famine. We have cleaner houses, better walking, purer water, and fresher air. In a thousand ways life is made more easy and comfortable. All this means better mental health. Statistics are often deceptive. The better hygienic conditions prevent many weaklings from succumbing to infectious diseases, and these are probably more liable to nervous diseases as they advance in life. Vital statistics show a greater increase in deaths from

heart and kidney troubles than from nervous diseases. Paralysis and apoplexy, classed as brain diseases, are due to disease in the circulatory apparatus. Increase in insanity may be more apparent than real. Physicians recognize as insanity many mild forms of mental disease not formerly regarded as such. Popular ideas have changed. Insanity being acknowledged a disease and not a disgrace, many more persons are admitted to asylums now than formerly.

All nervous diseases are not due to the demands of modern life upon the brain. Broken heads, broken backs, and other traumatic nervous affections, diphtheritic paralysis, locomotor ataxia, and meningitis are due to other causes. Another large proportion of nervous diseases is due to bacteria. Some forms are thought to be of an infectious nature; others are thought to be produced by the action of poisons generated by the germs of other diseases. Other poisons, not of bacterial origin, may cause nervous diseases, as the so-called lead palsy. Arsenic, alcohol, absinthe, mercury, and other substances give rise to nervous diseases.

Many new forms of nervous diseases may be attributed to greater knowledge and refinement of diagnosis. Paresis is actually no more prevalent than it was fifty or one hundred years ago. The author does not think that, speaking generally, it can be proved that nervous diseases have increased. He speaks particularly of American nervousness. Dr. Beard calls nervous prostration the American disease and seems to accept as an axiom that Americans are more nervous than any other race. He admits that locomotor ataxia and apoplexy are more frequent in Europe than in America. The author gives quite conclusive statistics to prove that hysteria is more common in Europe than here. The old idea that Americans are physically inferior has been overthrown. The civil war ended that. No armies endured more than ours in the field; no people endured more than those who stayed at home waiting and helping. Dr. Brown-Séquard found that American mammals survived injuries that were invariably fatal to the European, and our surgeons found a surprising percentage of recovery from gunshot wounds. The American soldier is as well developed as the European. The American schoolboy is equal to the boy of Eton and Rugby. The longevity is as great or greater in this country than in Europe. In international sports America has held her own. Our cavalry and express messengers on the plains have made better time without injury to horses or men than the picked riders of Austria and Germany in the famous ride between Berlin and Vienna. These instances show that in size, strength, skill, and endurance we are equal to the European. The American is energetic, pushing, restless, impatient, more in a hurry, and perhaps lives under a greater strain than his brother beyond the sea. He may have a nervous manner, but this is not nervousness in the sense of nervous disease. He shows fewer signs of nervous degeneracy and is less frequently a victim of severe nervous disease. Is there not, then, good reason to ask whether, on the whole, social conditions are not to-day more favorable to mental and nervous health than they have ever been before?

INTRA-UTERINE FETAL ENDOCARDITIS.

IN addition to various malformations of the heart and defects of development, the new-born infant may present evidences of endocarditis of intra-uterine or prenatal origin. Under such circumstances almost invariably the right side of the heart is affected, in consequence of being the more active during foetal life, just as the left side is usually involved when the endocarditis occurs during post-uterine existence. The most recent instance of this localization is reported by Brindeau,¹ who details the case of an infant dying a few hours after birth and presenting post-mortem evidences of tricuspid valvulitis with insufficiency. The child was born at term of a mother twenty-two years old, in excellent health, free from infectious diseases during pregnancy, and without a history of syphilis or rheumatism. The child was well developed, except for its head, which though well ossified was disproportionately small. Respiration was evidently interfered with and the face was deeply cyanotic. In the submaxillary region upon either side was a regular, soft tumefaction, as large as an egg upon one side and as a walnut upon the other, yielding on pressure, but resuming its original fulness on removal of the pressure. Each presented pulsation and appeared to communicate with the other. Auscultation disclosed a bruit synchronous with the cardiac systole. The child lived only a few hours after birth and the post-mortem examination disclosed a condition of tricuspid insufficiency. The heart was greatly enlarged, principally at the expense of the right side, and almost entirely filled the thoracic cavity. Puncture of the right auricle permitted the escape of a large quantity of blood, with the disappearance of the tumor upon either side of the face. The superior vena cava was greatly dilated and the jugular vein in even greater degree. The latter formed the facial swelling. All of the communicating veins were likewise dilated. The wall of the auricle was thinned, but that of the ventricle was thickened, exceeding even the thickness of the left ventricle. The tricuspid orifice was greatly dilated, permitting the introduction of the whole hand. The valve leaflets were thickened, shortened, and incompetent. The pulmonary orifice displayed no abnormality. The orifice of the superior vena cava was enlarged; that of the inferior was normal in size. The foramen of Botal was closed; the ductus arteriosus was obliterated. The left side of the heart presented no abnormality. Histologic examination of the tricuspid valve disclosed a round-cell infiltration in process of fibrous transformation, but without the presence of micro-organisms.

Zariquiey² has reported a case of tricuspid and pulmonary obstruction and insufficiency, with right-sided ventricular hypertrophy, in an infant dead at the age of eleven months, which presented at birth cyanosis and a soft, prolonged cardiac murmur following the first sound of the heart, and occupying the period of silence. The murmur was audible over the whole cardiac area, though heard with greatest intensity at the

left base, and was propagated toward the left clavicle.

Railton¹ has reported the case of a boy who died at the age of four years, and presented, in addition to a deficiency of the interventricular septum and right-sided hypertrophy of the heart, old tricuspid valvulitis, which was believed to be of prenatal origin, together with recent endocarditis, which was assumed to be a continuation of the original process.

That a pregnant woman suffering from infectious disease may give birth, prematurely or at term, to a child suffering from the same disease has long been recognized; and recent experience demonstrates that the transmission takes place through the placenta. We have also learned that any infectious process is capable of causing endocarditis. It may thus happen that the pregnant woman is attacked with rheumatism, or typhoid fever, or influenza, or pneumonia, or other infection, while her unborn infant, though possibly escaping the primary disease, is the victim of an inflammation of the endocardium of the right side of the heart, the consequences of which persist throughout life.

THE CONDITION OF THE STOMACH IN PERNICIOUS ANÆMIA.

WHETHER or not anæmia may be primary—in the sense of originating in modifications of the normal processes of hæmogenesis and hæmolysis—is a question that we are not prepared to discuss here. Of its possibility there can be little denial, although demonstrable proof may be wanting; and it is a well-recognized clinical fact that in a considerable number of cases of profound and even fatal anæmia an adequate cause of the blood state may elude detection. The fact likewise must not be ignored that recovery—often but transitory, though sometimes, perhaps, permanent—may take place in cases presenting the typical clinical picture of pernicious anæmia. In a number of these cases it is not unlikely that destructive changes are induced in the blood as a result of processes that take place in the stomach and intestines as a result of motor and secretory insufficiency. By reason of such conditions not only is the nutritive supply curtailed and the blood thus deprived of the elements necessary for its regeneration, but also is opportunity afforded for the development of chemic products capable when absorbed into the blood of exerting directly deleterious effects, and thus leading to increased destruction. Whether, however, these two factors are sufficient alone to induce the lesions and bring about the train of symptoms constituting the clinical picture of pernicious anæmia, is yet to be determined. That they may act at least as contributing influences on any given case none will deny. Of such a relation an excellent illustration is afforded by two fatal cases of pernicious anæmia, reported by Hayem² at a recent meeting of the Société Médicale des Hôpitaux. One occurred in a woman, sixty years old, in whom the most conspicuous lesion found was a considerable de-

¹ Journal de Médecine de Paris, 1896, No. 13, p. 150.

² Maladies de l'Enfance November, 1894, p. 620.

² Hayem: La Presse Médicale, 1896, No. 26.

gree of atrophy of the mucous membrane of the stomach. In the second the most careful scrutiny failed to show any morbid change in the gastric mucosa. These observations seem to show that pernicious anæmia may be accompanied by gastric lesions, although there is no necessary relation between the two and the latter may be wanting. It is, however, possible that the gastric disorder may exert a hæmolytic influence, as demonstrated by the improvement that takes place in the state of the blood in cases of gastric derangement attended with anæmia, but which are to be distinguished from cases of pernicious anæmia by the histochemic characters of the blood.

News of the Week.

St. Francis Hospital, New York.—Dr. Frank E. Miller has been appointed resident physician to St. Francis Hospital, to fill the vacancy occasioned by the death of Dr. John H. Ripley.

The New Lunacy Law.—The obnoxious lunacy bill for the State of New York has been signed by the governor and becomes a law. It legislates out of office on December 31, 1896, the boards of managers of the various State hospitals, excepting those of the Manhattan and the Middletown hospitals, and authorizes the governor to appoint their successors on or before December 31st. Thus the control of the asylums of the State, with the four and one-half millions of appropriation, will be transferred to the dominant political machine. It now remains to be demonstrated whether or not the ambitious lunacy commission has not virtually committed suicide with its own medicine.

American Pædiatric Society.—The American Pædiatric Society will hold its eighth annual meeting at Montreal, Canada, May 25, 26, and 27, 1896.

The Archiv für Verdauungs-Krankheiten, which has just completed the first volume, proves what can be done in special work. An admirable article is contributed by Prof. O. Rosenbach, of Breslau, entitled "Perihepatitis Simplex with Remarks about Peristalsis, Plethora Abdominalis, and Hemorrhoidal Conditions." Another article worthy of special mention is entitled "Dilatation of the Oesophagus and the Power of Absorption of the Oesophageal Mucous Membrane." These and other articles serve to demonstrate the scientific standing of the *Archiv* and give a fair idea of its promising future along these lines of progressive work. The most prominent names of specialists in this branch have been added as collaborators, and Dr. Boas, of Berlin, deserves great credit for the successful venture in this new field of journalism. We congratulate the editor accordingly, and wish him all the success he is sure to deserve.

Another Office Thief.—Dr. Forbes R. McCreery writes: "I would like to draw the attention of the profession to the fact that the office thief is again in evidence. Saturday afternoon a man called at my office and asked to be allowed to wait until I came in. He was permitted to do so. On my return he was gone, and with him a valuable clock. The clock was recov-

ered by the ward detective a few hours later at the nearest pawnshop. He probably also appropriated a paper cutter and a pair of bandage scissors that have been missing from my desk. The man was moderately tall, somewhat muscular, of a sallow complexion, and had a thick, rather short, dark moustache, and a remarkably heavy head of hair, somewhat curly, dark colored, and not parted. He was fairly well-dressed in a suit of dark clothes, and appeared to be a clerk or man of some such occupation. I give this description of the man in the hope that I may thus save other physicians from similar loss, and that possibly the man may be apprehended. He will unquestionably visit others of the profession before long."

New York Post-Graduate Medical School.—At the last meeting of the board of directors, Dr. Eugene Fuller was elected professor of venereal and genito-urinary surgery, and Dr. John McG. Woodbury was elected professor of orthopaedic surgery.

University of Buffalo Medical Department Alumni Association.—The twenty-first annual meeting was held Tuesday, May 5, 1896, making the fiftieth commencement of the medical department. The president's address was delivered by Willis M. Baker, M.D. The following papers were read: "Colpoperineorrhaphy," by Henry J. Garrigues, M.D., New York City; "The State of the Gastric Mucosa in Secretory Disorders of the Stomach," by Max Einhorn, M.D., New York City; "Reconstructive Surgery of the Tubes and Ovaries," by Robert T. Morris, M.D., New York City; "Some Notes on the Coronary Arteries," by George Dock, M.D., Ann Arbor, Mich. A banquet concluded the exercises.

American Gynecological Society.—The programme for the coming meeting of the American Gynecological Society will be as follows:

Tuesday, May 26th, 9:30 A.M.—"Address of Welcome," by Dr. William T. Lusk, New York. 1. "Vaginal and Senile Endometritis," by Dr. Paul F. Mundé, New York. 2. "Liability to Prosecution for Damages in Abdominal Surgery," by Dr. Cyrus A. Kirkley, Toledo, O. 3. "Gynecology and General Medicine," by Dr. Chauncey D. Palmer, Cincinnati. 4. "Woman and her Diseases versus Gynecology," by Dr. H. P. Newman, Chicago. *Afternoon Session at 3:* 5. "Aids in Obstetric Teaching," by Dr. J. Clifton Edgar, New York. 6. "Pregnancy following Removal of Both Tubes and Ovaries," by Dr. S. C. Gordon, Portland, Me. 7. "Double Ovariectomy followed by Pregnancy," by Dr. R. S. Sutton, Pittsburg. 8. "Treatment of Intraligamentous and Retroperitoneal Uterine Fibromyomata," by Dr. William H. Wathen, Louisville. 9. "Treatment of Retro-Displacements of the Uterus," by Dr. E. E. Montgomery, Philadelphia.

Wednesday, May 27th, 9:30 A.M.—10. "President's Address." 11. "Technique of Vaginal Hysterectomy," by Dr. Paul Ségond, Paris, France. 12. "Treatment of Extra-Uterine Pregnancy," by Dr. Howard Kelly, Baltimore. 13. "Treatment of Early Rupture of Extra-Uterine Pregnancy," by Dr. Fernand Henrotin, Chicago, Ill. 14. "Suspensio Uteri with Reference to its Influence upon Pregnancy and Labor," by

Dr. Charles P. Noble, Philadelphia, Pa. *Afternoon Session at 3:* 15. "The Relative Merits of Vaginal Hysterectomy by Ordinary Methods and Supra-Vaginal Excision by Galvano-Cautery," by Dr. John Byrne, Brooklyn. 16. "Diagnosis and Treatment of Ureteritis in Women," by Dr. Edward Reynolds, Boston. 17. "Implantation of Ureter into Bladder," by Dr. H. J. Boldt, New York. 18. "Surgical Injuries of the Ureter," by Dr. J. M. Baldy, Philadelphia. Business meeting at 5:30 P.M.

Thursday, May 28th, 9:30 A.M.—19. "New Method of Closing the Abdominal Wound," by Dr. E. C. Dudley, Chicago. 20. "Intestinal Bacteria as a Source of Infection Complicating Obstetric Operations," by Dr. Edward P. Davis, Philadelphia. 21. "Drainage of the Stump in Abdominal Hysterectomy," by Dr. H. T. Byford, Chicago. 22. "Myomectomy with Fatal Secondary Hemorrhage," by Dr. H. D. Fry, Washington, D. C. 23. "Foreign Bodies in the Peritoneal Cavity," by Dr. Archibald McLaren, St. Paul. 24. "Cæsarean Section: Total Hysterectomy versus Suture of the Uterus," by Dr. H. C. Coe, New York. 25. "The Zoological Position of the Menstrual Wave," by Dr. Arthur W. Johnstone, Cincinnati. 26. "In Memoriam Dr. Thomas Keith," by Dr. A. J. C. Skene, Brooklyn. 27. "In Memoriam Dr. W. W. Jaggard," by Dr. James H. Etheridge, Chicago. 28. "In Memoriam Dr. Robert Battey," by Dr. Thaddeus A. Reamy, Cincinnati.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the U. S. Navy for the weeks ending May 2 and May 9, 1896. April 25th.—Passed Assistant Surgeon H. N. T. Harris, detached from the *San Francisco*, proceeds home and is granted three months' leave, with permission to leave the United States. April 27th.—Assistant Surgeon F. M. Shipp, ordered to examination for promotion May 4th at New York City. April 28th.—Medical Inspector G. F. Winslow ordered to New London Station May 9th. Surgeon Clement Biddle detached from the *New London Station* May 9th and ordered to the *Monongahela* May 14th. April 29th.—Assistant Surgeon J. M. Moore promoted to passed assistant surgeon. May 2d.—Passed Assistant Surgeon A. M. D. McCormick detached from the Naval Academy and ordered to the *Bancroft*. Medical Inspector Daniel McMurtrie ordered for examination for promotion May 8th. May 5th.—Surgeon W. A. McClurg detached from the *Concord* and ordered home with three months' leave. Passed Assistant Surgeon P. H. Bryant detached from the *Petrel* and ordered home with three months' leave. May 6th.—Medical Inspector J. M. Flint, Surgeon J. C. Byrnes, and Passed Assistant Surgeon C. F. Stokes appointed a board to examine applicants for admission to the Naval Academy.

The Fees of Medical Witnesses in Great Britain.

—In Scotland medical witnesses receive two guineas for each day they are cited to appear in the circuit court of the town in which they are residing, and three guineas if the court is held at a distance. There are also allowances for travelling and other expenses. In England and Wales the fee is one guinea per diem,

one round-trip railway fare, and an allowance of two shillings per night. If the court is held in the city in which the witness resides, there are no allowances beyond the guinea a day. The association of police surgeons of Great Britain and Ireland is agitating the question of demanding larger fees for witnesses. It recently requested the home secretary to receive a delegation to confer with him on the desirability of revising and increasing the present scale of fees, but he declined to discuss the question, seeming to think that \$5 a day was good enough pay for a doctor.

Obituary Notes.—DR. GRAYSON MALLET-PREVOST, formerly a surgeon in the United States army during the Mexican war and subsequently for many years a resident of Mexico, died on May 1st, at the Presbyterian Hospital in Philadelphia. He was graduated from the University of Pennsylvania in 1844, and entered the army as a surgeon, being stationed at West Point. When the Mexican war broke out shortly afterward, he went to the front and served on the staff of General Wool. During the latter part of the campaign he was chief surgeon of one of the main divisions of the army. After the war he settled in the city of Zacatecas, returning to Philadelphia in 1866, and again resuming the practice of his profession at Zacatecas in 1878. Dr. Prevost was deeply interested in the cause of Protestant missions, and was the means of establishing the first Protestant church in Mexico.—DR. SAMUEL O. SULTZBACH died of pneumonia at Marietta, Pa., on May 3d, at the age of fifty-four years. He was a graduate of Jefferson Medical College, and practised his profession for twenty years in Philadelphia, removing to Marietta, his native place, a year ago.—DR. LEONARD R. KOECKER, for many years an able and active dental surgeon, died at Philadelphia on May 6th, at the age of seventy-four years. He was a graduate of Jefferson Medical College and was well known as a lover of literature and art, as well as a refined mechanic. He was a skilful amateur bookbinder and an adept in the construction of delicate and intricate machinery.—DR. D. A. AUSTIN, of Dresden, O., died at his home in that town on April 28th. Dr. Austin was an old resident of Muskingum County, and was prominently identified with the abolition movement in southeastern Ohio before the war, having assisted in the escape of many slaves by the "underground railway."—DR. THOMAS HENRY TROTT, of Washington, died suddenly of apoplexy at his residence. Dr. Trott was born in Washington in 1844, and was graduated from Georgetown College shortly after the close of the war. He was an interne at Bellevue Hospital in this city.—DR. CONSTANTIN PAUL, of Paris, died on April 12th, from albuminuria. He was chiefly known for his writings on diseases of the heart, though he was also the author of many works on therapeutic subjects. He was a member of the Academy of Medicine of Paris. He also received the decoration of the Grand Cross of the Legion of Honor. He was sixty-three years old.—DR. JOSEPH SPAETH, of Vienna, died on March 29th, at the age of seventy-three years. He was well known as an obstetrician, but retired from active practice and teaching about ten years ago.

Society Reports.

MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND.

Ninety-Eighth Annual Session, Held in the Hall of the Faculty, April 28 to May 1, 1896.

DR. CHARLES G. HILL, PRESIDENT, IN THE CHAIR.
DRS. J. S. FULTON, R. T. WILSON, AND W. G. TOWNSEND, SECRETARIES.

First Day—Tuesday, April 28th.

THE ninety-eighth annual session of the Medical and Chirurgical Faculty of the State of Maryland was called to order at the hall of the faculty, 847 North Eutaw Street, April 28th, at twelve o'clock noon.

Thyroid Feeding of the Insane.—After the reading of the minutes of the preceding meeting and the report of examiners and announcements of candidates, DR. CHARLES G. HILL delivered the President's address on the subject of "Some Observations on the Effects of Thyroid Feeding in the Insane." After referring to the literature of the subject, he said he had used the treatment in forty cases, some of which were acute, some chronic, and some in old persons. He had the following results: Unimproved, 8; improved, 12; greatly improved, 14; cured, 5; died, 7. He then reviewed a few typical cases and spoke of the effects of the treatment in general. In some there were elevation of temperature, gastric disturbances, and albuminuria. He could not say how the remedy acted, but was pleased with his success.

Diagnosis of Insanity by the General Practitioner.—DR. E. N. BRUSH then read a paper on the "Diagnosis of Insanity by the General Practitioner." He spoke in general of the ignorance of the average physician in matters pertaining to insanity. He said that the laws of commitment varied in the different States; that in New York, Pennsylvania, and Maryland a written certificate was necessary to commit a person to an insane asylum and two physicians were obliged to sign the papers. Some of the diagnoses were quite absurd. He divided insanity into two classes: 1. Those due to inherent brain defects, among which we class idiocy with certain degenerative forms of insanity, of which paranoia was the great type; and 2. Conditions due to diseases of the brain or to disturbances of the physiological function by disease of other organs of the body. Under the second head are included melancholia, mania, dementia, and general paresis. It is difficult to get a careful and correct history of a case. Persons will deny any family taint and try to deceive the physician. The general practitioner is not skilled in asking the necessary questions and may be deceived. Even where there is no hereditary history of insanity, the phthisical taint on one side and the neurotic on the other may produce insane offspring. It is well to learn as much as possible of the patient first before seeing him and then to examine him afterward. An insane person is usually shrewd and crafty, and the examiner must use tact. Note the patient's attitude. Is he ill at ease? Is he quiet? Examine the skin, tongue, eyelids, hair, etc. There is rarely a clear complexion in the beginning of insanity. Persons insane often give the most lucid and sane answers, and paranoiacs who act in the most intelligent manner until their hobby comes up are frequent.

DR. HENRY M. HURD said that the general practitioner was not usually familiar with the technical terms of insanity. He cannot tell what he sees. It is sometimes easy to see that a person is insane, but

hard to say why this is so. The diagnosis should be made by the general practitioner. Insanity should be studied in the medical schools, but it is rarely touched on and no examination on that subject is held. The certificates that come from the general practitioner are usually correct and the mistakes are occasional only. Another difficulty arises from the fact that many definitions of insanity are legal and not medical, and the mistake is that the physician tries to show that the patient is legally and not medically insane. The legal diagnosis is a delusion and a snare. It is behind the medical. Physicians are often too accommodating, and when friends come and call on the physician and state what they think and ask for a certificate, the physician is sometimes willing to sign one without seeing the patient. The physician should investigate every case, and sign no paper unless he has seen and studied it.

Development of the Nervous System.—DR. LEWELLYS F. BARKER then made some remarks on "Some Aspects of the Study of the Human Nervous System with Particular Reference to its Development." He spoke of the neurons and types of cells. He said that these cells were separate and yet connected in a way that was too complex to explain. The development of the nerve cells depends on simple mechanical principles. They grow out and send their branches in the direction of least resistance. The neuron is the morphological and physiological unit. The study of the nerve anatomy of recent years would necessitate a recast of our knowledge of this subject. There are four varieties of skin sensation: sense of pressure, heat, cold, and pain. There are also definite sense areas in the brain. The new-born baby has a cerebrum with no medullated fibres. There is a great field for investigation in nerve study with the microscope since the newer methods of staining have been introduced.

DR. G. J. PRESTON spoke of the great advances made in neuro-histology in the past ten years. The neuro-histologist is far ahead of the physiologist. The clinician should make a careful study of all his cases and not only profit by the researches of the laboratory student, but help him.

DR. J. D. BLAKE asked if the collateral branches of the axon were real branches or were they simply fibrillæ passing down from the cell with the body of the axon for a certain distance and then branching off? He also asked if Dr. Barker had not said that the fibres in the pyramidal tract did not cross. How did he explain crossed paralysis?

DR. BARKER replied that the lateral pyramidal tract does cross over, but the direct tract does not.

DR. H. J. BERKLEV then made some remarks on the "Psychical Nerve Cell in Health and Disease." He explained the different shapes of the cells; some were pyramidal, some like whetstones, and others irregular. The branches of these cells have on them small lateral branches. In poisoning from alcohol, ricin, etc., the nerve cells and branches show thickening.

DR. A. K. BOND asked how wasted nerve cells could be affected by the thyroid treatment in twenty-four hours.

DR. BERKLEV replied that the thyroid extract caused a congestion around the nerve cell and a temporary improvement only. The nerve cell degenerates in a very short time, and as it is a complete substance in itself it does not recover. He is not very much pleased with the thyroid treatment.

Discussion on Diabetes Mellitus.—DR. WILLIAM H. WELCH, in speaking of the pathology of this disease, said that no lesion was universally present in diabetes; nevertheless it is hardly correct to say that there is no lesion characteristic. There is one which is pathognomonic, but it stands in no relation of cause and effect. It is constant in this disease and is found

in certain cells in the kidney. Armani described it in Cantani's book about twenty years ago. It is little recognized. It was supposed to be a dropsical affection of the cell, but now we know it is not. It is a glycogenic metamorphosis of the cells. The epithelial cells lose their clearness, but the nucleus is clear. This is found chiefly in the ascending arm of the tube, but elsewhere as well. If the specimen is so prepared that the glycogen is still retained there, it can be easily seen under the microscope. The specimen is put into boiling water, absolute alcohol, or water with iodine. These cells are filled with glycogen, and in all cases which he has examined, and they are not many, the glycogen was present. The diagnosis of this disease can always be made at the autopsy, but there is no reason to suppose that it is a cause; more probably it is a secondary effect. The causal lesions which we know are of two classes—of the central nervous system and of the pancreas. The extirpation work of physiologists called our attention to this first. Bernhard von Mering and others first described lesions in the medulla oblongata. These have been found in many cases. Bouchardat, Lancereaux, Frerichs, and Senator all understood this disease and antedated the experimental work, and indeed it was known in the last century. It is only in the last seven years that more attention has been given to the pancreas in this connection. The total extirpation of the pancreas in dogs has caused diabetes. This is not due to a lesion of the surrounding part, but to the interruption of the function of the pancreas. The proportion of cases of diabetes associated with pancreatic lesions is at least fifty per cent. The lesions of the pancreas vary in their character. Hansemann says that one lesion which is invariably associated with diabetes is granulation atrophy of the pancreas. It has its analogy in granular nephritis. There is an increase of the connective tissue, a thickening of the walls of the vessels, and a diminution of the glandular substance. There is no other lesion which destroys the function of the pancreas that will cause it. Calculus of the duct and new growths may cause conditions almost similar. These facts may not be so reliable when we consider that the pancreas is examined at the post-mortem in every case of diabetes, but is rarely looked at in other diseases. He holds that all cases of diabetes are due to changes in the pancreas. There is no characteristic lesion of the liver; indeed, it is often not affected at all. Some lay great stress on the dilatation of the blood-vessels of the liver. This is not demonstrable and not important. In some cases the liver cells are changed and there is a glycogenic metamorphosis of the nucleus of the cells. He does not believe that the sympathetic nervous system has anything to do with the cause of the disease. There is some change in the blood. Glycogen has been seen inside the leucocytes. Diabetics are specially predisposed to complications, especially to infection from pyogenic organisms, boils, carbuncles, etc. Senator says that lobar pneumonia is a rare complication; Osler says it is very common. Klemperer says that it is not common, probably because the organism of pneumonia does not grow well in the presence of sugar; but Welch says on the contrary that the presence of sugar favors its growth. In these cases colon bacillus is found.

DR. JOHN S. FULTON then spoke of the etiology of this disease. When the food supply of carbohydrates is excessive the glycogen reservoir is overtaxed. If the ingestion of sugar goes beyond the physiological line, glycosuria appears for a short time. Heredity, age, sex, social condition, geographical position, race, contagion, temperament, and certain diseases are all predisposing and determining causes of diabetes.

Varieties of Clinical History of Diabetes.—DR.

WILLIAM OSLER then spoke of the "Varieties and Clinical History of Diabetes." Three questions are asked by the physician: First, Has the patient actually sugar in his urine? He referred to a case of alkaptonuria. A man was rejected for life insurance because he was supposed to have glycosuria. Further investigation of this case in 1887 showed the absence of sugar and the presence of a substance called alkapton. Dr. Osler had a case last year which was supposed to be diabetes. Fehling's and other tests showed the presence of sugar, but the fermentation test and the polariscope showed that no sugar was present. This man also had alkaptonuria, and, strange to say, was a brother of the first man referred to. Second, Is it true diabetes or is it a transient glycosuria caused by an excess of starchy food, nervous trouble, or is it a toxic form of glycosuria? Third, Given a patient with diabetes, is it a mild or a severe case? In a mild case, all we have to do is to cut off the carbohydrates for three days and put the patient on an ordinary meat diet, and the sugar will disappear in from one to three days. Most cases we see are in men between forty-five and fifty years old. The disease can be controlled by diet. He gave instances in which an excess of starchy food increased the amount of sugar very markedly, but on a strictly nitrogenous diet the sugar was kept within bounds and the man could follow his business. A case in which the carbohydrates are excluded for three days and sugar still remains is a grave case. The disease runs a rapid course in children. Adults can stand it much longer, and in exceptional cases they have been known to live for many years with the disease.

DR. H. FRIEDENWALD then spoke of the "Ocular Manifestations of Diabetes." Diabetic affections of the eye are due either to general debility, to disturbances of nutrition, or to the production of the toxic substance in the blood. Visual disturbances are general enfeeblement depending upon weakness of the external ocular muscle and still more of the muscles of accommodation. The affections probably due to nutritive disturbances are cataract, retinitis, and hemorrhages within the eyeball. Diabetic cataract is not so frequent as is generally supposed. Disease of the eye may also be caused by a poisonous product circulating in the blood.

DR. T. C. GILCHRIST then spoke of "Cutaneous Affections in Diabetes." In diabetes the skin is perhaps more affected than any other organ of the body. The most characteristic cutaneous lesions are found in the genital regions. There are also functional affections and trophic changes. The commonest diabetic manifestations on the general surface of the skin are boils and carbuncles. Boils occur early and carbuncles late in the disease. Gangrene is also a serious complication of diabetes.

Prophylaxis and Treatment of Diabetes.—DR. I. E. ATKINSON then spoke of the "Prophylaxis and Treatment of Diabetes." From the variety of its pathology we would seem to have no way of treating it etiotogically. Measures for prevention can only be taken in a few cases. In hereditary cases, in obese and gormandizing persons, and in those who have recovered from one attack, we can take measures to prevent its recurrence. The medicinal treatment is entirely unsatisfactory. Arsenic occasionally benefits. The latest remedy recommended by West, of England, in the *British Medical Journal*, is twenty grains of uranium nitrate three times a day. One drug which should be spoken of is opium. It has very little influence over the disease, but it checks the glycosuria and polyuria. Codeine and morphine are the best forms in which to give opium. The habitual use of opium in this disease is not desirable. It should be given intermittently. The suggested treatment with pancreatic extract is of

no especial advantage. The most satisfactory treatment is by diet, but the deprivation of starchy food and of bread especially is a great hardship. Diabetic patients are as untruthful as opium eaters, and very little confidence can be placed in their word. Aleuronat bread and peanut-flour bread have been highly recommended. Mineral waters are also used. The main object of treatment is the maintenance of albumin. The amount of food necessary may be calculated mathematically according to the weight of the patient. He must have fat or alcohol to make up for the loss. Never put the care of a patient in his own hands. He should never go to the table, and should have his food arranged for him so as to insure variety of diet.

DR. A. K. BOND said that the subject of diabetes in children had not been sufficiently considered. It was rapidly fatal in early life, and treatment seemed to be of little avail.

DR. A. FRIEDENWALD said that the books taught us that diabetic cases usually ended in coma, but of the ten patients whom he had had in his practice in the last few years only two had died of coma.

Second Day—Wednesday, April 29th.

Recovery with Existing Depressed Fracture of Skull.—DR. R. PERCY SMITH then exhibited a patient who had a compound fracture of the skull with loss of brain tissue. The boy had been kicked by a horse in the forehead and been given up to die. Dr. Smith injected nitroglycerin and later gave digitalis. The boy's condition improved. He removed some bits of bone, treated the wound antiseptically, gave careful diet, and the boy entirely recovered with a loss of only one ounce of brain substance. The tablet of bone is still depressed.

DR. R. WINSLOW thought there might be danger yet and that the bone ought not to be left depressed, but should be operated on.

DR. J. H. BRANHAM thought the result wonderful, and under the circumstances Dr. Smith had done all that could be done.

DR. J. C. HARRIS said that the injury was near the supraorbital vessels of the nerves and an operation might be dangerous.

DR. SMITH said in conclusion that the family opposed an operation, and he did the best he could under the circumstances.

Operations for Facial Neuralgia.—DR. L. M. TIFFANY then spoke of "Operative Measures for the Relief of Facial Neuralgia." He said it was not possible to state the present status of this operation; one could not say what the result of the operation would be. Many operations are done with entire relief to the patient and little loss of power. There have been about eighty-five to ninety-five cases recorded. The mortality was larger than was usually supposed. He had had ten cases himself. One patient died on the twenty-fifth day from sepsis, who should not have died. Secondary operations are being done now; he had operated on one case twice. He had had cases in which the nerve and ganglion had both been removed and yet the pain remained. In one case the man had entire sensation in the skin of the forehead, and yet his nerve was in a bottle. He has had no recurrence of the pain in any case. After section of the nerve and removal of the ganglion the sensation will gradually come back and the sense of heat and of cold, but not motion and pain.

DR. J. M. T. FINNEY referred to several cases. One patient got well, one had a slight return of the pain, and one died the day of the operation.

DR. R. WINSLOW related a case of removal of the fifth nerve and its branches and a part of the nerve behind the ganglion, and now the patient has pain on the other

side of his face, and a double operation would cause paralysis of the muscles of mastication on both sides.

DR. J. C. HARRIS asked about the habits of the patients and where they lived before being operated on.

DR. TIFFANY did not remember where they lived. He thinks the motor root can be left. In the second case related he took hold of the motor root and caused the muscles of mastication to contract on that side, and he wishes now that he had left the nerve.

DR. I. R. TRIMBLE then related three cases of "Injuries to the Kidney with Surgical Treatment."

DR. RANDOLPH WINSLOW made some remarks "On Surgical Disease of the Kidney." After describing the anatomy of the kidney, he showed the distinction between movable and floating organ. It is more common in females than in males. The symptoms are subjective and objective.

DR. J. M. T. FINNEY spoke of the "X" Rays in Surgery." He showed several fine photographs. All normal tissues except bones transmit the light; only bony tumors may be seen. Pictures of the fetus show the position. He thought there were great possibilities for this new means of diagnosis. The skiascope also has a future.

The Renal Catheter and Diagnosis of Stone in the Kidney.—DR. HOWARD A. KELLY then made some remarks on the "Use of the Renal Catheter in the Diagnosis of Stone in the Kidney." He showed plates and explained how easy it was with his cystoscope and head mirror, with the woman in the knee-chest position, to introduce the catheter into the bladder and into either ureter at will. The presence of stone in the pelvis of the kidney could be thus detected. He used a hard-rubber bougie coated with dental wax, which he applied to the bougie by dipping it into the melted wax. He thus obtained a smooth, glistening surface, which showed the slightest scratch from the stone. He sometimes found it better to add a little olive oil to the wax. He also used a catheter, coating its tip with wax, except at the eye, through which he could draw at will fluid from any part of the kidney or ureter. He had made the diagnosis of stones in the kidney in many cases in this way, and he showed several specimens. In introducing the bougie or catheter covered with wax, care must be taken that it does not strike the cystoscope or any other object which might scratch its surface and deceive the surgeon. He brought this before the society and hoped that no surgeon would attempt to operate on stone in the kidney in woman without first attempting a diagnosis in this simple way.

Third Day—Thursday, April 30th.

DR. R. TUNSTALL TAYLOR read a paper entitled "Treatment of Lateral Curvature of the Spine." This was caused by faulty position. Cases came from long standing, carrying heavy schoolbooks, violin playing, sitting at school on improperly made chairs and benches, and other causes. Too many physicians do not treat these cases at all, but turn them over to the instrument maker and to those using Swedish movement. He then in a general way gave directions as to exercise, gymnastics, class drills, baths, and showed the apparatus with plaster jacket for the correction of the various deformities and the strengthening of the muscles.

DR. E. M. SCHAEFFER said that if punning were not a crime he would derive the word "scoliosis" from the word "school," as so many children contracted curvature of the spine at school. Scoliosis was not known to the Greeks, because they lived out doors and were not cramped with tight clothes. It first appeared about the sixteenth century and was brought about by the tight dressing of the French.

Operative Treatment of Gall Stones.—DR. W. S. HALSTED then made some remarks on the "Operative Treatment of Gall Stones." The surgery of gall stones from the duct and gall bladder is still in its infancy. As in other branches in surgery, the time will come when we will not operate at all for many conditions for which we do operations now. For example, a large part of surgery is done for the removal of cancer, and the time will possibly come soon when cancer will be treated by inoculation. But he thinks that gall stones will always be operated on. Langenbuch's idea was to extirpate the gall bladder, but this is not done very often. Another operation soon to be given up is Winiwarter's cholecystenterostomy. This was done for stones in the common duct, but now it is not done except for cancer of the duct and head of the pancreas. The head of the pancreas is so hard in these cases that it feels like cancer. Another form of operation which has been abandoned is the two-act operation. At the first operation all the ducts should be explored if possible; it is not always possible. It is not always easy to explore the cystic duct, but one can explore the common duct. It can be done by cutting through the mesocolon and drawing the omentum up and the duodenum out, when the common duct will be seen. Some prefer the vertical and some the transverse position. He prefers the vertical because it gives him more room in which to operate. It may be necessary to excise the ends of the lower ribs, but this is not desirable, as the cut ends cause great pain. An osteoplastic operation might be an improvement. All the operations should be done at one sitting. Special needles for sewing up the gall bladder should be used. They should be small, No. 12, to sew up the walls of the common duct. The walls are usually very thin, but when a stone has been there for years the walls are thicker. There is not much experience in common-duct surgery. He related one or two cases of the latter. The presence of gall stones does not always demand an operation. Not all cases need to be operated on, but it is well to operate before the stone gets into the common duct.

DR. S. T. EARLE then reported two cases of "Tuberculous Fistula in Ano." He described these two cases and his manner of operation, and his object was to show the importance of a microscopical examination in all cases of fistula in ano.

DR. HALSTED said that he had never seen a case of primary rectal tuberculosis. He had seen two cases of rectal tuberculosis during the past year. He had also seen cases of primary vaginal tuberculosis in which the disease occurred nowhere else in the body except a beginning peritoneal tuberculosis; this he found out by an abdominal exploration which had ruptured the uterus. He had once a very interesting case of laryngeal and pharyngeal tuberculosis which he had cured by cauterization of the mucous membrane. It is not always easy to recognize these lesions.

DR. EARLE said in 1884-85 he had made one hundred and sixty autopsies and had found no tuberculous ulceration of the rectum.

DR. H. H. BIEDLER then exhibited a case of "Trephining for a Local Paralysis with Cure." He had undertaken this operation with very little knowledge of the cause of the trouble and with little expectation of such good results.

DR. E. M. REID said that the case had been on the medical side of the hospital, and tenderness on percussion had been found on the left side of the head; syphilis had been suspected, and the case had been recommended to the surgical ward.

Gonorrhæal Endocarditis.—DR. WILLIAM S. THAYER then made some remarks on "Gonorrhæal Endocarditis." Since Neisser in 1885 discovered the gonococcus, many troubles which were formerly obscure had been now shown to be caused by this organism.

There may be a pure infection, or there may be a mixed infection, or the gonococci may enter and make a way for other organisms, or pyogenic organisms may find their way in and drive out the gonococci. Also these local processes may be non-bacterial. He had seen at the Hopkins Hospital two cases of gonorrhæal endocarditis, in both of which the patient died. In the first case the cultures were made from flowing blood taken from the arm. From the growth obtained the gonococcus was suspected, but was not certain. In the second case it was found, and examination of the blood and also of the clot on the valve of the heart verified the diagnosis.

DR. W. A. DUVALL asked how long a time elapsed between the initial lesion and the endocarditis, and also concerning the line of treatment followed.

DR. THAYER replied that very little was known in one case, but in another case recorded five days elapsed, which is a very short time. He has no record of his cases before they came in, but in one of them the severe chills which took place showed that further infection with the gonococcus had occurred. It is hard to say what to do with these cases. In one case the gonococcus was also found in the genital organs.

DR. J. D. BLAKE then reported "Sixteen Cases of Laryngeal Croup Treated by Intubation and with Antitoxin." The oldest patient was seven years, the youngest four months. Twelve recovered and four died. In one case the antitoxin was used on the second day and in another on the ninth. In two cases no organisms were found in the throat, but they can carry contagion to other cases. He then showed a simple but very effective instrument for removing the tube.

DR. C. C. HEMMETER asked if he had observed any difference between the German and American antitoxin.

DR. BLAKE replied that there were no discriminating results for either.

Gastro-Intestinal Manifestations of Hysteria.—

DR. GEORGE J. PRESTON then read a paper entitled "The Gastro-Intestinal Manifestations of Hysteria." He first spoke of contraction of the œsophagus causing rejection of the food. Blood was often vomited; this was bright red in color and simulated other affections. Many cases of so-called vicarious menstruation were really hysterical in character. Hysterical anorexia was common. Hysterical patients seemed to be able to live on very little food and often go an incredibly long time with very little to eat. They will often attempt to deceive by starving in public and stuffing in private. They suffer greatly with distention of the bowels with gas.

DR. HEMMETER said this paper was written from the standpoint of a neurologist. All the symptoms related seem to come from the nervous system. Certain forms of these troubles are intestinal and are due to auto-intoxication.

DR. PRESTON replied that we cannot classify the pathology of neuroses, hence we have to run the gamut of all the specialties. In very many cases we can find no evidence of a pathological lesion.

In the evening the annual oration was delivered by DR. SOLOMON SOLIS-COHEN, of Philadelphia. His subject was "The Path of Progress in Modern Therapeutics." After this, the portraits of Dr. George W. Miltenberger and Dr. H. P. C. Wilson were presented to the society with appropriate addresses by DR. S. C. CHEW and DR. T. A. ASHEY.

Fourth Day—Friday, May 1st.

DR. JOHN C. HEMMETER then read two papers as follows: one on the "Possibility of Intubation of the Duodenum," and the other on the "Effects of Persistent Intestinal Putrefaction upon the Kidneys."

DR. JOSEPH T. SMITH then reported several cases showing the importance of a careful examination of the urine in suspected disease of the kidney and showing also that when we find abnormal ingredients we must know how to interpret them.

DR. HEMMETER referred to the importance of examining the patient on both sides before any operative treatment on the kidney, and referred to a case in which one kidney had been removed for some disease and it was found out afterward that that was the only kidney the man had.

DR. E. M. SCHAEFFER then read a paper entitled "The Physical Director of the Second and Nineteenth Centuries." It was an earnest plea to more logically convert medical practice into terms of sanitary art throughout all the specialties, and advocated a wider recourse to the natural therapeutics of the old Greek gymnasia or modern sanatorium.

Prevention of Thirst after Abdominal Operations.

—DR. JOHN G. CLARK then spoke of the "Prevention of Thirst Following Operations upon the Abdominal Cavity." Thirst is severe after operations, often as a result of the anæsthetic. Many methods have been suggested; some suggest to give freely of water several days before the operation, but so many operations must be done within twenty-four hours after the patient is seen that this suggestion cannot always be followed. In many cases vomiting is so severe that water cannot be retained. He had tried enemata of salt solution, 0.6 per cent., immediately after the operation. Comparing patients treated in this way with those given no water, the former were found to pass a larger amount of water in the first three days, the latter in the last three days, so that by the seventh day all had passed about the same amount. He finds the routine use of this injection of great efficacy in preventing thirst.

DR. T. H. ASHEY then reported a case of "Accidental Rupture of a Pregnant Uterus; Hysterectomy; Resection of Eight Inches of Intestine; Recovery."

Frequency of Contracted Pelvis in Baltimore.—

DR. J. W. WILLIAMS then read a paper on "The Frequency of the Occurrence of Contracted Pelves in Baltimore," in which he reported the results of the measurement of one hundred women who were seen at the Johns Hopkins dispensary. His conclusions from these studies were that the pelvis of Baltimore women were much below the normal.

DR. A. K. BOND said he thought the title of the paper was misleading, as the author should have stated, not that the contracted pelvis had occurred in Baltimore, but that they were a small number of selected cases seen at the hospital dispensary. He did not think that it was fair to draw results from a few picked cases seen at a special dispensary.

DR. WILMER BRINTON said that of six hundred cases which he had seen in the last few years many were below the measurements stated by Dr. Williams, and yet in only one case was an operation necessary.

DR. L. E. NEALE said that while he had a large experience in pelvimetry he found it was impossible to decide on an operation simply from the arbitrary rules of some authority. He had found many cases which fell below the given degrees of measurement, and in which labor took its normal course, and he had found others in which the measurements exceeded these stated and yet in which an operation was necessary.

DR. WILLIAMS said in conclusion that he had no intention of drawing deductions from one hundred cases seen at the Hopkins dispensary, but he simply wished to give the results of his experiments in pelvimetry.

DR. THOMAS S. CULLEN then read a paper on "Adeno-Myoma of the Uterus."

DR. W. W. RUSSELL then read a paper on "Post

Operative Recurrence and Metastasis in Carcinoma of the Uterus."

Other papers were read by title.

Officers for 1896-97.—*President*, Dr. William Osler; *First Vice-President*, Dr. Wilmer Brinton; *Second Vice-President*, Dr. Randolph Winslow.

AMERICAN MEDICAL ASSOCIATION.

Forty-Seventh Annual Meeting, Held at Atlanta, Ga., May 5, 6, 7, and 8, 1896—Continued.

R. BEVERLY COLE, M.D., PRESIDENT, IN THE CHAIR.

General Session. Fourth Day—Friday, May 8th.

THE closing session of the association was called to order at the usual hour by the president.

The Treasurer's Report.—DR. H. P. NEWMAN, of Chicago, presented his report as treasurer of the association. This showed an encouraging increase in membership, and consequently in receipts. The balance in the treasury is now greater than ever before. A change has been made in the fiscal year whereby it now coincides with the calendar year.

The Rush Monument.—DR. ROHÉ read a telegram which he had received from the chairman of the Rush monument committee, Dr. Albert L. Gihon, announcing that the Navy Department has assigned a site for the monument in the park facing the Museum of Hygiene in Washington.

Address on State Medicine.—DR. GEORGE H. ROHÉ, of Baltimore, then read his address, taking for his subject "The Purification of Public Water Supplies." The most vitally important sanitary problem now confronting American municipalities is unquestionably the supply of pure water for drinking and other purposes. The fact that the occurrence of typhoid fever depends almost entirely upon an infected water supply is sufficient to demonstrate the importance of having the water supply free from pollution. Cholera is another disease in which outbreaks and extension of the pest are dependent upon an infected water supply. But apart from the production of these specific diseases, pure water, or water free from all sorts of uncleanness, is demanded by the "sanitary conscience" of the public.

It is, of course, better, if possible, to obtain a pure water supply than to attempt to purify a source of supply which has become polluted. But in most cases the procurement of such an unpolluted supply is practically barred by financial considerations. We are therefore reduced to one of two alternatives—either to limit as far as possible or to prevent absolutely (which is practically impossible) the access of impurities to the sources of supply, or else to purify the water after it has become polluted. It will be found to be practically impossible, in most instances, to abandon a source of water supply that may be polluted and go a great distance in search of a pure supply. The expense of such an undertaking is too great. Fortunately, however, we have a means at hand for purifying a polluted water supply. This is filtration. Formerly filtration meant simply straining out from water all gross impurities and changing a dirty or muddy water into a clear and limpid fluid. We now know that water may be perfectly clear and limpid, and yet be extremely impure by reason of its content of organic matter or dangerous micro-organisms. A great impetus to filtration was given by the experiments conducted under the auspices of the Massachusetts State Board of Health at Lawrence in that State, and carried out so thoroughly by Mr. Hiram F.

Mills and Mr. Allen Hazen. These experiments, carried on with painstaking care for a number of years, prove conclusively that water, no matter how polluted, can be rendered pure by simply filtering the same through sand filters, provided certain cautions are observed regarding the construction of the filters, the rate of filtration, and other conditions varying with the character of the water to be purified. For many years, filtration through sand has been used by European municipalities to secure purification of water, and the construction and practical management of filters have been investigated with great care. Comparative studies of the efficiency of sand filters and of various processes of so-called "mechanical filtration" have been made recently in Providence, R. I., and at Lawrence, Mass. While the results obtained by different investigators have not been in entire agreement, the prevailing opinion of sanitarians and engineers is that sand filtration, where it can be adopted, gives the best results in purification, at the lowest cost of construction and maintenance. Koch has given a clear explanation of the process of sand filtration. The real filtration, he says, does not take place in the sand, but, by deposit from the still unpurified water, a layer of mud is formed on the top of the sand, and this is the real filter which retains the suspended constituents from the water. The important points are that a proper layer of slime should be formed, that it should not be disturbed during the process of filtration, and that when by further continuous deposit it becomes too thick, and therefore too impermeable to water, it should be removed. Different natural waters are capable of producing the filtering mud layer in very different degrees, according to the amount of mineral and vegetable matter held in suspension. In sand filtration, therefore, we are not dealing with so simple a matter as is often supposed. The sand layer should never be allowed to get below a certain thickness, about thirty centimetres, and a speed of about one hundred millimetres in the hour must be allowed for the movement of the water through the sand layer to obtain the most perfect purification. Koch further states that a daily or tri-weekly bacteriological examination of the filtered water must be made in order to test the performance of the filter. If a filter works satisfactorily in every respect, experience shows that there will be found less than one hundred germs capable of development in one cubic centimetre of water, and this is irrespective of the number of bacteria contained in the water before filtration. The slightest changes in the rapidity of filtration, or the disturbance of the surface of the filter bed, become manifest on bacteriological examination.

The cholera epidemic in Hamburg in 1892 furnished an object lesson of great value. Hamburg and Altona both draw their water supply from the river Elbe. In Hamburg, in 1892, the water was furnished directly to consumers without filtration; in Altona, on the other hand, the water had been for a number of years filtered. The Hamburg supply was drawn from the river at a point where there was comparatively little pollution, but the Altona supply was drawn from the Elbe immediately after the stream had received the sewage of the entire population of Hamburg, numbering nearly eight hundred thousand. As a matter of fact, cholera bacteria were discovered in the Elbe water below the main outlet of the Hamburg sewers. There was every reason to expect, therefore, that the cholera would have been more virulent in Altona than in Hamburg, but the contrary was the case.

For a number of years the city of Lawrence in Massachusetts had suffered from typhoid fever to an unusual degree. For the six years from 1887 to 1892 the deaths from typhoid fever in that city averaged fifty

annually, a proportion of one hundred and nineteen per hundred thousand of population. In 1893 the drinking-water, drawn from the Merrimac River, was subjected to filtration, and at once the typhoid death rate began to fall. In 1895, two years after the filtered water had been in general use in the city, the number of deaths had fallen to sixteen, of which nine occurred among operatives working in certain mills, where unfiltered river water was used for washing-purposes, and was also used for drinking by the operatives, because it was more accessible than the city water. In two cases the disease was believed to have been imported, and in five the origin was not accounted for.

Two processes must be kept in view in the construction of filters—one, the straining out of the bacteria always present in water; and the other, the oxidization of organic matter and its conversion into inorganic compounds. These imply that the materials of which the filter is constructed shall be sufficiently fine to hold back all suspended matters, and that a sufficient supply of oxygen shall always be present in order to allow the oxidizing processes to go on. In most natural waters there is a sufficiently large quantity of free oxygen to allow the oxidizing processes to go on continually, but in cases in which the water is highly polluted it is necessary to permit access of extra quantities of oxygen, in order that all the organic matter may be oxidized. This may be accomplished either by aeration of the water before filtration, or by carrying on the filtration intermittently, allowing the air to penetrate the interspaces in the filter before the water is again turned on the filter. This is what is done in intermittent filtration.

In the experiments at Lawrence it was found that an average of 98.54 per cent. of the bacteria found in river water were removed by filtration under favorable conditions.

Within the last two years an extended series of experiments upon filtration with so-called "mechanical filters" was made in Providence, R. I., with the view of adopting a system of filtration combining efficiency with economy. The apparatus most thoroughly tested is known as the "Morison filter," and its construction is described as follows:

"The filter bed of crushed quartz was two feet ten inches in depth, supported upon a base of iron with circular perforations of about four inches in size, which were covered with screens. The crushed quartz used was the 'effective size' of 0.59 millimetres. The filter was washed by a reverse current, which caused the quartz to boil. The agitation and friction of the particles were increased by means of a rake with long teeth, which revolved about a central column in the filter; the rake penetrating the bed by a screw motion from top to bottom."

One-half grain of basic sulphate of aluminium was used to the gallon of water filtered, in order to produce a film upon the surface of the filter. This constitutes the real filtering layer, corresponding to the mud layer in the natural or sand filter. The results obtained in these experiments showed that with careful management from ninety-two to ninety-nine per cent. of the bacteria contained in the water could be removed by mechanical filters. Further investigation demonstrated, however, that the installation and management of these filters would be more expensive than sand filtration, with no increase in efficiency.

On the whole, it is probable that sand filtration, having been thoroughly tested both by experiment and by practical experience, must be regarded as the most efficient method of purifying a polluted water supply, and that when carefully and intelligently managed it can be depended upon for purification has been shown in the experience of Altona and Lawrence.

On motion, the thanks of the association were extended to Dr. Rohé for his interesting address.

DR. L. DUNCAN BULKLEY, of New York, on behalf of the executive committee, introduced the following resolutions:

"Resolved, That the committee of arrangements for next year be directed to prepare signs for each State and Territory, also for the District of Columbia, and the army, navy, and the marine hospital service, and so locate them in the hall of meeting that the delegates shall meet beneath them for the selection of members of the nominating committee.

"Resolved, That the elections for such members of the nominating committee shall only be legal when held in these localities.

"Resolved, That elections shall be held not sooner than ten nor later than thirty minutes after adjournment of the first general session of the association."

These were unanimously adopted.

The Home of the Association.—DR. GARCELON, of Maine, said that the establishment of a building-fund had been authorized, and the question now to be decided was where this building should be erected. He therefore introduced a resolution that this should be determined by a vote of the members, the ballots to be sent by mail during June and July, and the result of the count to be announced in the journal upon the completion of the ballot.

Report of the Committee on Public Health.—DR. JEROME COCHRANE, of Alabama, presented the report of this committee. The original bill to establish a department of public health was so defective that it was withdrawn. Since this movement was begun the powers of the Marine Hospital Service have been so extended that the organization is now, in fact, though not in name, a national department of public health. This being so, there were but three plans from which the present committee had to choose. The first was to secure legislation depriving the Marine Hospital Service of its public-health functions and establishing a new department after the original plan; the second was to accept the Marine Hospital service as it now existed and attempt nothing further; the third was to try to improve the Marine Hospital service, as far at least as its public-health functions are concerned, and to render it still more effective with more ample powers and a still greater field of activity. The third plan seemed to be the most desirable one, but in carrying it out it was necessary not to interfere with or to curtail the powers of the State boards of health; the Marine Hospital service should act always in harmony with these State boards and never independently of them or in antagonism to them. Some of these boards are still very weak, and opposition to them by a national organization would destroy what measure of usefulness they now possess. Additional legislation is needed to make the Marine Hospital service more efficient, and this legislation should contain at least two provisions—first, that the national department should act in the several States by and in co-operation with the State boards of health; and second, that an advisory council consisting of one representative of each State board of health should meet annually in Washington.

The committee asked for authorization from the association to draw up a new bill on the lines sketched in this report, after consultation with the American Public Health Association and with the conference of State boards of health.

The report was accepted and the committee empowered to act in accordance with the suggestions therein contained.

The Metric System.—A resolution was introduced from the section on materia medica, pharmacy, and therapeutics calling upon Congress to make the metric

system of weights and measures the only legal system in the United States. This was adopted.

A Belated Protest.—The committee on the president's address made a partial report, and introduced a resolution to the effect that the committee of the Twelfth International Congress at Moscow be notified that unless the use of English be permitted at the congress this association would appoint no delegates. This was carried with great enthusiasm, although a member informed the meeting that the use of English had recently been made permissible; hence the resolution was without reason.

Election of Officers.—The nominating committee proposed and the members present unanimously elected the following officers for the coming year:

President, Dr. Nicholas Senn, of Illinois; *First Vice-President,* Surgeon-General George M. Sternberg, U. S. Army; *Second Vice-President,* Dr. Edmond Souchon, of Louisiana; *Third Vice-President,* Dr. J. D. Thomas, of Pennsylvania; *Fourth Vice-President,* Dr. Willis F. Westmoreland, of Georgia; *Chairman of the Committee of Arrangements,* Dr. H. A. Hare, of Philadelphia.

The President-Elect was then introduced to the members by the retiring president. He said that every American-born youth cherishes the desire to become president of the United States, and while only one man attains this honor once every four years, all are made better by their struggle for it. In like manner every physician in the Union should cherish the hope of one day securing this prize, the greatest in the gift of the greatest medical organization in the world, and although all would not succeed, all would be made better by their endeavor to make themselves worthy of such an exalted station. Next year the association will celebrate in Philadelphia, its birth-place, the fiftieth year of its existence, and Dr. Senn predicted that the attendance at that meeting would be the largest ever noted in the annals of the organization.

There was a defect in these annual meetings which ought to be remedied, and the general sessions too often resembled more closely a political convention than a scientific assemblage. The speaker hoped this would be remedied. Much time has been wasted in attacking the most sacred medical document in existence, namely, the code of ethics. Without this code the association would degenerate into medical anarchy. This cornerstone of the organization must not be tampered with. Political work should be done elsewhere than on the floor in general sessions. He then thanked his hearers for the honor they had bestowed upon him, and promised to do all that in him lay to merit their confidence.

Proposed Amendments.—DR. BURT ELLIS, of California, gave notice of two proposed amendments, which the president requested the secretary to make a special note of. The first one provided for the annual election of the secretary, instead of leaving this officer, as at present, a permanent and practically irremovable one. The second provided for the admission to the association of members of State or local medical societies whose rules or code of ethics might agree in principle with the code of ethics of the association. These were the two amendments which were introduced at the Baltimore meeting and which the secretary had been accused of suppressing.

Stomatology.—The section on dental and oral surgery gave notice of a proposed change of name to the "Stomatological Section."

After the passage of the usual vote of thanks to the ladies and physicians of Atlanta, and to the railways and other corporations and persons from whom the association or its members had accepted courtesies, the forty-seventh annual meeting was declared adjourned.

SECTION ON PRACTICE OF MEDICINE.

WILLIAM E. QUINE, M.D., OF CHICAGO, CHAIRMAN.

First Day—Tuesday, May 5th.

Address of the Chairman.—DR. QUINE observed the rules of the association and gave a brief review of the progress of medicine for the past year.

Animal Extracts.—Bone marrow, first suggested as a therapeutic agent by Brown-Séquard and d'Arsonval, he said had been brought prominently forward in the treatment of anæmia by Frazer, of Edinburgh. Bone marrow, red or yellow, in the form of glycerite or otherwise, had now been tried in leukæmia and other forms of pernicious anæmia, and also in chlorosis, hemorrhagic and other cases of anæmia not belonging to the pernicious types. In some instances there had been marked improvement, but in a case of pernicious anæmia of his own and one of Dr. Danforth the benefit had been only temporary: recurrence of severe symptoms took place, the malarial organism appeared in the blood toward the end, and death ensued. The mode of action of bone marrow was not known. It could not be like that of thyroid extract in myxædema, or of adrenal extract in Addison's disease.

Regarding adrenal extract in Addison's disease, conclusive proof had not been adduced that it possessed curative powers. In about half the reported cases improvement had been noted, but it was not certain that this would remain permanent, nor, indeed, that it had really been due to the extract, for it was well known that in the course of Addison's disease there were periods of temporary improvement. Dr. Quine had used the glyceride of the adrenal gland in one case, giving two or three drachms a day; but about the third day the patient, a woman, complained of nausea and faintness. The dose was reduced to half a drachm, but she still felt that it was doing her harm and would kill her. He thereupon discontinued it, and she died of the progress of her disease in about four days.

Abortive Treatment of Typhoid Fever.—Lastly, the chairman stated the claims for the abortive or antiseptic treatment of typhoid fever advanced independently by Dr. Woodbridge, of Ohio, and Dr. Thistle, of England. If one admitted the correctness of the statistics, it was evident that there was some virtue in the treatment adopted.

Dr. Woodbridge held that practically every case of typhoid fever could thus be conducted to a favorable termination. Dr. Quine's own experience with intestinal antiseptics, although more limited, had given good results.

The discussion upon Dr. Quine's address was over an hour's duration, and related chiefly to the Woodbridge treatment of typhoid fever. DR. PRIESTLY, of Iowa, DR. BYRNE, of Philadelphia, and a few of the other speakers gave a limited experience with that portion of the treatment consisting in administering antiseptics, in which they had obtained good results. DR. KRAUS, of Iowa, had, on the contrary, had a very unfavorable experience, losing two cases out of seven—a mortality rate altogether out of proportion to what had followed a much larger experience with other methods. DR. H. A. HARE thought that when benefit had been obtained it was rather to be attributed to increasing the activity of the liver, which would be done by podophyllin, etc. The majority of the speakers considered the treatment illogical, and if the freedom of diet were permitted which Dr. Woodbridge said he gave his patients, it must result in hemorrhage, perforation, or other damage. The questions of diagnosis and difference in severity of different epidemics had an important bearing upon the statistics and the conclusions to be drawn from them.

DR. WILLIAM OSLER referred to the difference between the action of thyroid in myxædema, suprarenal gland in Addison's disease, and that of bone marrow in anæmia or of intestinal antiseptics in typhoid fever. In the former the remedies were truly specific, supplying a want in the system and arresting the disease.

SECTION ON SURGERY AND ANATOMY.

First Day—Tuesday, May 5th.

Address of the Chairman.—DR. C. A. WHEATON, of St. Paul, Minn., made the annual address, in which he reviewed at some length the history of this section and mentioned the names of many of the older men who have been prominent in its work. He deplored the fact that many of these men too often absent themselves from these meetings, thus depriving the section of the benefit of their superior genius and accomplishments. In referring to this condition of affairs he said: "It deprives us in our deliberations of the aid of the other members of our profession whose efforts for the conservation and preservation of life has nothing to do with the knife except in the passive sense, but whose counsel we need and whose assistance often is absolutely essential in guiding our precious charges to a safe harbor." In referring to one or two of these leaders in surgery, he mentioned Sir William Jenner, who gave us vaccination; Morton, Wells, and Duncan, who gave us anæsthesia; and others. He laid stress upon the fact that instead of asexualizing our suffering sisters we are now groping along conservative lines, endeavoring to preserve the organs and functions with which God and nature endowed her. In referring to the medico-legal relations of injuries to the cerebro-spinal axis and its bony encasement, the author hoped that the matter would receive during this session the attention its importance deserved. Speaking of the teachings of Erichsen, the author said: "We followed these teachings for many years, blindly, I think, and it is a question in my mind whether the modern substitute, neurasthenia, is not a monster equally desperate and threatening, and which may prove to be another siren that may lead us to commit greater professional inaccuracies and entail greater humiliation. The question of the hour is, in this connection, What can we as representatives of this body do to remedy this admitted evil? I for one believe that equal justice to both plaintiff and defendant will not obtain until such time as the so-called expert is placed by a statute beyond the influence of monetary considerations."

In conclusion the speaker said: "I do not wish to be understood as disparaging one's individual evolution in a special line, for God knows we are both weak enough in any of them, but with a view of maintaining the integrity of this association, and particularly the surgical section, for it is an important integral part of the whole, and its life and future usefulness depend upon the hearty co-operation of the pioneers who have hewn the way and made it possible for the younger and less experienced to follow and participate in the formulation of a professional fabric which will be a credit to our leaders, add to the laurels of the American profession, and amalgamate and strengthen this organization. I venture to say that there is not a successful specialist in any branch to-day who is not in a large measure dependent upon his 'general medicine' for his following and success, and if my premises are correct he is obligated to attend these gatherings, participate in their labors, and reap the benefits justly earned. If he is a man of stout heart, a good campaigner, and has a large income, he may be able to attend all the other association meetings; but to this one he should pledge his special fealty because of its national character, because of its cosmopolitan per-

sonality, and finally because the character of work done by this section reflects the quality of the whole."

Subphrenic Abscess and Its Relation to Pyothorax.—DR. CARL BECK, of New York, stated that in five cases of subphrenic abscess which he had observed, only twice was he able to make a correct diagnosis before operation. The fact that subphrenic abscess is very often confounded with pyothorax is well known, and such errors impress one gravely with the necessity of widening his limited diagnostic knowledge upon the subject. Subphrenic abscess may even be said to take the rank at the present time of appendicitis of yore, when it was thought that under extremely rare circumstances perforation of the vermiform appendix, caused by "the obligate grape seed," might occur. It used then to be said that a cure in such unfortunate cases was, of course, out of the question. As soon as the profession at large will take the same interest in subphrenic abscess that they do in appendicitis, the number of cases, which in the whole present literature amounts to less than two hundred, will rapidly swell to an enormous number, and accordingly will the prognosis, except in those of malignant origin, be most favorable.

After referring at some length to the fact that the history of the case was a most important guide in differentiation, and mentioning at some length the various physical signs to be detected, Dr. Beck said that it is sometimes impossible to distinguish an encysted pyothorax from a subphrenic abscess. The pathognomonic signs of such effusions urged by Leyden were absence of cough and expectoration, slight displacement of the heart, and rapid change of note if the patient is rapidly turned. According to his observation, pleuritic effusion, particularly pyothorax, sometimes occurs without these symptoms. The motions of the exploratory needle introduced into the abscess were also regarded as pathognomonic. But bearing in mind that in subphrenic abscess the function of the diaphragm is greatly impaired, and that, furthermore, the point of the exploratory needle may be fixed by the diaphragm as well as by the abscess membrane, neither the presence nor the absence of the motion can be regarded as a determining pathognomonic factor.

The author referred to Litten's diaphragm phenomenon and to Jendrassik's observation of a well-marked concave undulating curve parallel to the costal margins in the mammary as well as the axillary line during deep inspiration, the value of the former of which two methods, however, he did not consider established. In the author's opinion, aside from the history there are but few absolutely reliable pathognomonic data for the diagnosis of subphrenic abscess, and the main question will practically always remain as to the presence of an abscess.

Dr. Beck discussed at some length the method of treating subphrenic abscess, and after stating that the same aseptic precaution should be observed as in any other operation, said that if the first trial be negative the needle should be introduced several times into different portions, as the pus cavity may either be of small extent, may contain a cheesy accumulation, or may be divided into several minor cavities by adhesions. In the first event the cavity may be missed altogether by the exploratory needle; and in the second the needle, being introduced into the solid cheesy mass, can draw no pus. After each negative result a wire should be pushed through the needle (which must not be of too small a calibre). Thus, some pus which had remained adherent to the inner surface of the needle will become attached to the wire. Occasionally it will be useful to fill the syringe with sterile water after the operation and force the water through the needle into a Petri dish. In case cheesy masses are present small particles are sometimes drawn into the calibre of the needle, which cannot be seen by the

naked eye, but which by being mixed with the sterile water can be recognized under the microscope. In case the microscope does not give sufficient information, resort should be had to cultures of the fluid. The treatment of pyothorax is practically the same as that of subphrenic abscess, that is, resection of a piece of a rib, as it is only in this way that a sufficiently wide opening is secured for thorough evacuation.

Thoracoplasty (Schede's) and Visceral Pleurectomy.—DR. ALEXANDER HUGH FERGUSON, of Chicago, read this paper. Thoracoplasty, as first done by Schede, is an heroic measure for the otherwise hopeless cases of chronic empyema, and consists in the removal of the chest wall. The author described the operation at some length, and stated that, in spite of this operation and all other procedures for the relief of this affection, some cases are not cured. He stated that the assertion made by Schede, that amyloid degeneration and tuberculosis do not contraindicate this operation, is true within certain limits. Dr. Ferguson described Schede's thoracoplasty as performed by him (the author) in July, 1895, in which case a good result was obtained, the wound healing by first intention and the patient gaining flesh so rapidly that he was able to be about in a remarkably short time. At the end of five months' careful treatment after the operation, a long central sinus not having closed, the operation of visceral pleurectomy was performed, which resulted in the complete restoration of his health. The operation of visceral pleurectomy was first performed in America by Dr. George R. Fowler, in October, 1893, since which time several others have been performed, a brief outline of which the author gave.

A number of excellent photographs and drawings accompanied this paper, showing the methods of operation as performed by Dr. Ferguson.

DR. BAYARD HOLMES, of Chicago, in discussing Dr. Ferguson's paper, said that he had performed three operations of this kind, and two of the patients are now alive and well. In the third case there was no improvement after the operation, and the patient subsequently died of tuberculosis. In one of these three cases drainage between the ribs had been instituted for over three months, and the young man had been sent home to die. After excision of the rib he made a careful examination and decided that it would be impossible to bring the chest wall in contact with the stump of the lung. He therefore removed the chest wall by rapidly cutting in both directions, dissecting out the ribs, cutting off the parietal pleura, which was one-half inch thick, and also the pulmonary pleura, which was of the same thickness. He then brought the surfaces together and drained with gauze around the opening, with the result that the patient made an excellent recovery. Two months afterward there was no further occasion for dressing except for the external wounds. The only adult on whom the speaker had operated was a man thirty-five years of age, who had been suffering with empyema which had been neglected for more than a year. In this case a similar operation was performed after two attempts had been made to close the cavity by the Estlander operation. After the third operation the patient made a good recovery, but it was necessary later to do two or three operations for the removal of infected bone where the ribs had become infected from a discharge of pus. A third case of empyema had been treated by the simple Estlander operation, and the patient seemed to recover and went home. In this case a pleural cavity was filled with pus, which existed for a long time until the patient finally came back. The cavity was again opened, when the lung was found to be collapsed and the pleura was much thickened. After so radical an operation as this the patient died with suppurative disease, which showed that it had tuberculosis as the

foundation. Acute miliary tuberculosis was present in the abdominal cavity at the post-mortem. It was a peritoneal tuberculosis.

DR. JAMES H. DUNN, of Minneapolis, said that during the past few years he had been much interested in observing several cases of this operation, and it was his belief that the necessity for doing the operation is usually due to the failure in diagnosis and to the want of proper drainage. However, he did think that when operations are necessary in the treatment of empyema and the Estlander method has been employed, the results have usually been fatal. When it has been successful, he thought that proper drainage would have produced equally good results. If a thoracoplastic operation is necessary, he believed that this one is the most desirable, but if one thinks that the ribs prevent the chest wall from falling in, he is in error, as the ribs are not able to do anything of the kind. The cavity would be obliterated without the slightest difficulty, so far as the ribs are concerned. What does prevent the collapse of the cavity is the presence of old granulation tissue. In the speaker's opinion many thoracoplastic operations have been done that were not necessary, as proper drainage would have cured the cases anyway. Of course, in some cases operation is necessary, and he believed the one that Dr. Ferguson had presented was the proper one in order to get primary healing, that is, the resection of the chest wall and the removal of the granulation tissue. In speaking on this matter he referred not only to his own cases, in which he had removed ribs two or three times, but to those of his colleagues who have pursued the same course. He did not mean to say that none of the patients have recovered, for one of his own did, but not until he had practically done this operation.

DR. FERGUSON, in closing the discussion, said that Estlander's operation is a grave one, as also is pleurectomy; but Schede's operation is a graver one. He did not think, in looking over the statistics of the cases, that more than one or two of the operations have been performed without clear indications. As to the proper order in which these various operations should be done, he did not think that thoracoplasty should be performed until Estlander's operation has failed, as many patients undergoing this latter operation get well. Neither did he think that pleurectomy should be thought of until Schede's operation has been done.

Extra-Uterine Pregnancy.—DR. HOWARD KELLY, of Baltimore, spoke at some length of his new method of treating this affection, and mentioned the excellent results he had obtained. He spoke of several causes for error, not only in the diagnosis but in the treatment. Among other experiences he mentioned the fact that he had opened dermoid cysts, pelvic abscesses, and small ovarian cysts, all of which he had mistaken for extra-uterine pregnancies. All of these he evacuated through the vagina. If there is a large pelvic hamatocele and it is opened from below and then the sac is evacuated, it will very rarely be necessary to open the abdomen.

DR. NICHOLAS SENN, of Chicago, said that for once Dr. Kelly and himself agreed thoroughly.

DR. KELLY, in closing the discussion, advised all to look out for the rectum, and also to be very careful to keep clear of the uterine artery and the ureters.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

J. TABER JOHNSON, M.D., OF WASHINGTON, D. C.,
CHAIRMAN.

First Day—Tuesday, May 5th.

Address of the Chairman.—DR. J. TABER JOHNSON, of Washington, in his address briefly reviewed the progress of the past year in obstetrics and gynecology.

He called attention to the fact that the treatment of puerperal infection has become much simplified, and now amounts practically to absolute cleanliness; that as few examinations as possible should be made, and that douches should not be used when there is no rise of temperature. For the purposes of exploration in suspected retention of morbid material the index finger is the best instrument; the curette is condemned by many authors. Hysterectomy is valuable in selected cases, but is useless where the infection had spread beyond the uterus.

Symphiseotomy, he said, has been revived as a substitute for Cæsarean section and craniotomy, but in his experience so much injury to the tissues has often occurred and unpleasant sequelæ have followed, that it is a question whether Cæsarean section, with the present methods of operation, is not preferable. In regard to placenta prævia nothing new has been brought forward except the proposition to do Cæsarean section. But the diagnosis is not generally made until hemorrhage occurs, and then it is the duty of the physician to save the mother. Where the hemorrhage is slight and the os undilated, the tampon can be used. After dilatation of the os, the child's leg can be brought down to act as a tampon and the progress of labor watched. He condemned the rapid extraction of the child. One case of puerperal diphtheria has been reported by Nisso and successfully treated by antitoxin.

The discussion of the treatment of uterine displacements has been quite general, and the advocates of Alexander's operation, ventral and vaginal fixation, have presented their claims, but the question of superiority is still unsettled. The same is true in regard to the vaginal and abdominal operations for the removal of tumors, etc. Great improvement in the methods for the removal of fibroid tumors has taken place and the mortality has been reduced from eighty per cent. to ten per cent. There has also been great improvement in the technique of operating, and the direct transfusion into the tissues of considerable quantities of the normal saline solution has doubtless saved many lives.

He hoped the coming year would see great improvements in the administration of anæsthetics, and that the application of the Roentgen rays would clear up many doubtful points of diagnosis.

A Note on Cervical Stenosis as a Factor in Pelvic and Uterine Disease.—DR. HENRY P. NEWMAN, of Chicago, said that twenty years ago stenosis of the cervical canal was thought to be very common, and the operations and instruments devised for its relief had made the reputations of the gynecologists of that day. Now it is even denied that such a condition exists. That is going too far, since it is not a rare condition; but it is doubtful if it ever is congenital. In the opinion of the author the condition is generally due to a persistence of the normal natal type, due to improper hygienic condition and management at the time of puberty.

He wished, therefore, to put in a plea, not for the treatment of the condition when it exists, but for the prevention of its occurrence and the consequent sterility and disorders of menstruation which lead to endometritis, metritis, salpingitis, and the nervous phenomena associated with these diseases. While there is tendency in some directions to give girls the same opportunity to develop that boys have, yet the conditions found in our public schools and in the factories and stores where growing girls are employed all tend to retard the development of the generative organs and produce this condition of stenosis. It is the duty of the profession to recognize this, and labor for the prevention of this trouble by insisting on a better hygiene.

How to Remove Pus Tubes without Rupture.—

DR. J. S. STONE, of Washington, D. C., stated that while all pus is not infective, it is desirable not to soil the peritoneum, if possible. His experience in operating upon cases with pus sacs has led him to adopt the following technique:

Clamps are placed upon one of the tubes, closely hugging the uterus and embracing one inch of the broad ligament. The ovarian artery is tied or clamped as near the pelvic wall as possible and a ligature is placed on each severed end, or it may be placed before section, and the incision made between the points. No bleeding can take place, and the surgeon can leisurely enucleate the tube and ovary with its contents. It affords a great amount of space, and the tube comes prominently into view when separated from the uterus. When an infected stump is left an exsection of the cornua is demanded. The ovaro-uterine artery is ligated, the forceps removed, and another deeper ligature taken if necessary. The Trendelenburg position is most desirable. Flushing or drainage of the cavity is unnecessary. The advantages are more space; the larger blood supply is cut off; small silk or catgut can be used, as there are no ligatures *en masse*; there can be no infection of ligatures or stitches; no danger of hemorrhage, and it facilitates the enucleation by affording another point of anterior cleavage.

Dr. Stone presented a specimen which he had removed entirely by this method. It consisted of a pus sac measuring eight inches in circumference and fourteen inches from one extremity to the other.

Extra-Uterine Pregnancy Viewed from a Clinical Standpoint.—DR. W. G. MACDONALD, of Albany, N. Y., said that while the surgery of extra-uterine pregnancy dates back only thirteen years, to the time when Lawson Tait performed the first operation, yet it has reached a point of development that leaves little to be desired. Yet women still die from ectopic gestation. Too much time and space have been spent in discussing the pathology of this affection and the various methods of treatment, and too little in formulating exact rules by which this justly dreaded accident may be discovered early and the lives of many women be saved.

Recent work in appendicitis has given us very reliable guides in the early diagnosis of this affection, and the same ought to be true of extra-uterine pregnancy. As a rule, operations are performed after rupture has taken place, but then any delay is dangerous. The diagnosis before rupture is most important, but is very difficult. It is a fallacy to believe that some previous disease of the generative organs is necessary for the production of ectopic gestation. It may happen in perfectly normal women. Metrorrhagia also in the majority of cases is not common before rupture. But any woman who has shown any of the early signs of pregnancy, such as cessation of menstruation, nausea, etc., and then develops any abnormal irregularity should at once become an object of suspicion. A careful examination should be made and the advice of an expert be obtained. Usually this examination will reveal the presence of a small tumor at one side of the uterus. This, with the history, will often be sufficient to confirm the diagnosis and warrant an exploratory incision. After rupture the pain and signs of collapse from hemorrhage are sufficient. A bicornal uterus or the presence of fibroids may render the diagnosis more difficult. When the diagnosis is made, the operation should be performed at once, as delays are fraught with grave danger.

Symptoms, Diagnosis, and Time for Operation in Ruptured Tubal Pregnancy.—DR. JOSEPH PRICE, of Philadelphia, stated that the causes of extra-uterine pregnancy may be anatomical or moral. It may have its origin in some anatomical change in the tube or perversion of the function of the cilia, or pos-

sibly may result from attempts to prevent conception. The determination of the exact cause is uncertain. The attacks usually come on suddenly. A vigorous, healthy woman may be seized while going about her usual occupations, or even in bed after a quiet night's rest, and suddenly become pale and collapsed. Sharp pain generally follows, which may be quite general and accompanied by hemorrhage. These symptoms may increase in severity or subside, to be again repeated. If there is a large effusion it can easily be recognized by the finger, but there may be only a sense of tension and resistance. Two or three days after the rupture has occurred there is no difficulty in making out the tumor. Frequently there is a history of sterility, some uterine disease, or an abortion occurring a month or two previous. There is also peculiar nervous disturbance and an absence of the usual signs of pregnancy.

Vesical and rectal disturbance, such as distention and tympany, are common. Twenty-five per cent. die within twenty hours after rupture from hemorrhage. The most fatal cases are those in which the rupture occurs close to the uterus. The only treatment is an operation, and this should be performed as quickly as possible. The chief danger is from hemorrhage, but the prompt infusion of the normal saline solution will save many lives. In those rare cases which go on until the child reaches full term, there is generally very little trouble in extracting the child alive, but the great danger is to the mother in the removal of the placenta, and the operation should never be delayed to this time if it has been possible to make the diagnosis before. The child is to be sacrificed for the mother.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL QUESTIONS IN PARLIAMENT—TUBERCULOSIS—PAUPER SCHOOLS—REPORTS OF MEDICAL OFFICERS OF COUNTY COUNCIL AND SCHOOL BOARD—THE GLOUCESTER EPIDEMIC—MEDICAL SOCIETY—EXHIBITS—MEDITERRANEAN FEVER.

LONDON, April 24, 1896.

AN unusual number of medical subjects have come before Parliament this week, introduced for the most part in the form of questions. The report of the tuberculosis commission is not to lead, as many hoped, to immediate action. The government regards it as authentic in respect to the scientific problems, and now proposes to refer the question to another commission to report as to the administrative measures required. It might have been supposed to be the duty of the government to settle these. How many lives may be sacrificed by delay none can say. Questions on medical witnesses, inebriates, rabies and hydrophobia, venereal diseases in the army, pleuro-pneumonia, vaccination, and other subjects of professional interest have been asked and secured official replies of the usual character.

The report of the committee on the metropolitan pauper schools has obtained great attention from the general press and will probably result in a number of changes. The committee recommends that no more large schools be built, that the existing schools be not enlarged, and that the number for which they are certified be considerably reduced. The evils of crowding together a large number of these children are fully admitted, and it is recommended that a central authority, unconnected with the poor-law system, should look

after these children. The boarding-out system is pronounced successful. Some of the recommendations respecting the education of these children have been already embodied in the government education bill.

The report of the medical officer of health of the County Council for 1894 is just out, and extends to nearly two hundred folio pages, containing numerous tables, charts, and diagrams. Mr. Murphy has bestowed great labor on his report and it will be of much value to sanitarians, as it comprises carefully gathered statistics of nearly four and one-half millions of people.

Another official report, that of the school-board medical officer, Dr. W. R. Smith, has also appeared. It deals with the prevalence of diphtheria in London and its alleged connection with elementary schools.

The mention of the school board reminds one that its suggestion for a conference between the attendance committee and representatives of the profession was accepted at a further meeting on Thursday, and it may be hoped that the action of the board as to medical certificates will be altered.

The terrible epidemic of small-pox at Gloucester continues, and heart-rending accounts of the suffering entailed are published. There were two hundred and one fresh cases reported in last week's return and forty-five deaths. Altogether thirteen hundred and two cases have occurred in this city of thirty-nine thousand five hundred inhabitants, where the vaccination laws have been so persistently set at naught and the value of its protective influence ridiculed. It is a sad lesson. I hear that the trade of the place is reduced to the supply of the barest necessities, that ruin stares many in the face, that the greatest terror prevails, and that "the town looks like a city of the dead." Vaccination and re-vaccination are now going on in spite of the fanatics.

The last of the clinical evenings arranged by the Medical Society of London for the present session took place on Monday. There was a case of lymphatic obstruction of unknown origin in a girl of twenty-three. The left foot began to swell four years ago. The swelling has gradually extended until the leg and thigh are both enormously swollen. The seat of the blockage has not been ascertained, though it has been sought under anesthetics. It was said the length of the limb was somewhat increased.

Another patient was a lad from whose face a hairy mole had been excised. The result is a scar passing into keloid. It was proposed to remove this and fill the gap with grafts on Thiersch's plan. In objection to this a member suggested the danger of producing ectropion of the corresponding eye. Perhaps the patient would better have kept his "large hairy mole."

A man, aged thirty-one, with dulness extending from the liver below the umbilicus, was shown. There had been vomiting and some jaundice. The smooth, rounded tumor, evidently containing fluid, was probably a hydatid cyst.

A girl with a tumor of the abdominal wall, dating from an injury last year, was shown. It seemed to be sarcomatous.

An infant was exhibited with a swelling in the neck, only seen when the child cried, when it became prominent and dusky. The swelling seemed to be a venous angioma, as it was dull on percussion.

Mediterranean endemic fever has only of late years attracted much attention and is not referred to in textbooks, except the most recent, although Marston described it in 1861, and it has been met with in certain localities, such as Malta, from an early period, sometimes as an epidemic.

A note on the disease was communicated to the Royal Medical and Chirurgical Society at its last meeting by Surgeon-Captain M. Louis Hughes, who found that clinically this fever had a peculiarly irreg-

ular temperature curve, consisting of intermittent waves of pyrexia of a distinctly remittent type. These waves of pyrexial intensity were separated by periods of apyrexia or abatement of severity, giving a peculiar relapsing character to the fever. In some instances the daily remissions became so marked that the temperature might become intermittent (but non-paroxysmal) in character. Its duration was long and indefinite, the average pyrexia duration being from sixty to seventy days, and the average stay in hospital over ninety days, while patients had been known to suffer from the pyrexial condition for over six months. This pyrexia was accompanied by progressive anæmia, a tendency to constipation, swelling and effusion in various joints, profuse perspirations, and a peculiar irritability of the nervous system, characterized by sciatica and other neurotic symptoms. Pathologically the spleen was enlarged and softened; many of the organs were congested, but the intestines were free from ulceration. The microscopical appearances were those of toxic irritation of the tissues. A definite species of micro-organism (discovered by Bruce in 1886) was constantly present in those tissues in which from clinical symptoms and post-mortem appearances it might be expected to be present. Pure cultures of the "micrococcus militensis" produced by inoculation into the tissues of monkeys a similar form of pyrexia, and in all other points fulfilled the postulates laid down by Koch. The disease prevailed during the hot, dry months between May and October, with a maximum prevalence in July, August, and September. It was not contagious, nor did there appear to be any close connection between its prevalence and the milk, water, or food supplies. Its dissemination appeared to be brought about on shore by an aerial infection arising from drains or soil infected by the excrement of previous sufferers from the disease. By this means it entered the human system by way of the throat or air passages. Its prevalence followed a ratio inverse to the amount and continuance of the rainfall. The mortality did not exceed two per cent. of cases, but the duration of sickness was very long. There is no specific. Careful nursing and dietary, confinement to bed during the acute stages, removal from all sources of reinfection, and a moderate regulation of temperature by the external application of cold were the measures of most importance.

Dr. Thin said that when in Malta last autumn he carefully examined the blood of six patients in different stages to see if the parasite of malaria was present. He could discover neither parasites nor pigment in the blood or in the spleen of those whom he examined. Typhoid symptoms were characterized by their absence and the intestinal lesions were not of typhoid nature. One characteristic of the disease seemed to be that the patients were quite unaware of the gravity of their condition. Professor Pisani, of Malta, had told him that whereas formerly the fever was confined to those parts of Malta where English soldiers or sailors were commonly present, it was now common in the country districts. In the neighboring island of Gozo the fever was formerly absent and patients were sent to convalesce there, but now the fever had taken root there as well. The fever was the most serious disease connected with Malta. At Hong-Kong a fever of the same type had recently reappeared. In Sicily the disease was formerly not known, but there was an epidemic in 1872. For some years afterward a few sporadic cases occurred; then in 1884 an epidemic broke out at Catania, and also in country districts where the air and sanitary conditions were beyond suspicion. Cases also occurred on the sides of Etna. It was a fever with an absence of symptoms that were specific or pathognomonic, and in most instances there was excessive sweating. At the apex of the lung a condition

was often present which suggested phthisis, but was not phthisis. He held that the government should take steps to have the fever fully investigated.

Dr. Norman Moore said that Dr. George Cleghorn, in a book on the "Diseases of Minorca," described an affection which was clearly Mediterranean fever, and which was existent in Minorca between 1740 and 1751, at the time when the island was occupied by our troops. Dr. Cleghorn was, of course, prejudiced with the old classification of fevers, and he regarded this as a variety of tertian; but his descriptions were very clear and he recorded one hundred post-mortem examinations. He mentioned that definite destructive ulceration of the mucous membrane of the large intestine sometimes occurred; that certain varieties of skin rash appeared in the course of the affection; and that it was often complicated with pleurisy, and doubtless under this term he included croupous pneumonia also.

Dr. Patrick Manson said he had little experience of this fever. He had seen several cases in London and one or two in China. In Amoy he once witnessed an epidemic of a fever in which there were two pyrexial waves separated by an apyrexial interval. From what was known of this disease it certainly was neither malaria nor typhoid. Every credit is due to Surgeon-Captains Bruce and Hughes for the work they have done on the subject.

THE TREATMENT OF HEART DISEASES BY BATHS AND GYMNASTICS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Having lately read several articles in English and American medical journals about the so-called Nauheim treatment of heart diseases, I found that the merits of the late Professor Beneke in this matter were not sufficiently acknowledged, and those of another well-known physician of Nauheim, namely, Dr. Groedel, have not even been mentioned. Likewise nothing was said about the gymnastic treatment of heart diseases having been first applied in Sweden. Will you therefore kindly allow me to make the following remarks.

Beneke reported as early as 1859 and 1861 about the effect of Nauheim baths on heart diseases. Special papers on this subject appeared in the years 1870, 1872, and 1875. In these we find that Beneke treated not only valvular lesions of rheumatic origin, but all kinds of heart diseases, and I beg to call particular attention to the fact that he not only found a soothing effect produced by the baths upon the heart's action, but also a striking improvement of the compensation in cases in which no other treatment had been of any effect.

The next paper on this subject was written by Dr. Groedel in the year 1878, and appeared in the *Berliner klinische Wochenschrift*. This was the first announcement "that the baths increase the energy of the heart's action," which was thus expressed in the first work of Dr. A. Schott two years later: "Baths are a first-class tonic for the diseased heart."

A number of papers followed, written both by A. Schott and Groedel, then later on by Th. Schott. Among those by Groedel I will only mention: "The Effect of Baths on Respiration and Circulation," *Berlin. klin. Woch.*, 1880; "The Treatment of Heart Diseases," *ibid.*, 1883; "Nervous Heart Diseases," *ibid.*, 1890; "Bad Nauheim and the Treatment of Chronic Heart Diseases," *St. Petersburg med. Woch.*, 1893; on the same subject, *Lancet*, 1895; "Baths in Cases of Arteriosclerosis," *Deut. med. Zeitschr.*, 1895.

As regards gymnastics for heart diseases, Schott's first paper appeared in 1885, but publications by

Swedish physicians in regard to the application and advantages of gymnastics on disordered circulation are of much older date. Dr. Saetherberg, of Stockholm, who made use of gymnastics for cardiac lesions as early as the year 1847, described his experiences in *Hygieia* in 1862, and he was followed in the same paper by Wretling, of Gottenburg, in 1867, and Lander in the *Nord. med. Archiv*, 1872 (*cf.* "Beiträge zur mechanischen Behandlung," von Dr. H. Nebel, Bergmann, Wiesbaden, 1888).

It is undoubtedly the merit of the late A. Schott to have first applied gymnastics in Nauheim; however, the modifications made by him in the Swedish system are so insignificant that it cannot be called a method invented by himself. Groedel, who also referred a year later to good results attained with gymnastics, prefers gymnastics with Lander's machines in certain cases to manual exercises (*vide* Groedel's "Medical Guide to Nauheim," Bindernagel, Friedberg, 6th ed., 1893; English ed., 1895). I personally have also seen the best results produced by Lander's mechanical gymnastics.

Summing up all this, we find that Beneke having invented the bath treatment for heart diseases, and Swedish physicians the gymnastics, there is no real reason for calling the two treatments combined Schott's method. The latter has endeavored to explain the effects of baths and gymnastics, and in doing so he has assisted in making both methods of treatment better known; but others, especially Groedel, have also contributed to this end. In Germany, where the course of these events could be better followed from the very beginning, nobody ever thinks of speaking or writing about a "Schott method"; we seldom hear even of a "Nauheim method," but simply of Nauheim as a health resort for patients with heart disease.

HERMANN NEBEL, M.D.

FRANKFORT-ON-THE-MAIN, April 2, 1896.

GRADUATED TIME-EXPOSURE SKIAGRAPHS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In many instances the significance of the appearances revealed by the skiagraph could be much more easily and accurately determined if several plates of different times of exposure could be made of the same object.

These may be readily obtained in the following manner, which I recently suggested to Mr. C. F. Lacombe, of Denver, Col., who by the way, has obtained some of the finest skiagraphs yet made in this country:

Using sheets of sensitized paper (bromide-of-silver) instead of glass plates, fasten them, one sheet overlapping another and each held by spring clips, to a plate-holder, leaving on each a tag exposed so that it can be withdrawn separately. Then after varying intervals of time, according to the object under examination, the sheets are to be removed one by one, thus giving a different period of exposure for each one, yet preserving the general uniformity of the pictures and saving much time and also wear of the Crookes tubes.

G. H. STOVER, M.D.

EATON, COL.

ASEPSIS IN LONDON.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The notes of several of your correspondents concerning asepsis as practised in London lead me to relate my experience.

The first operation I saw there was at the London

Hospital, when Mr. Frederick Treves performed laparotomy for ovarian cyst. Some of the instruments were boiled, while others were not. An officious male nurse took particular delight in handling the instruments, even though his hands were unclean, and once he picked up a retractor that had fallen on the floor, rinsed it at the faucet, and returned it to the tray.

During the operation the cystic fluid began pouring out on to the floor, and Sir Frederick calmly stooped down and turned up his trousers, then rinsed his hands in a sponge basin and proceeded with the operation.

At Samaritan Free Hospital I saw a prominent surgeon perform ovariectomy with absolutely no attention to asepsis, simply plain water from the faucet being used. At Middlesex Hospital I saw the other extreme, asepsis being carried to the extent of filtering the air as it passed into the operating-amphitheatre.

In Edinburgh the same laxness was in evidence.

H. J. HERRICK, JR.

CLEVELAND, OHIO.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 9, 1896:

	Cases.	Deaths.
Tuberculosis.....	224	134
Typhoid fever.....	6	2
Scarlet fever.....	94	10
Cerebro-spinal meningitis.....	6	5
Measles.....	300	11
Diphtheria.....	257	40
Small-pox.....	1	1

Insects Used in Therapeutics.—At the present day the number of kinds of insects used in medicine is very small, the cochineal, cantharides, and *Blatta orientalis* comprising about the whole list. But in former days, and down even to the end of the eighteenth century, a large number of species was used. In this, as in every other department of the *armamentarium medicum*, in popular medicine at least, the nastier the substance the more potent the remedy. Thus, woodlice were used to cure indigestion, or, to put it in the lingo of that day, were potent to "dissolve the mucilaginous tartar of the body," "open obstructions of the viscera," etc. When it came to treat epilepsy, the *grand mal*, something more powerful was necessary; so we are not surprised to find the old physicians recommending bedbugs as an almost infallible remedy. Aristophanes, Aristotle, Pliny, and Dioscorides, all maintain the efficacy of these disgusting creatures in quartan fever. Pliny says that seven bedbugs swallowed at the beginning of an attack will certainly work a cure.—*The National Druggist*.

Taking the Air without Going out.—Elderly people and others who may be temporarily house-bound and prevented from enjoying a regular daily stroll outdoors can devise a fair substitute as follows: Bundle up as if for the usual constitutional, select a large sunny room, preferably at the top of the house, open wide the windows, shut off the heat and move around briskly, going to the window and inhaling the fresh air deeply through the nostrils. We have often called attention to the fact that house air, with its many impurities, overheated condition, and general lifelessness, is one of the principal predisposing causes to colds and catarrhal affections. Where a patient or invalid is confined to bed, if the shoulders

are kept well covered and the head lightly protected, the windows may be opened and the room flushed with fresh air without any special risk, provided the current does not strike them too directly. The danger from want of proper ventilation is decidedly greater. Deep inhalations of air at the open window, taken gently through the nose, impart an enlivening and tonic influence to the whole nervous system, which can soon be demonstrated by a personal experiment.—*The Health Magazine*, April, 1896.

Medical Women in Austria.—The Emperor of Austria has issued a decree admitting women to the medical and philosophical faculties of the Hungarian universities. A clause in this new decree, however, refers to the fact that no female student will be admitted to any university without the special permission of the minister of justice.

Chinese Methods of Predicting the Sex before Birth.—A round, prominent abdomen projecting forward so as to interfere with locomotion indicates a girl, while a uterus extending very high upward means a boy. A fresh color of the skin, with only slight pigmentation, especially of the areola and slight change in the features, points toward a girl, the opposite condition to a boy; violent movements of the foetal extremities also indicate a girl. When after the seventh month the right hand of the foetus can be felt moving in the left side of the mother's abdomen—there may be some doubt about the mother's ability to distinguish the right hand of the foetus from the left—it is male. The most interesting methods cited are two which point to a very high development of the mathematical faculty among the Chinese. The first depends upon the second figure of the mother's age and the probable month of conception. If both figures are odd or both even, the child will be a boy. If one is odd and the other even, a girl is expected. The most complicated method of all was published in 1593, by the wise man, Fschweng-Fa'wei: To the number 49, evidently a number regarded as sacred, add the number of the month of conception, and from the sum subtract the age of the mother; then subtract 1 (for the heavens), 2 (for the earth), 3 (for mankind), 4 (for time), 5 (for the elements), 6 (for the musical scale), 7 (for the plants). If the remainder is an odd number, the child will be a boy; if even, a girl. If the remainder is larger than the number eight, that number is also subtracted (for the directions of the wind), and the decision made according to the final remainder. Even European residents of China believe in this method.—J. J. MATIGNON, *Archives de Tocologie et Gynecologie*, June, 1895.

The Production of Monstrosities.—Dr. Ryder is inclined to regard the double-tailed goldfish as "the actual realization of an eight-limbed vertebrate," a thing most contradictory of our present basis of animal classification. These fish have been produced in Japan, he concludes, for at least two centuries, and they there command high prices among the wealthy classes, the finest or most abnormal variations being in great demand. By taking the eggs of the normal species of goldfish and shaking them or disturbing them in some way, the Japanese get double monsters, some with double heads and a single tail and some with double tails. Naturally the complete double monsters would be unlikely to live, while those with only the duplication of the tail, having the problem of life in no way complicated for them, would be quite likely to survive. These monstrosities, being selected and bred, would in all probability hand onward the tendency to reproduce the double tail, which in time would become fixed and characteristic, if judicious selection were maintained by interested breeders, as has been the case with many breeds of dogs, horses, fowls, and pig-

eons. Barfurth, experimenting upon tadpoles, has found the duplication of the tail in them has much to do with the manner in which it is removed. For example, if the tip of the tail were snipped off exactly at right angles to the axis of the body, the tail was regenerated of the normal form and straight backward. If removed at an acute angle, regeneration took place so that the new tip was directed either upward or downward, according as the inclined, regenerated, cut surface looked upward or downward. These facts cannot be dismissed as useless in connection with the problem of inheritance in general; for while as we rise in the scale of organization the tendency to regenerate lost parts becomes more restricted, the tendency to produce monstrosities due to disturbances of development remains in full force, as is illustrated by the disposition to reproduce extra toes in the cat, the same tendency hereditary in the Dorking fowl, or even the disposition to reproduce extra thumbs or toes in the human family.—*Popular Science News*.

House Nerves.—In describing the depressing form of ailment which is designated "house nerves," *The Hospital* observes that in Russia "tea and Tolstoi" are guilty agents, while in America the negro question, iced drinks, candy, and business hurry help the complaint. Outdoor exercise and innocent amusement are prescribed as the panacea, but it is not easy to apply a remedy to persons who have already contracted a morbid attachment to the evil causes of their nervous condition.

Premature Occupation of New Houses; a Test for Relative Humidity of Habitable Apartments.—Regarding newly built houses, Sanitarians, for the most part, teach us that a period of four months in summer and six in winter ought to be allowed between the end of the building operations and the entrance of the inhabitants into a house. In this way will be avoided the accidents that arise from the premature occupation of an apartment. It is scarcely necessary to add that as soon as the house has begun to be occupied, to avoid dampness it should be heated and ventilated; treated, in a word, by all the usual means to maintain a healthy condition of the apartment. If the dampness persists in spite of all these precautions, the proprietor is responsible for the defects in his building. Physicians are sometimes requested to estimate the relative dampness of an apartment or room. This is not always easy by simple inspection, as a room may be damp although saltpetre does not grow on its walls or mould in its corners. The following is an exact means of appreciation and one that is within every one's scope: In the room in question a kilogram of fresh lime should be placed after hermetically closing doors and windows. In twenty-four hours it should be weighed, and if the kilogram has absorbed more than ten grains of water (that is, more than one per cent.), the room should be considered damp and classed as unhealthy. The question of dampness of dwellings is a frequent cause of dispute between landlord and tenant, naturally solved in the affirmative by the latter and in the negative by the former. The question can be settled in the future by the test of the hydration of lime of which I have just spoken, and which will give irrefutable proof or refutation of the validity of such complaint. The dampness of dwellings is a cause of illness. The death rate is greater in quarters where the apartments are damp than where they are dry. Ventilation is defective where the walls are impregnated with water; the porosity of the walls is done away with and can only be re-established after the evaporation of the water has been completed, and the heat required to effect this evaporation is furnished by the person living in the room. This is the cause of the vivid impression of cold which we experience

in damp places, and it is a well-known fact that exposure to the action of cold renders the organism more accessible to the attack of morbid germs. The rotting of walls, which appears particularly in places where the water used in building contained nitrates and chlorides, is caused by changes from dryness to dampness and *vice versa*. It gives rise to fragmentation of the mortar and even of the building-stones themselves. Finally, frost can split a wall that is soaked in moisture. The dampness of dwellings is due to internal or external causes. There can be no doubt that a new building ought to be treated for a certain length of time by ventilation and heat with a view to evaporating the really enormous amount of water incorporated with the building materials. According to Pettenkofer, a three-story house requiring one hundred and sixty-seven thousand bricks would need some eight hundred and thirty-five thousand litres of water to build. When this evaporation has been effected great care should be taken in insuring proper drainage for rain and other water.—*The Journal of the American Medical Association*.

Accident Neuroses.—In spite of the extent of its literature, says an editorial writer in the *Boston Medical and Surgical Journal*, of March 19th, the question of the immediate and ultimate effect of traumatic or psychic shock on the nervous system remains one of the most important with which practical medicine has to deal. At this point perhaps more than at any other medicine comes into contact with problems which do not lie directly within its own sphere. The moral effect upon the community, and especially upon the working class, of the more or less indiscriminate bestowal of damages for real or fancied injury, involves a question of extreme sociological importance, and one which we, as physicians, too often overlook in our greater interest in the purely medical aspect of the matter. This ethical side of the question is doubtless more prominent in the European countries than in our own, where the various organizations of workmen have reached a greater degree of perfection than in the United States. In conversation with a sociologist of distinction some years ago, the writer recalls a statement made by him, that he regarded the attitude of mind inculcated by the general bestowal of damages in Germany and England, whose social conditions he was then studying, as one of the most ominous with which sociology in the future would have to deal. If this be true, it is certainly the duty of physicians at large, into whose hands the cases first come, to have as clear an idea as possible of the subtlety of the problem with which they are called upon to deal, and to realize fully the wide bearings of their expert decisions. Prof. Adolf Strümpell has again gone over much of the disputed ground with characteristic precision and clearness of detail. There can at present be no doubt whatever that many of the symptoms following accident are psychical, however they may be physically manifested. This is generally accepted and needs no proof. A matter also well recognized is that the chance of money redress is now much greater than formerly; hence an inevitable tendency, inherent in human nature, to exaggerate and through more or less voluntary auto-suggestion to construct an organized complex of symptoms, which otherwise might have sunk into the background of consciousness and disappeared. As a result, then, of a persistent sort of introspection, many disturbances are brought into existence, which have generally gone by the name of "traumatic neuroses" since the introduction of that specific term by Oppenheim. On the whole this designation has been unfortunate. It served a valuable purpose in defining a condition which was in need of special study, but inevitable confusion has

arisen from the fact that the term has been continually used without a proper conception of its exact meaning—a fault, however, not to be attributed to its originator. "Trauma" has come, in the popular mind, to be identified with "accident"; a "traumatic neurosis" means popularly an "accident neurosis." Experience will no doubt show that the term "traumatic neurosis" should be used with more and more caution, and never as indicating a special disease. No doubt both practically and scientifically we shall do as well to speak of "accident hypochondria," "accident neurasthenia," "accident hysteria," since it is evident that not every trauma is an accident. Frequently the diagnosis between an organic lesion and one due to a purely mental effect is easy to make by methods which are familiar to every experienced physician. The general appearance of an accident patient and his attitude toward himself are exceedingly characteristic. Almost without exception his tendency is to exaggerate, and, as a natural consequence of his self-observation, pain and weakness are felt with an increasing intensity. This is the result of the introspective frame of mind into which the accident with its attendant circumstances and the further prospect of litigation have plunged him. The point of importance is entirely apart from the question of simulation—that the symptoms, in large measure, are attributable to a subtle mental condition and are therefore mentally produced. A clear realization of this fact is essential to a proper judgment as to the so-called "objective symptoms" of accident cases. Most common of these are the anæsthesias, or, better, analgesias. Naturally, beyond the patient's statements, the physician has no means of judging of their presence. There can be little doubt that such conditions, whose actual existence is not to be doubted, have their being through suggestion and may be so increased; hence the advisability of not making too detailed an examination of sensibility. Much stress has been laid upon these anæsthesias; they have been exhaustively studied, and in the future should be relegated to a position of less importance. Especially is this true in determining ability for future manual work, since only rarely do sensory disturbances affect one's power in this direction. For practical purposes the determination of the visual field is of still less importance, especially when no complaint of defective vision is made. It is also a matter of common knowledge that respiration and heart action are strongly influenced by the psychical state, although of course not actually determined by it. The same may be said of the deep reflexes. On analysis, therefore, it appears that the so-called objective symptoms are in reality subjective, and that their diagnostic worth lies in the fact that their presence points more or less distinctly to the absence of organic disease.

The stumbling-block in the whole matter of the accident neuroses lies in the interpretation and significance of the term "simulation." Recrimination and argument without end have centred about this word, certainly to a quite unnecessary degree. Recognizing the fact that we have to do with a clinical picture largely of psychical origin, it at once becomes evident that a changing set of symptoms by no means points to conscious simulation. Theoretically the distinction between hysterical or hypochondriacal conditions and simulated ones is easy to draw and is of the most extreme importance to define with accuracy. In the first case we have to do distinctly with pathological fixed ideas which are deeply rooted in the patient's mental life and entirely beyond his control; in the second case, in simulation, we have to do with ideas which the patient evolves at will and which he may lay aside at will. The distinction is, of course, fundamental. The hysterical person himself believes in the existence

of his paralysis, and has, for example, actually lost the means of normally innervating his arm. That he may raise the arm under the influence of certain stimuli in no way implies, as is too often supposed, that he is thereby a simulator. The true simulant naturally wilfully inhibits the normal innervation of the arm. In other words, in one case the will is involuntarily in abeyance; in the other voluntarily. It hardly need be said that the practical application of these self-evident principles is not always easy; on the contrary, the most skilled diagnostician must often fail of a perfectly correct determination. The problem is a psychological one and must depend for its solution upon a great variety of factors, which will vary with the varying character and mental endowment of the subject. The reproach so often heard that expert physicians of equal education frequently testify in diametrically opposite ways is only in part justified. The personal attitude and point of view of the physician toward his patient may with all conscientiousness be widened to the extent of apparent contradiction. A definite rule of diagnosis is impossible to apply, as must unfortunately so often be the case, in dealing with matters in the psychical sphere. Especially difficult of diagnosis are head injuries of varying degrees of severity. The point of vital interest is, whether from a so-called "*commotio cerebri*" without gross lesion of the brain, finer material changes may persist and give rise later to cerebral symptoms—as, for example, headache, vertigo, mental disturbances—which otherwise would be interpreted as of purely psychical origin. Such a possibility is, at least, always present, however unlikely in many cases, and we should certainly be on our guard in the estimation of such true "traumatic neuroses." The whole subject of treatment is one of peculiar interest. Its essence, as Strümpell points out, is so far as possible to prevent the establishment of the hypochondriacal ideas which later are much more difficult if not incapable of removal. Treatment from the very first should be a psychical one, and should be persisted in as long as or longer than the false ideas prevail. The anticipation of a trial with the hope of reward for supposed or real injuries received, must inevitably be a serious hindrance to the therapeutic measures undertaken. During the time of suspense it is more than likely that an attitude of mind may be established which no effort, however painstaking, can later alter. Hence the perfectly well-established fact that the bestowal of damages does not usually cure the disease, as the radical simulationists would have us believe. Strümpell's conclusions in the articles to which allusion has already been made are so moderate and fair that we give them in substance here: (1) The name "traumatic neurosis" in its common acceptation should no longer be used as the expression for a definite and special disease. (2) It is probable that a true "traumatic neurosis" exists in the sense of a chronic organic change resulting from a severe *commotio cerebri* or *commotio spinalis*. Such cases are, however, rare. (3) The so-called objective symptoms of accident neuroses do not properly deserve the name. All such symptoms are dependent upon the psychical state of the patient. (4) The distinction between simulation, purposive exaggeration, and a true neurosis is easy theoretically. Practically the difficulties in diagnosis are often great. The changing character of certain symptoms does not necessarily imply simulation. (5) It is of the utmost practical importance, whenever possible, to prevent the onset of the neurosis. Palliation has a much more brilliant outcome than treatment when the condition is established. (6) In all cases it is the duty of the physician to bring it about that the patient shall again gradually accustom himself to work.

HOPEFUL OUTLOOK CONCERNING THE TREATMENT OF TRUE (GRAVE) OR PANCREATIC DIABETES.

By TALBOT JONES, M.D.,

ST. PAUL, MINN.,

VISITING PHYSICIAN TO THE CITY AND COUNTY, ST. LUKE'S, AND BETHESDA HOSPITALS, ETC.

AFTER a prolonged and painstaking investigation of diabetes mellitus, viewed from various standpoints—clinical, chemical, physiological—one is apt to arise from the study with three impressions so strong as to overshadow all others:

(1) That diabetes is not a univocal malady. The term or designation serves to express divers morbid forms, *i.e.*, the cerebral, the dietetic, the hepatic, the hereditary, and the pancreatic; and many of these types are so dissimilar in etiology, symptomatology, and prognosis as to scarcely possess anything in common except the presence of sugar in the urine.

(2) That "lean" (grave) or true diabetes mellitus is due, in a large percentage of cases, to degenerative or destructive lesions of the pancreas (sclerosis, atrophy, cysts, etc.), which prevent this gland from elaborating the glycolytic ferment, the presence of which in the blood determines the destruction of sugar.

(3) That in "grave" or true diabetes mellitus, where destructive lesions of the pancreas render it impossible for that gland to further elaborate the glycolytic ferment whose presence in the blood determines the destruction of sugar, the recent experiments of Lépine, Torup, Battistini, and others, in which they employed in the treatment of diabetes artificial ferments made from malt by Lépine, made from the pancreas by Torup and Battistini, are so promising that one is justified in hoping that agents have been found which will ameliorate the condition if not actually cure diabetes, in the same way that the enzyme or ferment elaborated by the thyroid gland now cures myxœdema.

With the first proposition, that the term or designation diabetes expresses divers morbid forms or types of the malady, there can be no serious differences of opinion; so this phase of the subject is instantly dismissed.

The second proposition, that degenerative or destructive lesions of the pancreas *ab initio* stand in a causal relation to "lean" (grave) or true diabetes mellitus in a large percentage of all cases, will not perhaps be readily accepted in the absence of incontrovertible evidence; and the burden of proof, of course, devolves on those who uphold this contention. Let us, then, in the briefest possible way, state the principal facts on which the existence of pancreatic diabetes is affirmed. This was shown first by Professor Lancereaux, in 1877, who presented to the Paris academy morbid specimens of the pancreas. Two years subsequently Lapierre confirmed this view. "The disease," as he describes it, "begins suddenly, and manifests itself by intense thirst and hunger, then by abundant polyuria with sugar oscillating between three hundred and six hun-

dred grams per day, and rapid emaciation, with loss of all the forces, and finally complications (bronchopneumonia, diabetic coma, phthisis) that carry off the patient."¹ In twenty cases fourteen showed atrophy of the pancreas well pronounced.

These observations were still further verified by the remarkable results of von Mehring and Minkowsky's experiments, who extirpated the pancreas in dogs. They found that sugar appeared in the urine a short time after the extirpation of the pancreas and persisted until death of the animal, and, "in addition to the glycosuria, there was great thirst, hunger, and rapid emaciation."

Dominicis, the Italian physiologist, who formerly held a contrary opinion, has also embraced this view, and in his late series of experiments attained identical results. Redmond, Marinisco, and Chaput also hold the same opinion and conclude "that total destruction of the pancreas produces permanent diabetes." "Hedon excised the pancreas in twenty-two dogs, and in each case diabetic urine was passed the day after and persisted until death, with all the characteristic symptoms of saccharine diabetes."² Thirolaix, as a result of his numerous experiments, arrived at the same conclusion. Professor Lépine, who was co-referee in the recent Lyons congress, has recorded forty cases of complete removal of the pancreas in dogs. "After complete removal he has always noted the appearance of sugar in the urine within forty-eight hours, and the diabetes is permanent. He believes that the blood has the power of constantly destroying glucose by the action of a ferment made in the pancreas (glycolytic ferment). This ferment is diminished in diseases of the pancreas and wanting when that gland is destroyed." Thirolaix has modified his former theory, and has adopted Lépine's conclusion "that the pancreas produces the principal glycolytic ferment which destroys glucose in the blood," and thus prevents its reaching the urine. De Renzi and Reale, as a result of their many experiments, assert that diabetes is caused in seventy-five per cent. of all animals in which they have entirely extirpated the pancreas. "Minkowsky, in reviewing his work, says that diabetes never fails to appear after complete removal of the pancreas if the animals live long enough after the extirpation. This statement is founded on fifty-five experiments made on dogs. Three times only did sugar fail to appear in the urine, but the dogs succumbed during the first twenty-four hours."³

Lépine, in his communication to the recent congress, October 29, 1894, defines his glycolytic theory: "The 'ferment' is taken up by the leucocytes and carried by them to the tissues, where it aids glycolysis."

Minkowsky, by an ingenious experiment, proved that if a portion of the pancreas (of an animal from which it had been extirpated) was transplanted beneath the peritoneum, the diabetic condition was averted, only to appear when the transplanted organ was removed by a further operation.

The pancreas may be destroyed by connective-tissue or fatty overgrowth, by tumors, or by calculi, and dia-

betes thereby result. The most frequent lesion is simple atrophy, and, according to Housemann, may be found in corpulent diabetics as well as in the emaciated. Cysts of the pancreas also sometimes produce diabetes. Bull, of New York, recently operated on a diabetic subject, and on post-mortem examination found a cyst of the pancreas. Churton, of London, had an identical experience, and if time permitted numerous similar cases could be cited.

This and other adducible evidence shows, this conclusion being unavoidable, that a relationship really exists in the great majority of cases between the pancreas and grave diabetes mellitus. An admirable *résumé* of the subject appeared recently in the *Boston Medical and Surgical Journal*, to which the reader is referred if he cares to pursue the inquiry still further. In addition to the authors quoted whose views favor this contention, the work of Comby, Tiessier, Charrin, Renault, Glenard, and others are recorded *in extenso*. The rational conclusion deducible from this study is that "grave" diabetes mellitus is due in the great majority of cases to degenerative or destructive lesions of the pancreas, which impair or destroy the gland's function of pouring into the blood through the lymphatics the glycolytic ferment, the presence of which in the blood determines the destruction of sugar.

But it may be asked, Does the acceptance of this theory bring us one step nearer a remedy for this hitherto incurable malady than we were before? Its attempted answer involves a consideration of the third proposition stated in the beginning of this paper. Professor Lépine, of Lyons,¹ entertaining the belief that the arrest of the destruction of sugar is owing to an absence or deficiency of the diastasic ferment, records the result of treatment of four cases of grave diabetes with a glycolytic ferment prepared from malt. In all four cases there was a distinct improvement and details of these cases are given. "As regards the sugar excretion, in the first case, before treatment the mean quantity for twenty-four hours was 140 grams: under the influence of the ferment it was 70 grams. In the second case the sugar was reduced from 41 to 11 grams; in the third case from 116 to 80 grams; in the fourth case from 257 to 124 grams, but later to only 116 grams. It had no injurious effects, but the improvement is only temporary."

Reviewing these results, this author observes "that theoretically the treatment of diabetes appears to be discovered."² It remains to be determined what the practical means are which would supply the deficiency of the ferment, as the subcutaneous injection of a ferment is an exceptionable means and might cause accidents."³

His method of preparing his malt extract, the dosage, etc., are not stated. These experiments of Lépine's are interesting and hopeful, but his warmest admirer could scarcely pronounce them conclusive.

Torup, professor of physiology in the University of Christiania, whose name has been for many years identified with the study of diabetes, has recently recorded his experience. After extirpating the pancreas in dogs and rendering them diabetic, he then used by subcutaneous injection a glycolytic ferment made from the healthy pancreas. His method of preparing this ferment, the dosage, and technique of the operation are not given. Sugar wholly disappeared from the blood of diabetic animals under the use of this ferment, and this destruction of sugar was permanent so long as the injections were continued. When exhibited by the mouth it was unsuccessful, as it was in some way destroyed by the chemistry of the stomach.⁴

Battistini¹ records the results observed in two human diabetics in whom he used the pancreatic emulsion. "A marked improvement was noted." His emulsion consisted of equal parts of a pancreas and glycerin. This was then diluted with sterilized distilled water, and from five to twenty cubic centimetres used as a dose administered by subcutaneous injection.

Other evidence of the same import is at hand. In his notable address as chairman of the section of physiology delivered before the British Medical Association in 1895, Prof. A. E. Schäfer, of London, referring to the pancreatic secretion and its effects on diabetic animals, remarked: "The injection of pancreatic juice into the veins prevented the diabetes, but the operation was a dangerous one. Raw pancreas administered by the mouth had no effect."² It has been stated by Valli that in dogs which have been rendered diabetic by removal of the pancreas, injection of pancreatic emulsion into the blood causes a disappearance of the diabetic symptoms. . . . With regard, however, to these statements, it may be remarked that the danger of injecting emulsions of raw pancreas into the blood would be great, on account of the tendency which extracts of gland cells have to produce intravascular clotting."³ It would be interesting to know whether or not the pancreatic extract, "dangerous when injected into the veins," would be likewise dangerous if administered by ordinary subcutaneous injection. Probably not, since it is well known that hundreds of injections of various gland cells—for example, the thyroid extract by Murray, the testicular extract by Brown-Séquard—have been administered, yet no reports have ever been published of intravascular clotting or other disagreeable or dangerous effects following their use.

If space permitted additional evidence could be adduced to prove that sugar is destroyed, in the blood of animals rendered artificially diabetic, by the injection of a pancreatic extract. Previous to these experiments the important and hitherto unsolved problem in the treatment of pancreatic diabetes was the discovery of an agent that would destroy sugar in the blood; for it is the presence of sugar in the circulation to which must be ascribed the chief mischief to the diabetic, and, *ceteris paribus*, the larger its amount the graver his condition, and *vice versa*. "In the course of all my experience in diabetes I have never known anything serious to arise as a part of the disease so long as the urine was kept free from sugar."⁴ But as sugar is being constantly formed in the liver, not only from carbohydrates but also from albuminates and fats; and, in pancreatic diabetes, as sugar production is constantly going on, but without coincident and equivalent sugar destruction, herein probably lies the explanation of past failures in the treatment of diabetes. Our efforts have been directed against further sugar production (diabetic dietary, drugs, etc.) rather than toward sugar destruction. It is a consideration of these facts in progressive general physiology which

Christiania last summer, had a conversation with Professor Torup relative to his researches in diabetes. The latter remarked that as a result of prolonged study and numerous investigations he believed it to be fully established that sugar is destroyed in the blood of diabetic animals by pancreatic extracts, and that, in his opinion, this phase of the problem is therefore solved. He dwelt insistently upon the necessity for the subcutaneous use of the pancreatic extract, and remarked that a very small dose only was sufficient to destroy sugar in the blood of diabetic dogs. He also stated to Dr. Boeckmann that he was about to establish a hospital in Christiania for the treatment of pancreatic diabetes in the human subject.

⁴ A prominent surgeon of this city, Dr. E. Boeckmann, while in

provokes our admiration of the labors of Thiroloix, Minkowsky, Lépine, Torup, Valli, Battistini, and others, who, apparently realizing the difficulties to be overcome and perceiving the causes of past failures, have set to work to overcome them. Their work signalizes a new departure in the therapeutics of this disease, but the principle they employ is not new; its exact analogue is seen in the successful employment of a thyroid extract against myxœdema. The destruction of sugar in the blood of a diabetic animal has been attained by other means than by the subcutaneous injection of a pancreatic extract. Pancreatic grafting into the abdominal cavity and into the skeletal muscles has been successfully performed. Reference has already been made to the experiment of Minkowsky, in which he proved "that if a portion of the pancreas (in an animal from which it had been extirpated) was transplanted beneath the peritoneum, the diabetic condition was averted, only to appear when the transplanted organ was removed by a further operation." Professor Schäfer, in his address already referred to, says: "A fragment of the gland either from the same or another animal may, in fact, be grafted elsewhere into the peritoneal cavity or under the skin. Provided the grafting be successful and the portion of the gland employed of sufficient size, removal of the pancreas is now no longer followed by the usual symptoms. The animal may, in fact, remain in perfect health. But if at any subsequent time the grafted portion of the pancreas is removed, diabetes supervenes, and the animal dies within a short time, as after primary removal.¹ It is interesting in this connection to note that Thiroloix, in considering the results of pancreatic grafting, an ingenious device practised by Minkowsky, Hédon, and himself (whereby the pancreas in dogs is brought out of the abdominal cavity and grafted into the muscles of the external walls), has modified his former theory and has now adopted Lépine's conclusion 'that the pancreas produces the principal glycolytic ferment which destroys glucose in the blood and thus prevents its reaching the urine.'² Schäfer, referring to the experiments made by Dr. G. R. Murray on the monkey, in which after the removal of its thyroid gland all the symptoms of myxœdema appeared, and which that observer claimed to have cured by injections of the thyroid juice, says: "He (Murray) does not, however, state how long the animal was kept under observation after treatment and whether the cure was permanent. It is, indeed, scarcely probable that the subcutaneous injection or the taking by the mouth of the thyroid juice would be followed by more than a temporary removal of the symptoms. The effects of grafts, however, are to all intents and purposes permanent, and it has been found, as in the case of the pancreas, that removal of the graft which has maintained the health of the animal after extirpation of its own thyroid is speedily followed—as with primary removal of the organ—by the usual symptoms of thyroidectomy."³

Thiroloix proved that "the grafting of the portion of the pancreas, the secreting part of which had been destroyed by injection of paraffin along the ducts, is also efficacious in preventing the advent of diabetes after removal of the pancreas."

The idea that pancreatic grafting can be successfully performed and that the grafts will grow, is not only shown by this mass of direct testimony, but is also strongly supported by analogy; its analogue being thyroid grafting for myxœdema.⁴

Too many successes have attended thyroid grafting, performed by numerous independent and widely separate observers, to longer seriously question its practical value. The mass of concurrent testimony as to its success is ample and conclusive; and, what is more to the point, this success has been achieved not only in the lower animals but also in man. The technique of the operation as performed on the human subject is thus described by Gibson, of Brisbane: "The grafting was done by removing both lobes of an etherized lamb's thyroid, incising them longitudinally and introducing them (1) within the sheath of the pectoral muscle and (2) on another occasion into the child's abdomen. The improvement in the child's condition was remarkable.¹ Thyroid grafting (in man) has been practised with good results in cachexia strumipriva, in sporadic cretinism, and in myxœdema by Kocher, Horseley, Bircher, and Gibson, of Brisbane."²

The analogies of pancreatic diabetes and myxœdema are so numerous and impressive as to render it probable that the ultimate technique of pancreatic grafting in man will be similar to that observed in thyroid grafting as described above.

Grafts of the pancreas and of the thyroid gland may or may not grow. If the former result ensues, the symptoms of diabetes and myxœdema respectively are ameliorated for a time, or "the animal may, in fact, remain in perfect health" (Schäfer).

But Schiff long ago pointed out, an observation since confirmed by Reverdin, Kocher, Bircher, and others, that after being *in situ* for a greater or less length of time, the grafts in many instances are very liable to undergo atrophy, to become indurated and converted into mere fibrous bands, and then to cease functioning, when the disease reappears. These changes in the grafts have been attributed to their altered environment, depression of vitality, diminished vascular supply, and to ill-understood changes of nervous innervation. In a certain proportion of cases the grafts do not grow at all. If thyroid grafting is now practically abandoned, this is not because the grafting was unsuccessful, but rather because subsequent experiments showed that the extract was just as efficient against myxœdema when given by the stomach—a far more convenient way of administration.

Just here it ought to be pointed out that although the similarities of myxœdema and pancreatic diabetes are, as we have shown, remarkably close and striking, in one particular a fundamental difference between them is noted. The thyroid ferment, whatever be its intimate nature, is clearly not destroyed by the stom-

duced by disturbances or lesions of the sympathetic system (vasomotor nerves).

(2) Both are due, in the majority of cases, to atrophy of a gland, the thyroid in myxœdema, the pancreas in true diabetes (Hausmann).

(3) Suppression of a peculiar enzyme or ferment made in the thyroid gland gives rise to the morbid complex of symptoms called myxœdema; suppression of the glycolytic ferment made in the pancreas gives rise to true diabetes.

(4) Total extirpation of the goitrous thyroid gland causes myxœdema in a respectable proportion of cases (Kocher); total extirpation of the pancreas causes diabetes in a large proportion of cases (seventy-five per cent., De Renzi and Reale; one hundred per cent., Minkowsky).

(5) If a small fragment of the pancreas be left in the abdominal cavity, after operation on that gland, diabetes is averted; if a small fragment of the thyroid gland be left after surgical operation on that gland, myxœdema is (usually) averted.

(6) In both diseases success has attended thyroid and pancreatic grafting (*vide* Thiroloix, Minkowsky, Valli, and Hédon's recent experiments).

(7) In both maladies treatment addresses itself to supplying artificially a ferment which these glands, owing to disease or destruction, are no longer capable of elaborating. Success has attended the treatment in myxœdema, and is now claimed for diabetes.

³ Ibid., p. 343.

⁴ The pathological analogies of pancreatic diabetes and myxœdema are numerous and striking, the parallelism extending even into the domain of treatment.

(1) Both maladies are probably systemic dystrophies superin-

ach chemistry or by the portal circulation, since cures of myxœdema are wrought when it is exhibited by the mouth. On the other hand, the pancreatic extract used against diabetes, given by the stomach, has been uniformly unsuccessful; and this is no doubt attributable to the fact that, being a nitrogenous body, it is itself destroyed by the pepsin and trypsin ferments of the stomach. A consideration of these facts in physiological chemistry will probably explain past failures to cure pancreatic diabetes when the pancreatic extract or raw pancreas was exhibited by the mouth. Normally, according to Professor Lépine, the glycolytic ferment elaborated by the pancreas is not poured into the duodenum along with its other secretions, but is taken up by the lymphatics and carried thence directly through the thoracic duct to the blood. It thus escapes alimentary digestion on the one hand and the portal circulation on the other. It would be well to keep this fact steadily in view when using artificial pancreatic emulsions for diabetes in man.

It will be seen that obstacles one by one are being gradually surmounted, difficulties are being overcome, and light is being thrown on the dark places; yet, despite all this, doubts are still suggested and difficulties presented at every turn. But medical science, like the Sibyl, only reveals her secrets to time leaf by leaf. Points needing further elucidation are: Whether or not diabetes in man will respond to pancreatic injections and to pancreatic grafting in the same way as does diabetes in animals; effects on the human organism of subcutaneous injections of the extract (on the heart, the respiration, the nervous system, etc.); the manner of preparing a sterilized pancreatic extract for clinical use; the proper dosage and frequency of injections; its freedom from danger or the reverse; the technique of its administration, and perhaps other matters. These, however, are matters of detail and the difficulties can no doubt be smoothed over by the exercise of a little patience and further experimentation in our hospitals and laboratories. The essential point, the fundamental proposition that sugar in the blood of diabetic animals is destroyed by artificial glycolytic ferments, appears to have been established by Valli, Battistini, Torup, Minkowsky, Thiroloux, and others. All else in comparison is of but secondary importance.¹

To sum up, I have endeavored to show:

(1) That a causal relationship is proven to exist, in a large proportion of cases, between "lean" or true diabetes mellitus and degenerative or destructive lesions of the pancreas.

(2) That sugar is destroyed in the blood of diabetic animals (*a*) by the subcutaneous injections of a pancreatic extract, and (*b*) by grafting the pancreas into the skeletal muscles and into the abdominal cavity.

(3) That there are striking pathological analogies between true diabetes and myxœdema, and that in the latter disease success has also attended both injections and thyroid grafting—a success achieved not only in animals but also in man.

(4) That the treatment of diabetes by means of a glycolytic ferment made from malt (Professor Lépine's method), while it decreases the quantity of glucose in the blood, does not wholly destroy it, and, *pro tanto*,

is less successful than the treatment with extracts made from the pancreas.

(5) That in the treatment of true diabetes with pancreatic emulsions a prerequisite to success is its introduction into the circulation so as to avoid the stomach chemistry on the one hand and the portal circulation on the other.

After due consideration of the foregoing, three possibly successful methods of treatment appear available:

(*a*) By rectal injection of a properly prepared pancreatic extract. According to most authorities the rectum is not a digesting but merely an absorbing organ. Thus introduced, the extract would escape digestion, and, being taken up by the lymphatics, would likewise escape the portal circulation.

(*b*) By the subcutaneous injection of a sterilized pancreatic extract of the requisite strength—using the same antiseptic precautions as are now observed in injecting the diphtheria antitoxin and Koch's tuberculin.

(*c*) By pancreatic grafting, which, in the lower animals at least, has been brilliantly successful.

As the physiologists have now pointed the way, it is to be hoped that practical results will follow close on the heels of their experimental investigations.

When we remember that true pancreatic diabetes is as fatal to-day as it was in 1674, when Willis demonstrated the presence of sugar in the urine, any new and rational treatment holding out the slightest promise of success deserves and should receive a careful, thorough, and painstaking clinical trial in our hospitals. Physicians who are constantly using subcutaneously the diphtheria antitoxin, tuberculin, and thyroid extract, should not hesitate to employ in the same way a pancreatic extract; and surgeons who are daily doing the most formidable operations and invading successfully almost every cavity in the body should not shrink from grafting the third of a pancreas into the sheath of the pectoral muscle or into the abdominal cavity.

This article is written in the hope that with the immense clinical material available in the large Eastern hospitals, the method of pancreatic injections and grafting will be put to a practical test, and the truth brought out as to its value or the reverse. It has been shown that pancreatic injections and grafting destroy sugar in the blood of diabetic animals; whether or not they will be equally successful in man remains to be determined. I hope to shortly supplement this paper with a report of cases of diabetes treated in this way. The whole subject in its present shape is now left to the discriminating judgment of the medical profession. Professor Schäfer closes his article to which reference has been made with these words: "That the subject has a vast future there can be little hesitation in predicting, for, in spite of the advances which have been made in elucidating it during the last few years, very many points still remain obscure. Nevertheless, the way which the physiologist has attempted to show may now safely be followed by the practitioner, and the result of these physiological observations and experiments, as well as clinical and pathological observations in the same direction, which are steadily accumulating, cannot fail to throw light upon and to assist in the diagnosis and treatment of many ill-understood symptoms of disease."

Varicose Veins.—Dr. Hirst recommends patients suffering from this malady to carry a firm ball, and in case of rupture and hemorrhage to apply the ball at the point of rupture and bind down tightly with a handkerchief. This will preserve life and strength until the arrival of a physician.

¹An extract of the pancreas for subcutaneous use in diabetes might be made in the same way that the extract of the thyroid gland is made for use in myxœdema, which, according to Murray, is prepared as follows: "The thyroid glands are removed from several sheep just after they have been killed. Each lobe is minced and then bruised in a mortar. For each lobe employed one cubic centimetre of glycerin and one cubic centimetre of a 0.5 per cent. solution of carbolic acid in boiled distilled water is added. The mixture is allowed to stand for twelve hours, and then squeezed through a cloth in a press, so as to obtain as much liquid as possible from the mixture. All the apparatus used in the preparation is previously cleansed by boiling water and a 1 to 20 carbolic-acid solution." Brit. Med. Jour., August, 1892.

GONORRHOEAL INFLAMMATION.¹

BY HERBERT J. HOPKINS, M.D., C.M.E.-E.,

PITTSBURG.

GONORRHOEA proper, as treated by the mass of physicians to-day, does not redound much to their credit. In the greatness of our desire to benefit the patient the mistake is often made of trying to do more than is at present possible. In this paper gonorrhœal conjunctivitis is first discussed in order to show the limitations of treatment, it being of course understood that gonorrhœal inflammation, whether of the urethra, vagina, or conjunctiva, is essentially the same disease, running the same course in about the same time and reacting in the same manner to like reagents.

Gonorrhœal conjunctivitis is the most intractable and destructive disease to which the eye is subject, and for this reason, as well as for its great frequency, it has received minute attention, and this in a locality open to free inspection and where errors in treatment are quickly followed by most disastrous consequences—conditions which naturally insure the highest possible perfection in its treatment. It is caused by the deposition upon the conjunctival membrane, in whatever way, of gonorrhœal discharge, and is of course itself communicable, *e.g.*, the discharge from one eye being capable of setting up the same disease in the other; or of causing a specific urethritis.

It runs a definite self-limited course lasting from four to six weeks, and it is impossible when it is fully developed to cut it short, though its severity can be mitigated and its phenomena controlled to such an extent as to preserve the affected tissue intact. If treatment be resorted to, however, immediately after exposure, the infecting virus can be readily destroyed and the disease prevented. This is best accomplished by nitrate of silver in a solution of from five to ten grains to one ounce of water applied freely to the part affected. It is open to the objection of causing considerable burning pain and any excess should be neutralized by a weak solution of sodium chloride.

Gonorrhœal conjunctivitis begins like, and in its earliest stages is almost indistinguishable in appearance from, simple acute conjunctivitis, but it soon assumes its own characteristic features.

During the initial stage, lasting about a week, before the discharge has changed to the thick creamy character of the second stage, reliance is placed upon frequent cleansing with weak non-irritating solutions, *e.g.*, of boracic acid alone or combined with perchloride of mercury, 1 to 10,000, or with peroxide of hydrogen. It is well, too, to begin the use of iced cloths (pieces of lint two inches square changed every two minutes from a block of ice to the lids) even in this early stage, and when once begun they are to be continuously employed night and day, a duty which taxes the energy of two nurses.

In selected cases, leeches applied to the temple or to the side of the nose are also of great benefit. It is not till the second stage, that of free discharge, is established that the stronger applications, *e.g.*, of nitrate of silver, are allowable, nor are they then if there be much hard, brawny swelling.

It cannot be too clearly understood, from its bearing upon the urethral inflammation, that the disease is a self-limited one, the duration of which we cannot shorten, though it can readily be prolonged. The proper treatment is essentially a cleansing, sedative one during the acute stages: Astringent solutions, *e.g.*, of tannin, zinc, alum, etc., are not of noticeable benefit before the final stage, at which time they are invaluable, restoring the relaxed and thickened membrane to its normal condition.

Though it is not directly involved in the inflammatory process the greatest danger in this disease is through the cornea, and its condition is a vital index by which to gauge the measure of our success. Its nutritive supply being interfered with by the inflammation of the surrounding tissues, its substance yields readily to the corrosive action of the discharges, the first evidence of trouble noticed being usually at the sclero-corneal junction in the form of a faint nebulous zone of infiltration, which speedily breaks down, forming a trench whose depth and length rapidly increase till perforation occurs, and even the whole cornea becomes detached and drops off. This ulcerative process may begin very early in the disease or not till near the end. As special measures to save the vitality of the cornea, hot fomentations are sometimes indicated instead of the iced cloths, and even scarification of the conjunctiva to deplete the strangulated tissues.

In children the well-known tendency of inflammation of mucous membranes to expand itself chiefly in the direction of cell proliferation and consequent free discharge is exemplified in this instance. In early life gonorrhœal conjunctivitis (ophthalmia neonatorum) is characterized by the very abundant creamy discharge and but comparatively little of the brawny swelling so noticeable in the adult, and as a consequence stronger and more frequent applications of nitrate of silver are recommended; but iced cloths to reduce swelling are not so urgently indicated.

It is important to note, from its bearing upon similar cases of urethritis, that under the classical term gonorrhœal conjunctivitis are grouped the simple purulent cases arising from infection from healthy abscesses, leucorrhœal discharges, and various chemical irritants in which the gonococcus has no part. These are comparatively mild in character, of shorter duration, and yield readily to antiseptics.

Treatment of Gonorrhœa.—It being granted that gonorrhœa is a self-limited disease, lasting from four to six weeks, and that it is impossible to shorten its course, our endeavor rationally would be to guide the disease to a safe termination, the particular point being to avoid complications and sequelæ, which I do not hesitate to affirm are frequently due to overzealous pursuance of the popular method of treatment by injections. In the acute forms of gonorrhœa the treatment ought to be a sedative, antiphlogistic, antiseptic one. Rest, physical and especially functional, should as much as possible be secured, and as contributing to this end bromides in large and repeated doses should be given. Anything which would tend to excite the sexual organs should be carefully excluded. It is in the urine, nature's self-provided irrigator, that our greatest reliance should be placed. Our aim should be to make it abundant, bland, and antiseptic. To accomplish this end, water is to be freely given; the diet, a skimmed-milk one by preference, should at least be free from spices, pastries, and liquors. An alkaline diuretic should be prescribed, and if tolerated cubebs and copaiba. Salol is less irritating and may be substituted. When eliminated through the urine it appears in the form of carbolic and salicylic acids.

Injections as ordinarily used are provocative of more harm than good in the earlier stages, though they are of unquestioned value after the force of the disease has spent itself. The following recommends itself to me:

R Cocaine hydrochlor. gr. x.
Antipyrin. gr. vi.
Zinci sulph. gr. vi.
Aque rosæ. ad $\frac{1}{2}$ iij.

S. For injection use one-half teaspoonful. Repeat three to six times daily after urinating.

Subsequently a more strictly astringent injection is indicated—zinc, silver, alum, tannin. Abortive cases—

¹ Read before the Austin Flint Medical Club, April 14, 1896.

occur in this, as in other diseases; but as stated before, little good can be expected from measures adopted for this purpose after the disease is established. The infecting virus shortly after exposure can readily be destroyed, however, and the disease thus prevented. During the first three weeks the physician is indeed worthy of his hire who insures to his patient comfort and freedom from some one of the following complications: Balanitis, phimosis, paraphimosis, follicular abscess, lymphangitis, bubo, Cowperitis, prostatitis, cystitis, epididymitis.

The violence of the inflammation and ill-directed efforts of cure may result in the necrosis of the epithelial layers in places, and even of the underlying connective tissue; a suppurating surface necessarily remains, giving rise to a chronic purulent discharge, to which the name chronic gonorrhœa is applied. When healing is complete the discharge ceases, and an organic stricture is likely to result. A condition of chronic inflammation of the mucous membrane lining the urethra (membranous portion especially) with scanty turbid secretion—gleet—is a common sequela of the acute variety; the subjects are usually in poor general health and require tonics, change of air, as well as continued use of astringent injections.

A CRITICISM ON THE "GUINEA-PIG TEST" FOR TUBERCULOSIS.

BY CHARLES WILSON INGRAHAM, M.D.,

BINGHAMTON, N. Y.

BACTERIOLOGISTS claim that it is much like "searching for a needle in a haystack" to endeavor to demonstrate tubercle bacilli by ordinary processes in substances such as water, milk, dust, and the like, in which it is impossible to concentrate the infection. Instead, therefore, of preparing slides after the manner for examining sputum, the common plan is to inject the suspected substance subcutaneously into the body of a guinea-pig, and if the animal develops tuberculosis, it is regarded as conclusive evidence that the material contained tuberculous infection. If, on the contrary, the pig does not develop the disease either locally or generally, it is assumed that the suspected substance was free of infectious matter.

The question arises, and very reasonably too, as to whether the results following the injection of suspected substances into the bodies of guinea-pigs are of sufficient accuracy and reliability to warrant a positive decision as to the presence or absence of suspected infection according to the presence or absence of tuberculous manifestations following the experiment.

It would seem that the accurate establishment of the presence or absence of tuberculous infection in fluids suspected of containing it is of such great importance that more precise means should be devised than the guinea-pig test as it is ordinarily conducted.

It is claimed that the guinea-pig is very susceptible to tuberculous infection, even in minute quantity, and for this reason is used in these experiments in preference to other animals, as there will almost certainly be a reaction following the introduction into the system of minute particles of infection. While this natural sensitiveness to tuberculous infection is advantageous in this respect, it is not entirely without disadvantages which possibly counteract the natural benefits.

It is generally admitted that anything which tends to reduce the general vitality of man or animals renders them more susceptible to the infection of tuberculosis. Now, is it not more than possible that injecting into the system various suspected fluids containing more or less septic matter, and inducing suppuration at the point of injection or causing general poisoning,

acute or chronic, will so reduce the general vitality of the guinea-pig as to render the animal abnormally susceptible to tuberculous infection from any source whatsoever? The presence in the system of pus germs, either from artificial or accidental sources, favors the development of tuberculosis; they render the subject much more susceptible to tubercle bacilli and favor the spread of the disease from a local point to a condition of general tuberculosis. This is shown, to a certain extent, by the frequency with which tuberculosis follows acute diseases which have been attended with the development and absorption of more or less septic matter, such as is present in typhoid fever and pneumonia. There is also a marked tendency to tuberculosis in individuals suffering from chronic suppurative processes, such as bone disease, ulcers, recurrent abscesses, carbuncles, and the like.

So, therefore, following the injection into the system of guinea-pigs of fluids which contain or cause the development of pus organisms in the system, it is probable that the animal becomes so susceptible to tuberculous infection as to contract the disease from natural sources. Another factor which would contribute to simultaneous tuberculosis, from sources independent of the injection into the system of suspected fluids, is that the great majority of these experiments are conducted in the larger cities, where the air contains the greatest proportion of tuberculous infection. The tendency to tuberculosis from natural sources is four times greater in the city of New York than in the highlands of the State. So, therefore, the results attending experiments in the city and in the country districts cannot approximate under the same standard. In the larger cities it is quite impossible that man or animal can escape repeated exposures to the infection of tuberculosis with the frequency which results in the enormous death rate from that disease, as for instance, in New York City, Brooklyn, Philadelphia. Considering that as the injection into the system of the guinea-pig of septic fluids induces a soil favorable to the lodgment and dissemination of tubercle bacilli from respiratory or intestinal sources, added to the natural susceptibility of the guinea-pig, is it scientific to assume on the simple fact that tubercles are found in the bodies of experimental animals either localized at the site of injection or generally disseminated following such treatment, that the fluid injected contained tubercle bacilli?

With these factors in view, it would seem advisable that all tests for tuberculosis be conducted by placing the experimental animal in a medium which offers the greatest freedom from all sources of accidental infection, particularly through the atmosphere, water, and food. To attain this the experiments must be conducted in the country, as remote as possible from any isolated cases of tuberculosis. By placing the animal in such a medium much will have been done to render the results attending any experiment approach more nearly a reliable standard.

Having arranged for the care of the experimental animals in the country air, we must next consider some other factors. The animal must be placed in surroundings, and must be given general and hygienic care, which shall be conducive to the maintenance of its vitality and disease-resisting powers. The results following the injection into the animal of suspected fluids, during the "reaction" of which the subject was treated as circumstances would permit, with no regard whatever to many features contributing to the ultimate result, is by no means a reliable or scientific experiment. The extent of accidental infection to which experimental animals are commonly exposed, whether used as a "control" subject or for purely test purposes, would be entirely out of proportion to the infection introduced, if indeed any was introduced, in the

suspected fluid. The "control" animals from which many scientific deductions are made are, when treated promiscuously, entirely unreliable. If this statement is too sweeping, we must at least admit that ordinary experiments are carelessly conducted, and only remotely in harmony with the accuracy which is obtained in other fields of chemical and bacteriological research.

Does the experimenter always attend to the cleansing and disinfecting of the coops in which his animals are kept? Does he sometimes place a supply of experimental animals in the same quarters which have contained former subjects, without intervening cleansing and disinfection? Unless this is attended to, the coops may become infected to the extent of inducing tuberculosis from this source alone in the animal undergoing experiment. The food of the guinea-pigs undergoing experiment must also be considered, both as regards its freedom from tuberculous infection and its properties for maintaining general nutrition. The experimenter is never positive that his test animals come to him absolutely free from tuberculous disease.

There are many accidents which tend to prevent the pigs from reaching the experimenter in a healthy condition. Because of the extraordinary susceptibility of these animals to tuberculosis and the numerous sources from which they are liable to contract the disease, it would seem that serious error might occur by infection before reaching the experimenter. It is quite probable that the majority of pigs come to the experimenter already infected with tuberculous disease. The breeder or breeder's family might be affected with the disease and transmit it to the animals under their care. Former generations of animals might have been tuberculous and have transmitted to their offspring an abnormal susceptibility, besides disseminating contagion about the breeding-quarters. Outside of the question of accidental infection, either before or after the animal reaches the experimenter's hands, it would seem that no system whatever is observed to obtain a definite standard of animals. In view of the importance oftentimes placed upon the results following the guinea-pig test, it would seem that experimenters should unite with the object of securing an approximate standard of general vitality in all animals utilized for experimental purposes. The obtaining of supplies from promiscuous sources is to be condemned as careless and unscientific. Either the State governments should take steps to secure standard material for tests, or private enterprise should combine to secure the same. In human beings we have practical every-day examples of the various elements which would contribute to render the present system of guinea-pig experimentation unreliable, and which demonstrate the necessity of securing a certain standard of constitutional vitality in these animals. The same variation of susceptibility to tuberculosis which obtains in the human race must obtain from promiscuous breeding of guinea-pigs. The injection into one person of tuberculous infection such as is injected into the guinea-pig would not give rise to the disease, either locally at the point of injection, in remote parts of the body, or as a general infection, with any degree of uniformity. In some local disease would be produced, in others general tuberculosis, all dependent upon the influence of age, heredity, environment, food, exercise, etc. In a general way all the factors which enter into the determination of human susceptibility to tuberculosis would obtain in tuberculosis of the lower animals. The writer does not claim that all the various accidents which he has here mentioned are liable to present in each case, though there can be no doubt that more than one enter into all cases of experimental tuberculosis, and therefore he believes the results following the common plan of injecting fluids

into the bodies of guinea-pigs without regard to these various factors cannot be depended upon as decisive evidence as to the presence or absence of tuberculous infection.

To summarize, these are the factors which singly or collectively may prevent accurate results:

- 1st. Simultaneous infection from ordinary sources.
- 2d. The influence of general environment.
- 3d. Infection from contaminated quarters, either before or after reaching the experimenter's care.
- 4th. The influence of food, bacteriologically and chemically.
- 5th. The influence of heredity.
- 6th. Direct infection from the breeder, the breeder's family, or the experimenter.

FAILURE OF CASTRATION TO CAUSE ATROPHY OF THE PROSTATE.

By CHARLES B. KELSEY, M.D.,

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE HOSPITAL.

THE patient, aged sixty-nine, came into the Post-Graduate Hospital suffering greatly with cystitis due to enlarged prostate. He had been unable to pass water for two or three months and had been catheterized by his wife every three or five hours. In addition to a very large prostate he had right inguinal hernia and hydrocele on the left. The urine was albuminous. Bassini's operation was done on the right side and both testicles were removed.

After three weeks of careful catheterization and washing out of the bladder, there being very slight improvement, if any, in his symptoms, a perineal section was made and permanent drainage established.

Two weeks and a half later (five weeks and a half after castration) the patient died of chronic nephritis. As far as could be seen his death was not in any way hastened by the operative interference.

Following is the report of the pathologist to the hospital, Dr. Brooks:

"NEW YORK, January 31, 1896.

"MY DEAR DR. KELSEY:—The following is a brief report upon the prostate removed from castrated patient:

"**Report.**—Mr. —, aged sixty-nine. Prostate removed six hours after death. Weight: 45 grams. Dimensions: antero-posterior diameter, $1\frac{3}{4}$ inches; transverse diameter (base), $2\frac{1}{2}$ inches; depth, 1 inch.

"**Gross Appearance.**—Color, dark red. Consistence firm, dense, moderately friable. The cut surface mottled and of a dark reddish-gray color; shows numerous delicate, silvery, grayish-white and grayish-red bands, united to form trabeculae of greater or less density and thickness, encircling prominent, irregularly outlined, nodulated foci which are pale yellowish-white in color and of succulent consistence. These foci vary in size from that of a milletseed to that of a small pea.

"**Microscopical Examination.**—In teased preparations from the fresh organ, the elements composing the stroma, unstriated muscle, fibrous and elastic tissues appeared to be well preserved and in normal proportion. Individual cells symmetrical; nuclei prominent, well-defined, and distinctly visible; protoplasm clear or faintly granular. Rarely a cell filled with minute droplets of fat was seen; also a few free fat droplets floating in the mounting-fluid (physiological salt solution) surrounding the fragments of tissue. Fibrous elements somewhat in excess of unstriated muscle structure. Most of the epithelial cells from glandular ducts presented no strikingly abnormal alterations. The greater portion of them possessed dis-

tinct nuclei and quite clear, nearly homogeneous, protoplasm containing but few granula. A very small number were partly disintegrated, slightly pigmented, and filled with minute fat granules and occasional large oil drops. These disorganized cells were prominent by virtue of their rarity.

"In unstained sections from frozen tissue, the stroma was seen to be composed of well-preserved, tortuously distributed, unstriated muscle fibres and more or less densely arranged fibrous connective tissue, the latter in excess. The stroma was decidedly greater in amount than glandular structure; though this was not much more pronounced than is frequently the case in the normal prostate, especially in the lateral lobes. On careful search, a few isolated cells containing distinct drops of fat, in minutest division, could now and then be found lying embedded between apparently normal muscle elements. Notwithstanding the presence of fat, the nuclei and general contour of these cells were perfectly retained. Sometimes free fat globules were seen lying between the connective-tissue fibres; but it is believed these could readily have been, and probably were, originated during cutting and mounting of the sections. The epithelia (often in double layers) lining the ducts appeared to be in normal relation to each other; contour uniform and nuclei distinct; protoplasm clear or but slightly granular. Fat was very rarely observed in the glandular structure, and then only in the form of minutest droplets and confined chiefly to lumina. Occasionally the lumen of a duct, presenting intact lining epithelia resting upon basement membrane, was seen partially or wholly occluded by an amorphous or finely granular substance enclosing several partially disintegrated cells and a few fat droplets. The great majority of the lumina of the ducts were comparatively free, or showed but slight traces of granular detritus or deposits of other nature. On the whole, the changes observed in the fresh tissues were not sufficiently pronounced to warrant the assumption that atrophic process had, to any great extent, been established.

"Study of frozen sections, hardened in formalin and alcohol and subsequently stained with Boehmer's hamatoxylin and borax carmine, revealed even less evidence of atrophic changes. Excluding fat, the description given above under examination of fresh tissue applies here. The best-stained portions of the sections were invariably the epithelial cells lining the tubules—the parts where alterations would most naturally be expected. The only change remarked was a slight increase in the amount of fibrous connective tissue as compared with the muscular structure. This alteration seemed to be confined to certain areas. In other areas the glandular structure was in excess, the various lobuli being almost in apposition. In some parts the separating partitions were composed almost wholly of muscular tissue. A small number of corpora amylacea were seen.

"H. T. BROOKS."

It will be seen from this very careful examination that neither in gross appearance nor in microscopic structure was there the slightest sign of any atrophic or degenerative change in the prostate gland.

13 EAST TWENTY-NINTH STREET.

Local Anæsthetics.—When a fluid is injected under the skin the nerve filaments are rendered insensible by driving away the blood and temporarily preventing its return, producing an anæmia. The writer, acting upon this principle, has succeeded by means of a perfectly neutral substance—sterilized olive oil—in producing an anæsthetic area.—Dr. LOUP, *Bulletin Médical*, 1896.

Progress of Medical Science.

Inflammatory Enlargements of the Head of the Pancreas.—Dr. Riedel, who has published some valuable work on cholelithiasis on previous occasions, directs attention to an interesting condition which he has met with in three instances in patients who were subjects of gall stones. Referring to this subject, *The Medical Chronicle*, March, 1896, says that in operations on the biliary passages the surgeon very frequently examines the state of the pancreas without previously breaking down any adhesions which may have formed between the biliary passages and the neighboring organs. In doing this the examining finger is very liable to mistake for biliary concretions in the duodenal end of the common bile duct a very hard condition of the lobules in the head of the pancreas. This abnormal hardness of the pancreatic lobules without any enlargement of the gland is, in Riedel's experience, relatively frequent in cases in which biliary calculi occur in the common bile duct. This duct generally unites with the pancreatic duct before they reach their common orifice in the duodenum, and, according to Wyss (*Virchow's Archiv*, xxxvi., 1866), the former duct frequently passes through the head of the pancreas itself. This was so in seven out of twenty-two cases examined. It is thus conceivable that any inflammation affecting the common bile duct can easily, at times, involve the pancreatic duct or the head of the gland itself by direct extension, causing probably an interstitial pancreatitis which is of a harmless nature in itself, and clears up when its exciting cause—namely, a calculus in the common bile duct—is removed. Occasionally, when a calculus is impacted at the duodenal end of the common duct, a more severe inflammatory process is set up in the head of the pancreas, which leads to the formation of a large tumor as hard as iron and situated in a critical position—namely, the junction of the common bile and pancreatic ducts. Originally set up by direct extension of the inflammation, this pancreatic enlargement in time takes on, to a certain degree, a character peculiar to itself. It may last for months or years before removal of its cause allows of its reabsorption, and unless the exciting cause be removed the pathological condition of the pancreas may of itself cause death. Its development is slow and the condition runs a protracted course. Micro-organisms probably have no part in its causation. As the inflammation involves the common orifice of the common bile and pancreatic ducts and obstructs the flow of the secretions from two very important glands, the new condition can be of more clinical importance than its exciting cause is. This marked pancreatic enlargement is rare, for Riedel met with it only three times in one hundred and twenty-two cases of gall-stone surgery. Its predisposing causes are not known, as calculi frequently occur in the common duct and even in the ostium duodenale without setting up any pancreatic inflammation, while a stone in the gall bladder seems to be sufficient to excite its development. In two of the three cases the patients had been the subjects of gall stones for several years, and in the third for at least one year and probably longer. The last patient died after operation, and a microscopical examination showed the tumor to consist of an interstitial pancreatitis without any evidences of malignancy. Riedel's notice was first attracted to the condition in a patient on whom he operated for gall stones. A single large stone was found in the gall bladder, while the cystic and common ducts were widely dilated, but contained no stones, and the head of the pancreas was felt to be enlarged to the size of a small apple by a tumor as

hard as iron and of a typically carcinomatous nature. The case was considered hopeless, but the patient improved rapidly after operation, and, from a cachectic condition, grew to be quite healthy looking and well nourished. Two and a quarter years after operation this patient is still quite well. The tumor in this case could not be felt either before or after the operation. In the second case the enlarged head of the pancreas was larger (the size of a fist), as hard as iron again, and calculi were extracted from the common bile duct and gall bladder. With the former case in mind, cancer of the pancreas was not diagnosed here. The patient improved after operation; the tumor, which before the operation could be easily felt, gradually vanished until it could no longer be palpated, and in a year and a half the patient had put on thirty pounds in weight and was still quite well. In both the above cases the enlargement of the head of the pancreas was almost certainly of an inflammatory nature. Confirmation of this supposition by pathological examination was fortunately impossible, but in the third and last case, the patient, who was very far gone when operated upon, died. At the operation no calculi could be felt in the biliary passages, which were, however, made out to be dilated, while a hard resistance in the situation of the head of the pancreas was considered to be an irregular enlargement of this organ, though it could hardly be called a tumor. Shortly after the operation the woman died. Post-mortem, the biliary passages were found to be widely dilated and their walls thin, while the gall bladder and the larger ducts contained many calculi of the size of pins' heads. The pancreatic duct was constricted near its orifice and dilated toward the body and tail of the gland. The pancreatic lobules felt firmer than normal, probably from fibrous development. Microscopic examination of the gland revealed interstitial pancreatitis. Malignant new growth could be definitely excluded. The last patient probably died from the effects of the pancreatitis, which had evidently been present for some time. Earlier operation would have given her a very good chance of recovery. The knowledge that a non-malignant pancreatitis occasionally occurs in the course of cholelithiasis is important as affecting the prognosis of cases in which this gland is felt to be enlarged either before or during operations on the biliary passages. There are no points by which the nature of this pancreatitis can be definitely recognized during life except a favorable progress of the case after operation and removal of its exciting cause. The conditions for which it may be mistaken, or *vice versa*, are carcinoma of the head of the pancreas and of the duodenum. In the latter condition, new growths in the papilla around the common duodenal orifice of the bile and pancreatic ducts, occasionally occur, and the palpating finger may mistake such for enlargements of the head of the pancreas.

New Views on Jaundice.—At a recent meeting of the Verein für innere Medizin, as reported in the *Münchener medicinische Wochenschrift*, February 25, 1896, Dr. Renvers, of Berlin, spoke on this subject. He claimed that the most recent investigations had shown that the doctrine of hæmatogenous jaundice could not be upheld. According to him, all varieties of icterus were hepatogenous. Catarrhal jaundice was not to be regarded as a merely mechanical damming-up of the bile behind an obstructive plug of mucus or as due to an inflammatory swelling of the bile ducts. It was decidedly toxic or infectious in character. There was, of course, a variety of jaundice caused by obstruction; but ordinary catarrhal jaundice was always due to toxic principles originating in the intestinal tract. Bacteria had repeatedly been found in the biliary pas-

sages in cases of this so-called catarrhal jaundice. Obstructive jaundice was due to gall stones or tumors, although hepatic abscess and cirrhosis of the liver could also cause it. In regard to jaundice caused by gall stones, Dr. Renvers maintained that it was generally inflammatory rather than obstructive. It was well known that in chronic jaundice complete closure of the bile ducts was rare. The biliary passages were usually sufficiently distended to permit the escape of some bile. It was for this reason that a correct diagnosis was often extremely difficult. Even previous attacks of hepatic colic were not always conclusive evidence of the presence of gall stones. The occurrence of rigors and fever were likewise misleading. The condition of the gall bladder was of far greater importance. In cases of stone the gall bladder was not always enlarged and very often it would be found positively smaller than normal. On the other hand, in most cases of malignant tumor the gall bladder would be found considerably enlarged. Acute inflammation of the gall bladder gave rise to grave symptoms closely resembling pyæmia. In these cases, too, the jaundice was due to infection, and the liver became secondarily involved.

Incontinence of Urine.—Dr. M. J. Stumpf (*Gazette des Hôpitaux*) employs the following method with favorable results. During sleep raise the pelvis of the child so as to form an angle of from one hundred and thirty to one hundred and forty degrees with the vertebral column. This position offers an obstruction to the passage of the urine into the urethra and the sphincter is not excited. Dr. Stumpf has cured twelve children and one adult in this way. After three weeks of treatment there need be no fear of recurrence and the child may be allowed to sleep in the normal position.

The Indications for Operation in Puerperal Sepsis.—According to views published by Dr. Lewis S. McMurtry in the *American Journal of Obstetrics*, pre-existing pus tubes, uterine fibroid, or ovarian dermoid converted by the trauma of labor into activity as an infecting source, should be treated by prompt resort to abdominal section. Septic endometritis, with or without putrefactive changes in retained clots and debris, should be removed by cleansing, antiseptics, and drainage. Thorough intra-uterine drainage and irrigation in appropriate cases arrest the septic process. Curettage in these cases, when the septic focus is limited to the uterine cavity, is too extensively used. The granular area of Bumm may be broken through, closed sinuses and veins at the placental site reopened—repeated chills and rising pulse and temperature marking the invasion of new areas of infection—and nature's barriers to increasing infection torn away by the indiscriminate use of the curette. Plugging up the uterine cavity is positively contraindicated; drainage should be facilitated and not obstructed in these cases. Purulent salpingitis, ovarian abscesses, and suppurative peritonitis, by progressive steps, may extend very rapidly, and the associated peritonitis may be circumscribed or diffuse; consequently careful and deliberate judgment must be exercised before resorting to cæliotomy. The time of the operation and the extent to which the operative procedure is to be carried also require sound judgment. Diffuse septic parenchymatous metritis and purulent metritis should be promptly treated by hysterectomy. Puerperal sepsis, wherein the local symptoms are those of diffuse peritonitis without localization of lesions, but wherein the uterus is presumably the focus of infection, is a grave condition and often justifies exploration and drainage, but hysterectomy will almost invariably prove disastrous.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 23, 1896.

THE LACK OF PROFESSIONAL BUSINESS.

IN these times of depression of professional business it is some comfort to be able, in a measure at least, to explain causes, even if it may appear to be impossible to effect cures. It is safe to assert that there is an ominous decline of patronage in every department of professional work. Very few if any of the hitherto successful practitioners are overworked. The falling off of receipts averages from a third to a half of those earned in previous years. Hard times explain this in a great measure, but not altogether.

The average number of sick is no less than formerly, but there is a growing disposition to avoid the so-called calamity of adding a doctor's bill to the other general and pressing expenses of household necessities. The man who formerly paid the physician a modest sum gets advice free in the dispensary, or pays a small bed fee in some of the many so-called hospital charities and has his medical and surgical advice thrown in free of extra charge. Many of the larger hospitals are run on the cheap boarding-house plan and openly compete with the family physician by reducing medical service to the lowest level of volunteer gratuity. This, however, is an old story, which hardly gives excuse for rehearsal save in connection with the fact that the practice upon which it is founded is steadily increasing to alarming proportions.

Medical charity is now a well-organized business with plenty of capital behind it, and is necessarily run on business principles. The hospital managers with patronizing smile tell the poor doctor that he is no business man; the doctor admits it, and with hat in hand begs for an opportunity to give his services free. He cooks the meal and grovels for the crumbs. There is no so-called trade protection in this much-lauded charity business that applies in any way to the medical man who is struggling to make an honest living. A dispensary with half a million behind it must necessarily imbue itself with a commercial spirit. There is very little sentiment in such a game. The bluff is higher education, the hollow echo a broader humanity.

By this and other means the public is educated to belittle professional services. The best newspapers lend their columns to the quacks and dare not fight with fraudulent advertisers. Clergymen sign certificates of false cures. Statesmen and would-be great men allow their likenesses in papers to prove that le-

gitimate medicine is nothing and that their lives were saved by the newest advertised nostrum.

It is melancholy to think that the physician himself is often to blame for the self-prescribing tendency of the public. The desire to please and satisfy the sick tempts prescribers to volunteer private clinical lectures to the family on the nature of the maladies in hand, the reasons for using certain drugs, their extended application to ordinary ailments, and their safety in proper hands. Even if the patient is not at first inclined to do so, he is often advised to repeat prescriptions at his own discretion, and too frequently drifts into a habit that is harder to cure and easier to endure than any other to which he may be exposed. Promiscuous prescribing on the part of laymen is an outbreak of hereditary taint from grandmothers, and needs only the slightest provocation to bring it into full recognition as the manifestation of an alarmingly prevalent evil. Worse than all, however, are the penny-a-line prescriptions contributed by medical men and paid for by the column, always to mislead and often to harm the ignoramus who takes them at their face value. Many apothecaries, when they have not curealls of their own, peddle the doctors' prescriptions and dodge the law by refusing to do more than sell a medicine. The patients themselves do the same thing with their friends, and one prescription may serve an entire community. The intelligent layman would scorn the imputation of ignorance of the fashionable drugs. He has his own remedy for grippe, headache, and rheumatism; his own cough mixture, his own mineral water, and his own tonic. His good doctor started him in the business and he naturally claims his rights as a free and independent citizen.

It would also appear that the laws governing the practice of medicine have been made to suppress rather than to encourage legitimate medicine. What else can be said in extenuation of the fact that the notorious advertising quacks are as safe from prosecution as are those who by dint of conscientious study have thoroughly qualified themselves to practise their profession in accordance with the highest and most exacting standards?

SUGAR AS A MUSCULAR FOOD.

SOME time ago Dr. Vaughan Harley published the results of some experiments which seemed to show that sugar had an almost specific value as a food for the muscles. These results were published in the *Journal of Physiology* for 1894, and the conclusions given were widely circulated. Dr. Harley, in a recent number of the *British Medical Journal*, returns to the subject. He states that physiologists have shown that sugar is the principal, if not the only, source of muscular activity. Other physiologists have shown that sugar is present in large amount in the blood during the activity of muscles, and that the blood returning from these muscles is free from sugar. Dr. Harley then states that, as the result of his long-continued experiments, he found that a person living upon sugar for twenty-four hours could do nearly as much work as upon an ordinary full diet. He also shows that

when nine ounces of sugar were taken in addition to an ordinary diet the gain in muscular power, or the power to do muscular work, ranged from ten to thirty-six per cent. He found that when sugar was added to a small diet there was an increase of from nine to twenty-one per cent. of muscular power. He considers that these experiments prove the value of sugar as a muscular food.

In the same issue of the *Journal*, Professor Mosso, of Genoa, has an article on "Sugar as a Food for Muscular Tissue," in which he asserts, as the result of his experiments, that sugar and other carbohydrates increase the capacity of muscle for work.

In support of the physiological and laboratory experiments, a considerable amount of clinical testimony is cited in favor of the sugar-food theory. Mr. C. A. Barber found that by adding several ounces of sugar daily to the diet of boys in school, they are made capable of doing more muscular work. This discovery will be of immense interest to the average schoolboy. The value of sugar as a food is illustrated in the effect of eating sugar by the West Indian and Southern negroes during the sugarcane season. Dr. Harley also quotes from the experience of Mr. Douglas Sladen, who says that "one of the most difficult forms of nourishment to go without, in the frosts of Canada as in the burning deserts of Australia, seems to be sugar." Another authority states that the lumbermen of Canada, than whom no finer or more muscular men exist, eat a great deal of sugar in the form of molasses. Mr. Glynn, making experiments upon the use of sugar as a food, found that while he was working in the open air he could take large amounts of it and it helped him to do the physical work. While doing sedentary work, however, he subsisted best upon proteids, sugar causing some digestive disturbance.

An entirely opposite view of the value of sugar as a muscular food is taken by Prof. D. T. Stokvis, of Amsterdam. Through the help of his pupil, Dr. Langemeyer, a long series of experiments with the ergograph was made. They found that sugar had no influence in increasing or perceptibly decreasing the muscular power, and they assert that Dr. Harley and Professor Mosso's results were vitiated by the element of personal equation. Professor Stokvis places on record a large number of tables in support of his views. He adds that "physiology teaches us that muscle is not only a most admirable living engine, in which chemical energy is transformed into mechanical work, but it is at the same time a great storehouse of chemical substances able to develop chemical energy." In his opinion it takes a long time to build up the muscular tissue, and the immediate ingestion of food does not particularly effect this. In healthy persons he thinks that fatigue and exhaustion are never caused by want of food, but solely and exclusively by want of rest, and although, he adds, it cannot be denied that the chemical energy produced by the combustion of sugar is one of the chief sources of muscular work, yet it is only one of them.

Professor Mosso and Dr. Harley both deny the validity of Professor Stokvis' reasoning, and so the mat-

ter at present stands, so far as sugar is concerned, undecided.

The people of the United States, we are told, consume fifty-two pounds of sugar *per capita* per year, or about one pound per week, and it is, therefore, a matter of considerable interest to know whether sugar is to a certain extent a specially good muscular food or whether it is only a useful element in the general dietary.

TREATMENT OF BRIGHT'S DISEASE IN FRANCE.

DR. LYONNAIS recently gave in *La Médecine Moderne* a *résumé* of treatment for parenchymatous nephritis, as it is usually carried out in France. At the outset, if the patient complains of severe pains in the kidney region, local revulsion is practised by means of mustard poultices, or, if the subject is strong, by the application of from five to ten wet cups. Blisters and applications of iodine are justly condemned as favoring congestion of the kidneys.

When the symptoms are slight we may anticipate a complete cure by instituting at once an exclusive milk diet, while we combat the anasarca, which is still slight, with purgatives, sudorifics, and diuretics. Drastic cathartics should be reserved to ward off symptoms of uræmia. Subcutaneous injections of pilocarpine are to be employed only in young and vigorous subjects. Vapor baths, hydrotherapy, dry rubbings can be employed with prudence, keeping in mind the susceptibility of subjects of Bright's to chilling of the surface and renal congestion. The best diuretic is milk, and this too is the best food. To avoid intolerance in protracted cases we may permit the addition of green vegetables, farinaceous foods, and fats, but we must forbid absolutely the use of dark meats, game, condiments, spices, alcohol, and beer. For those who have tired of milk, red wine may be prescribed, especially that containing a large proportion of tannin.

To remove the renal sclerosis one employs scarcely any other than the remedy so much used for sclerosis in general—iodine and the alkaline iodides, potassium, sodium, calcium.

Semmola has advised the iodide of sodium with another object. According to this observer it possesses the property of modifying the state of the albuminoid substances in the blood. Whatever there may be in this theory, it is certain the iodine and the iodides have a direct action upon the kidney in their elimination by this organ. Inhalations of oxygen may be reserved for special cases in which the patient's great depression makes the employment of this excellent means justifiable. The intestine furnishes a precious supplementary route for excretions which usually pass by way of the kidney, and permits us to guard against threatening accidents of uræmia for a long period. Purgatives are to be prescribed without hesitation each time a subject of Bright's complains of cephalalgia, heaviness in the head, shows intellectual hebetude, dyspnoea, etc., all of which are to be looked upon as precursors of uræmia. In an article upon the same subject by Dr. Paul Chéron in the *Gazette Médicale de*

Liège, some points are touched upon which may well supplement the *résumé* just given. Digitalis and its glucosides are thought to be fully indicated as diuretics in cardiac insufficiency. The dose should be small and continued for a short time only. Strophanthus acts more rapidly and is not irritating for the kidney. Pure water and mineral waters are excellent for washing out the tissues.

Theobromine produces a diuresis which continues for twenty-four hours. It is quite expensive.

Calomel may be given as a resolvent in chronic nephritis in daily dose of sixty to eighty centigrams for a period of three to five days, stopping as soon as diarrhœa occurs.

Lancereaux has obtained excellent results from cantharidin in dose of from six to twelve drops daily, while Sée and Dujardin-Beaumetz consider its use dangerous.

Hot baths at 40° C. should be continued for an hour and followed by means to keep up the perspiration for several hours. In advanced forms they should be avoided, according to Lecorché and Talamon, and are not free from danger, because of heart weakness and pulmonary congestion which they may occasion.

THE PRONUNCIATION OF "COCCI."

THERE is more trouble ahead for those who are trying to pronounce medical terms correctly. The *Cleveland Journal of Medicine* discusses, with mingled sadness and reproach, the prevailing mispronunciation of the word "micrococci" and similar terms ending in *cci*. That paper quotes the authority of the Century Dictionary, which gives *si* as the sole pronunciation of the last syllable. It also says that, according to general rule and analogy, the soft sound of the last *c* should be given. It begs its readers, therefore, if they are going to pronounce the word with the hard *c*, to be consistent and spell it with a *k*. There is no doubt that our contemporary is theoretically right, if he looks upon the word as English. As it was, however, originally Greek, and as the original letters were kappas, there is some reason also for using the hard sound. Reason or not, it has, so far as we can learn, become an almost universal practice to use the hard sound in pronouncing words with this termination, and Century Dictionary to the contrary notwithstanding, we venture to say that this form of pronunciation will prevail. The termination is not euphonious at the best, and the introduction of a sibilant into the final syllable makes it still harsher to the ear. Besides this, there is some lexicographical support for the hard pronunciation; at least, Foster's Dictionary gives the *si* as the first pronunciation and the hard sound as the second one.

Philadelphia Polyclinic.—Dr. Judson Daland has been elected professor of diseases of the chest, Dr. H. M. Christian, adjunct professor of genito-urinary surgery, and Dr. D. Riesman, adjunct professor of clinical medicine and therapeutics.

News of the Week.

Bellevue Hospital Medical College.—Dr. J. Lewis Smith, in consideration of his long connection with the college, extending over a period of more than twenty years, was appointed emeritus professor of diseases of children, Dr. George D. Stewart was appointed adjunct professor of anatomy, and Dr. William P. Northrup was appointed professor of pædiatrics.

Medical Legislation in Rhode Island.—The Senate of Rhode Island has granted an appropriation to the State board of health of \$1,000 for the suppression of tuberculosis. A bill is pending repealing the law requiring the vaccination of children before entering the public schools. We are glad to learn that the latter will in all probability fail to become a law.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the U. S. Navy for the week ending May 16, 1896. May 9th.—Medical Inspector R. A. Marmion detached from the *Newark*, ordered home, and placed on waiting orders. Surgeon L. B. Baldwin detached from the *Cincinnati* and ordered to the *Newark*. Surgeon N. H. Drake detached from the *Franklin* and ordered to the *Cincinnati*. Passed Assistant Surgeon I. W. Kite, detached from the Naval Hospital at New York and ordered to the *Franklin*. Passed Assistant Surgeon P. Leach detached from the Naval Hospital, New York. May 14th.—Medical Inspector R. A. Marmion ordered as member of the board of inspection and survey, June 3d, and member of the medical board, Navy Yard, Washington, D. C. Medical Director W. K. Van Reypen granted three months' leave of absence from June 3d, with permission to leave the United States.

Medical Laws for the District of Columbia.—A medical law has been enacted for the District of Columbia providing for government examinations by a board of medical supervisors of all candidates for medical license; also a law forbidding the disclosure of medical confidences, save those implying criminal actions.

Dr. Edward J. Forster, of Boston, died suddenly on the steamer *Puritan* in this city on May 15th. He had been in Philadelphia attending the meeting of the Association of Military Surgeons, and had just boarded the steamer on his way home. His death was due to apoplexy. Dr. Forster was born fifty years ago at Charlestown, and was graduated from the Harvard Medical School, afterward completing his studies abroad. He was the treasurer of the Massachusetts Medical Society, first vice-president of the Society of Military Surgeons, and for many years visiting physician of the Boston City Hospital. He was also a member of the Union and University clubs of Boston and of the 999th Artillery Club of Charlestown. He leaves a widow and three daughters.

The Cholera is increasing in Egypt and has crossed the Mediterranean to Marseilles, where several deaths have been reported daily during the past week. In Alexandria during the week there were two hundred

and sixteen cases and one hundred and sixty-one deaths, among those attacked being a number of the foreign residents. In Cairo also the spread of the disease has begun to excite alarm. Eleven new cases and nine deaths were reported there on May 16th.

The Camden County (N. J.) Medical Society held its annual meeting on May 12th and elected the following officers for the ensuing year: *President*, Dr. J. E. Hurff, of Blackwood; *Vice-President*, Dr. D. M. Stout, of Berlin; *Secretary*, Dr. B. S. Lewis; *Treasurer*, Dr. John J. Doron; *Historian*, Dr. H. H. Sherk; *Reporter*, Dr. D. E. Strock. Delegates were elected to the Medical Society of New Jersey, to the Gloucester County Medical Society, to the Berlin County Medical Society, and to the American Medical Association.

The Mountainside Hospital at Montclair, N. J., has received \$10,000 from the estate of the late John W. Pinkham, M.D., who at the time of his death was consulting physician to the institution.

Section Officers of the American Medical Association.—The following officers of sections were elected at the Atlanta meeting of the association:

OPHTHALMOLOGY.—Dr. George E. de Schweinitz, of Philadelphia, *chairman*, and Dr. Horace M. Starkey, of Chicago, *secretary*.

MATERIA MEDICA.—Dr. W. B. Hill, of Milwaukee, *chairman*, and Dr. F. Woodberry, of Philadelphia, *secretary*.

SURGERY.—Dr. R. H. Sayre, of New York, *chairman*, and Dr. B. Holmes, of Chicago, *secretary*.

OBSTETRICS.—Dr. M. B. Ward, of Topeka, *chairman*, and Dr. George H. Noble, of Atlanta, *secretary*.

LARYNGOLOGY AND OROLOGY.—Dr. W. E. Castleberry, of Chicago, *chairman*, and Dr. D. B. Kyle, of Philadelphia, *secretary*.

STATE MEDICINE.—Dr. Elmer Lee, of Chicago, *chairman*, and Dr. L. F. Bishop, of New York, *secretary*.

NEUROLOGY AND MEDICAL JURISPRUDENCE.—Dr. W. J. Herdman, of Ann Arbor, *chairman*, and Dr. Charles Hughes, of St. Louis, *secretary*.

DENTAL AND ORAL SURGERY.—Dr. R. R. Andrews, *chairman*, and Dr. Eugene S. Talbot, *secretary*.

Philadelphia Neurological Society.—At the meeting of the Philadelphia Neurological Society on April 27th, Dr. A. A. Eshner presented a case of astasia-abasia believed to be of hysterical origin. Dr. D. Riesman read a paper entitled "Chorea in the Adult, with the Report of a Case in a Man Aged Seventy-five Years," and presented the patient. Dr. Judson Daland made a preliminary report upon the post-mortem findings in two cases of electrocution. The most conspicuous features observed were considerable post-mortem elevation of temperature, general fluidity of the blood, and intense venous engorgement. Dr. F. X. Dercum showed a case of bilateral deafness following a fall upon the back of the head, without other noteworthy symptoms. Dr. C. W. Burr read the report of a case of hemiatrophy of the tongue. Dr. A. A. Eshner reported the case of a woman of twenty-three, free from hysterical manifestations, who pre-

sented from the age of seven irregular shock-like contractions, choreic in type, of the upper extremities.

The Second Pan-American Medical Congress will be held in Mexico, November 16-19, 1896. The president of the congress will be Dr. Carmona y Valle, the vice-president Dr. Lavista, and the secretary Dr. Licéaga.

An Unknown Fever of Assam.—A fever, called by the natives kala azar, has caused an excessive mortality among the foreign troops. The Indian government has recently appointed a medical officer to study the cause of the disease.

Succi, the Fasting Man, has recently been starving himself in Vienna, but much to his disgust he has been let alone by the doctors. He has had no medical watchers, no one has examined his urine or other excretions, his pulse has not been counted, and his temperature has not been taken. He was so put out by this unscientific neglect that he almost decided to begin eating again before the appointed term of fasting was reached.

The Michigan State Medical Society will hold its thirty-first annual meeting on June 4th and 5th. Among the visitors who are to read papers are Drs. Senn, of Chicago, and Jacobi, of New York.

Pocket Full of Spoons.—A physician recently appeared at a meeting of his medical association in this condition. He stated that he had accumulated them at the houses of his patients, and measured their capacity, which he found different in every case, ranging from two-thirds to three times the standard capacity. One teaspoon held exactly five times as much as another. He had brought them to serve as a warning to his colleagues in ordering their medicines.—*Journal of the American Medical Association.*

The Jacksonian Prize of the Royal College of Surgeons has been awarded to Dr. A. A. Kanthack for an essay upon tetanus. The subject for the prize for 1897 is announced as the pathology, diagnosis, and treatment of the various neoplasms met within the stomach, small intestine, cæcum, and colon.

Medical Superintendents in Insane Asylums.—At the recent meeting of the Florida Medical Association a resolution was passed urging upon all the members of the society to use their influence to have a competent medical man appointed as a superintendent of the State Insane Asylum.

Theosophy and Vivisection.—At the convention of the Theosophical Society of America, held during the past week, a resolution denouncing vivisection and hypnotism was introduced, but did not come to a vote.

The Woman's Medical Club, of Chicago, claims to be the first organization of the sort in the country. It has a membership of between twenty and thirty. We may before long have men's rights associations established for the purpose of agitating against the unjust exclusion of the male practitioner from medical societies.

Bellevue Dispensary has fallen in line with all well-regulated institutions of this character in having a trained nurse on duty there. Commissioner Faure, to whom so much is due in the remedying of old evils, has seen the need of a nurse to assist in the gynecological and surgical rooms, to prepare the gauzes, attend to the linen, and to see that the help do their work properly.

A Lecture on the Proper Pronunciation of Greek will be delivered by Dr. Achilles Rose in Hosack Hall of the New York Academy of Medicine, on Friday evening, June 5, 1896, at 8 o'clock. The meeting will be presided over by Dr. S. Stanhope Orris, professor of Greek at Princeton College, formerly director of the American School at Athens. Short addresses will be made by the Hon. D. N. Botassi, consul-general of Greece in New York, Professor Leotsakos, of Philadelphia, and C. E. Sprague, Esq., president of the Union Dime Savings Institution. Miss Marie Rose will sing the national hymn of Greece and recite in Greek. Greeks in national costume will sing and play their musical instruments.

Medico-Chirurgical Hospital of Philadelphia.—The cornerstone of the new amphitheatre of the Medico-Chirurgical College and Hospital of Philadelphia was laid on May 12th with Masonic ceremonies, in the presence of the governor and the mayor and other distinguished men. The new building will be seventy feet wide, ninety-five feet deep, and about fifty feet high to the main cornice, and will connect on the east with the hospital and on the west with the maternity department. The auditorium will accommodate six hundred students, and will be adequately provided with instrument and sterilizing rooms. There will be besides a waiting-room for patients, rooms for medical and surgical examinations, an etherizing-room, a private room for visitors, a room for the preparation of dressings, one for the storing of dressings, as well as private operating-rooms, accommodations for a registrar and records, and finally a room for skiagraphic purposes. The building will be, so far as possible, thoroughly fire-proof, and so constructed as to be readily rendered aseptic. Special consideration will be given to heating, lighting, and ventilation. At the fifteenth annual commencement of the Medico-Chirurgical College on May 13th the degree of doctor of medicine was conferred upon fifty-four regular and seven special students. The graduation address was delivered by Dr. L. Webster Fox.

Association of Military Surgeons of the United States.—The sixth annual convention of the Association of Military Surgeons of the United States was held at Philadelphia on May 12th, 13th, and 14th.

On the first day, after an opening prayer by the Rev. H. A. F. Hoyt, addresses of welcome were delivered by Governor Hastings on behalf of the State, by Maj.-Gen. George R. Snowden on behalf of the National Guard of Pennsylvania, by Mayor Warwick on behalf of the city, by Brig.-Gen. Thomas J. Stewart on behalf of the Medical Department, N.G.P., and by Dr. J. M. DaCosta on behalf of the

medical profession of the city. The president of the association, Col. Louis W. Read, M.D., made some remarks on the advantages of organization and reviewed recent advances in surgery. At the conclusion of the morning session the first flag of the association, constituted of a white ground bearing in the centre the red cross of the hospital corps upon which is an American shield and edged with green, was unfurled. Subsequently the members of the association were entertained at luncheon by Mr. W. B. Saunders.

In the afternoon, Col. C. H. Alden, M.D., read a paper on "Instruction of the Hospital Corps." Major D. A. Kuyk, of Virginia, read a paper on "The Hospital Corps of the National Guard." Capt. J. J. Irwin, M.D., of Ohio, read a paper entitled "The Annual Encampment and What it Teaches the Surgeon of the National Guard." In the evening a reception was tendered to the members at the Union League club house.

The second day's sessions were held in the auditorium of Houston Hall of the University of Pennsylvania. Col. N. Senn, M.D., of Illinois, described "A New Bullet Forceps," Dr. H. G. Beyer, U. S. N., read a paper entitled "The Physiology of Bathing and Swimming," and Lieut. H. L. Chase, M.D., of Massachusetts discussed the subject of "Baths, Bathing, and Swimming for Soldiers." After luncheon the members attended a clinic at the University Hospital, conducted by Dr. J. William White, who demonstrated the results obtained through the use of skiagraphy in surgery.

In the afternoon the following papers were read: "The Vitality of the Cholera Spirillum in its Relation to Certain Fruit Acids," by Dr. T. C. Craig, U. S. N.; "Notes by a Medical Officer in the East," by Dr. Charles C. Foster, of Massachusetts; "Notes and Comments on the French Field Sanitary Service, and What We May Learn from It," by Maj. Valery Havard, M.D., U. S. A.; "Some Thoughts on Wheeled Vehicles for the Transport of Wounded," by Maj. George W. Adair, M.D., U. S. A.; "Methods of Caring for Wounded in Field and Hospital of the Chinese and Japanese Armies," by Dr. C. U. Gravatt, U. S. N. Lieutenant Arnold, M.D., exhibited a litter constructed by Maj. W. F. de Niedman, M.D.

On the third day Maj. Paul R. Brown, M.D., U. S. A., read a paper on "Modern Methods of Anthropometric Identification so far as the United States Soldier is Concerned"; Capt. J. E. Pilcher, M.D., U. S. A., read a paper entitled "Methods of Instruction in First Aid"; and Capt. D. M. Appel, M.D., U. S. A., read a paper on "Asbestos Surgical Field Dressings." The following officers were elected for the ensuing year: *President*, Medical Director Albert L. Gihon, U. S. N.; *First Vice-President*, Brig.-Gen. E. J. Foster, of Massachusetts; *Second Vice-President*, Maj. John Van R. Hoff, U. S. A.; *Secretary*, Maj. Hermann Bergen, of Pennsylvania; *Treasurer*, Capt. James J. Erwin, of Ohio; *Editor*, Maj. Charles C. Foster, of Massachusetts; *Executive Committee*, Gen. John Cook, of New Hampshire, General Byers, of Wisconsin, Lieut.-Col. C. M. Woodward, of Michigan, Maj. P. F. Harvey, U. S. A., and Major Kuyk, of Virginia. It was decided to hold the next convention at Columbus, O.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Forty-Seventh Annual Meeting, Held at Atlanta, Ga., May 5, 6, 7, and 8, 1896—Concluded.

(Continued from page 715.)

SECTION ON PRACTICE OF MEDICINE.

WILLIAM E. QUINE, M.D., OF CHICAGO, CHAIRMAN.

Second Day—Wednesday, May 6th.

Some General Considerations in Relation to the Nature and Treatment of Disease.—DR. L. B. BAKER, of Pennsylvania, read the paper. That view of disease, he said, which regarded it as something extraneous, which could be cast out into a herd of swine, was the physiological equivalent of astrology and alchemy. It represented the disposition of all primitive people to personify sky, earth, and sea. It is not tenable that modern medicine should base its therapeutics upon such a view, and the paper entered a strong protest against the administration of medicines for the cure of disease to the almost total neglect of hygiene. Drugs have their use, but most assuredly they have been abused.

Nervous Shock and Disease of the Nervous System as a Cause of Pernicious Anæmia.—DR. JAMES B. HERRICK, of Chicago, read a paper with this title. The author's attention had been called to the possible causative relation of nervous shock to pernicious anæmia by a case which he related in detail. A healthy woman fell on the sidewalk, hurting her back and left side. She walked home, but from that time she found herself weaker physically and mentally, and was obliged to lie down most of the day. She felt dizzy, her legs began to swell, and she became pale. Her appetite was good. There was no evidence of organic lesion and no paralysis. The red globules were reduced to less than seven hundred thousand, and the leucocytes relatively increased. The liver was somewhat enlarged. After a year there had been gradual improvement, blood globules had increased to two and a half million, and hæmoglobin to eighty per cent. The further history was unknown.

The author recalled a case of cerebral hemorrhage with aphasia and left hemiplegia, in which there was most profound and fatal anæmia; also a fatal case of anæmia following sunstroke. A number of cases have been reported in literature, but the connection between the nervous shock and the anæmia, he said, have not been definitely studied.

Dr. Herrick felt warranted in drawing the conclusion that in some cases of pernicious anæmia there is a causal connection between shock or injury to the nervous system and the resulting anæmia. Whether such shock acts by interfering with the nervous mechanism of the digestive organs, the stomach, intestines, pancreas, the ultimate result being a severe anæmia, or whether through altered nervous influence there is abnormal performance of function on the part of the hæmatopoietic organs, it was impossible to say. It is not necessary to regard the nervous shock as the sole or even the prime cause.

How to Cure Rheumatism.—DR. ELMER LEE, of Chicago, said that it is upon the recognition of the physical alterations of the blood, consisting so far as known in diminution of the red globules and serum, that his treatment is based. Such changes seemed to throw the responsibility upon the capillary circulation rather than upon any change in blood chemistry. Coming to the treatment, he said it is hydiatic, requiring the use of water internally and externally.

None of the patients on coming to him had been taking sufficient water. Further, attention should be given to nutrition and elimination.

The Care of Cardiac Disease during the Quiescent Period.—DR. LOUIS FAUGÈRES BISHOP, of New York, read a paper with this title. One of the most honorable offices of the physician, he said, is the care of chronic disease. Modern accurate diagnosis and therapy have removed much of the dread of sudden death in heart disease. The care of chronic cardiac disease is the care of the myocardium and the protection of the endocardium from further acute inflammation. The danger of extension of chronic inflammation from the endocardium to the other structures of the heart is great. The value of suitable exercise in maintaining compensation is very great. Indolence is as fatal as overwork. Golf and quiet bicycle riding helps many indolent cases. When failure of compensation is threatened absolute rest is better than drugs. Hydrotherapy and massage are very useful in combating passive congestion. The patient, if intelligent, should be instructed as to the nature and requirements of his disease. The greatest evils to be avoided are indolence and dissipation on the one hand, and overwork and worry on the other. The proper care of such cases is far more satisfactory than the hopeless contest when the power of the myocardium has been exhausted.

The Action of Alcohol on the Organs of Special Sense.—DR. J. W. GROSVENOR, of New York, said in this paper that there is no difference of opinion among physiologists regarding the effects of large doses of alcohol. It is narcotic. All the senses are dulled—the pupils fail to respond to light, a sharp instrument does not cause pain, most volatile substances produce no influence on the olfactory nerve, and so with the other senses. The author quoted recent experiments by Ridge, Crouthers, and others, testing the effect of varying doses of alcohol on the special senses in total abstainers and those more or less given to the use of alcohol. The results showed diminished sense of pain, weight, hearing, etc., produced by small as well as large doses of alcohol, and in proportion to the dose administered, from half a drachm upward.

Dr. Grosvenor said that in his study of this subject the thoughts which have forced themselves upon his attention are as follows: 1. Guided by the chief characteristic of alcohol, its paralyzing influence, is it not more appropriate to call it a depressant than a stimulant? 2. If alcohol becomes popularly known as a depressant, will it not be less frequently used by the laity in those physical conditions which are commonly supposed to demand stimulation? 3. Knowing that alcohol is a depressant, even when given in small doses, ought not the medical profession to exercise great care in administering it in debilitated states of the system? 4. The use of alcoholics hypodermically in cases of heart failure or arrest of respiration caused either by ether or by chloroform narcosis is bad practice. 5. It is the duty of the profession to discard its use to the end that our national life may be characterized by physical and moral integrity, clear brains, steady hands, and brave hearts.

DRS. HARE, OCHTERLONY, and a number of members opposed the view that alcohol is never a stimulant, while some held that it is always depressant.

Lycopersicum Esculentum in Cardiopathia.—DR. W. T. ENGLISH, of Pennsylvania, in describing this plant, said it is indigenous to South America, but was introduced for its beauty into the United States and England. Then it came to be used as a food. The writer believes that the tomato has a more or less poisonous effect upon one-half to one-fourth of those who use it as food. It causes irregularity and inequality of heart rhythm and force, and

the effect upon those with previous heart disease has been deplorable. Among the unpleasant symptoms are gastric uneasiness, pyrosis, heartburn, acid eructations, sighing respiration, dyspnoea, etc. In pregnant women it produces particularly unpleasant circulatory symptoms. Many suffer from this form of poisoning unaware of the cause of their symptoms. The best remedy is avoidance of tomatoes. Antipyrin and alkalies and other remedies may be useful.

DR. PAUL PAQUIN, of St. Louis, and DR. HILL, of Milwaukee, expressed the opinion that the tomato is a healthy food, and that the symptoms described were due to fermentation in the stomach from use of tomatoes picked before ripe.

Officers Elected.—At this point the section elected Dr. J. H. Musser, of Philadelphia, *Chairman*, and Dr. J. T. Priestly, of Des Moines, *Secretary*, for the ensuing year.

Early Diagnosis of Cancer of the Stomach by Means of Chemical Analysis of the Gastric Contents.—DR. W. C. WEBER, of Cleveland, O., in this paper considered the diagnostic value of absence of hydrochloric acid from the stomach, of presence of lactic acid, and the different tests, the Congo red, tropæolin, etc. He expressed the belief that while advantage must be taken of other aids, such as examination of the blood, etc., yet chemical analysis of the stomach contents is becoming more and more valuable in early diagnosis, and is extremely important in order, if possible, to lead up to surgical interference before the appearance of cachexia and marked emaciation, which often precede physical signs of tumor and which are the precursors of a fatal termination.

DRS. HERRICK, of Chicago, PAQUIN, of St. Louis, and WAINWRIGHT, of Kansas City, corroborated the testimony of the author as to the need of aid from chemical analysis of the contents of the stomach in diagnosis of tumors requiring surgical interference before the case has become hopeless.

Third Day—Thursday, May 7th.

Intestinal Antisepsis, Diet, and Castration in Relation to the Treatment of Epilepsy.—DR. EVERETT FLOOD, of Massachusetts, was the author. The first epileptic attack in many instances is, he said, after excessive eating. Gluttony is common. From the outset of the child's life it should have suitable food, in proper amount, and at proper intervals. Regulation of diet has proven effective in stopping the attacks in many instances. Intestinal parasites are undoubtedly common in children, and should be removed. The author thought the controlling effect of certain drugs commonly administered in epilepsy may be due to their parasitic effect in the intestinal tract. Regarding castration, of which he had twenty-two cases to report, twenty of them in males, the results were favorable. First, and most important, the masturbation finally ceased in every case. The boy got plumper and had a clearer complexion. The voice became milder and pleasanter, and he was less inclined to violence and domineering. The possibility of reproduction was eliminated—a most useful safeguard. They did not entice other boys to masturbate. There were the same periods of fits, but each fit was shorter and milder in type. He thought castration is not so useful in females.

Report of Five Hundred Cases of Gastritis.—DR. FENTON B. TURCK, of Chicago, referred to his work published two years ago on the pathology and bacteriology of gastritis. He now protested against the appropriation abroad and in this country of the facts first published in that work without giving him credit.

Time permitted on the present occasion of reading only that part of his paper relating to some methods of diagnosing gastritis. Gastritis, or inflammation of the stomach, he said, can be determined by examination of the material adhering to the stomach wall. This is obtained by rotating a sponge at the end of a tube passed into the stomach and is composed of food detritus, of cells, of leucocytes, and of mucus. Such material furnished a most fertile soil for the development of micro-organisms. The presence of leucocytes indicates inflammation. Bacteria developing in large numbers, toxin is produced and is absorbed by the underlying cells of the stomach wall, giving rise to inflammation or chronic catarrh of the stomach. The author did not have time to read the analysis of his cases.

Chemistry and Bacteriology of the Stomach in Relation to Therapeutics.—DR. J. H. KELLOGG, of Michigan, gave methods and results of bacteriological and chemical studies of the contents of the stomach. It has been supposed that germs are always present in the stomach, and that they cannot be excluded, if indeed their presence was not an aid to digestion. A few observations were related in which the stomach contents gave no cultures whatever. The author has also made studies in relation to the number of bacteria ordinarily in the stomach having distinct characteristics. The number is large. One of the most poisonous gave a green appearance to bouillon, the shade of which was deeper on shaking. His studies also show that the stomach takes no small part in the conversion of starches. Regarding the saliva, he had found it to vary quantitatively and qualitatively, so that although the quantity in a given case may be deficient, this may be made up by quality, a small amount converting as much starch as a large amount in another case.

Constipation: Some of Its Effects and Its Non-Medicinal Treatment.—DR. E. S. PETTYJOHN, of Alma, Mich., gave a study of the history of three hundred cases, and showed that about sixty per cent. of all patients suffered from constipation, the number being proportionately larger among women. While the colon and rectum have not the digestive office long supposed, their absorptive power is greater, and the quantity absorbed is in proportion to the time of contact and concentration of the substance. The intestinal nervous system is complex. Since all functional action in the system is reciprocal, it follows that the functional activity of the chylipoietic system must affect the nutrition of the brain and entire nervous system. The absorption of toxic and excrementitious substances produced retrograde changes in the quality of the blood, diminution of the red corpuscles, and, by supplying an infected or imperfect nutriment to the brain, becomes a prominent factor in the production of cerebral anaemia and nervous debility. After further remarks on the effects of constipation, the treatment received attention. The first elements in the curative treatment, he said, are good food and good digestion. Coarser foods, such as would have a residue, were advised—whole wheat, hominy, figs, etc. Massage on anatomical principles, cannon ball, gymnastics, rowing, riding, faradic and galvanic currents, and hydro-therapeutics, including drinking large quantities of water, etc., should be insisted upon. "Those persons whose bowels are freed by an easy, regular movement every morning, so soon as they have breakfasted, are meek, affable, gracious, kind, and 'no' from their mouth comes with more grace than 'yes' from the mouth of one who is constipated."

Further Report on Serum-Therapy.—DR. PAUL PAQUIN, of St. Louis, in this paper first considered serum-therapy in tuberculosis. The serum of the ass was first used in Europe, but that of the horse prob-

ably in this country. The author felt confident that early tuberculosis can nearly always be arrested by either hygienic measures or serum-therapy, which tended to aid nature's own forces.

About sixty cases were reported in the paper, a number of them in the practice of physicians in different parts of the country. The results of this treatment, he said, are almost uniformly cessation of cough, fever, increase of weight, disappearance of tubercle bacilli from the sputum. Dr. Paquin usually begins with ten minims, and increased up to perhaps forty-five minims; at one time he injected as much as two hundred and forty minims. Some unfavorable symptoms were eruptions, and also fainting, pain in spine, etc., symptoms occasionally somewhat alarming. Dr. Paquin said he was surprised to find that in thirteen per cent. of his tuberculous patients there was some albumin in the urine before use of serum. In only one case did albumin appear after the treatment in which it had previously been absent.

Dr. Paquin, in answer to questions, said the horse undergoes a treatment similar to that in obtaining diphtheria antitoxin, tuberculin being injected into its system instead of toxin of diphtheria.

DR. A. M. HAIG, of Illinois, gave favorable experience with the horse serum in eight out of ten cases. Some of the cases had gone so far as to be regarded as hopeless, yet they were among those most improved.

Internal Secretion.—DR. J. B. MARVIN, of Kentucky, in this paper gave a general view of the relation of myxœdema to the thyroid gland, of the effect of removal of the spleen, etc. He thought it probable that exophthalmic goitre is an opposite condition from that of myxœdema, the latter being due to deficient thyroid secretion, the former to increased thyroid secretion.

SECTION ON SURGERY AND ANATOMY.

Second Day—May 6th.

Exploration and Treatment of Fissures from Skull Fractures.—DR. H. H. BEACH, of Boston, read a paper with this title. The modern treatment of fractures of the skull is in a word the impression that Lister and his teaching have made upon the surgical work of pre-antiseptic days. The results obtained before that time, through the application of principles based upon cleanliness as then understood, are not less astonishing than those of to-day, considering that the work was done in ignorance of bacteria and their appalling ravages. The confidence and boldness with which the surgeon may now undertake explorations involving the gravest consequences have really been the outcome of protection from septic disease afforded by the gradual development of aseptic principles.

With all these advantages, the mortality of skull fractures involving the base remains high. It has an association with such elevation of temperature as to point in the direction of septic infection as an explanation, and suggests a doubt of perfect asepsis in some cases. Without question a certain number is inevitable from severity of injury as well as from complications that are independent of sepsis. Crushing injuries of the head, with extensive laceration and destruction of tissue, together with abundant hemorrhage, will surely determine a proportion of more or less early and irremediably fatal results. Of the patients who survive the immediate effects of injury, a number are subject to a comparatively slight rise of temperature for a short time, associated with varying symptoms of concussion, and ultimately recover. The remainder improve for an uncertain period, then develop a temperature that gradually rises as the patient sinks to his

death. It is possible that, of this last group, some die from chronic inflammation of brain tissues following their contusion or laceration, and the interference with their nutrition through the pressure effects of masses of clot added to the degenerative changes characteristic of those processes. Progressively high temperatures common to fatal cases, however (though every care prescribed by aseptic rules be followed), and their similarity in other respects to those treated without asepsis, make it doubtful, to say the least, if sepsis has been completely eliminated from them. The reduction of this mortality is a problem that now confronts the surgeon, and, as an entering wedge toward its solution, the importance of a series of observations that will establish beyond doubt the relation of sepsis to the fatal cases cannot be overestimated. Much may be accomplished by the systematic and accurate observation of all cases of fractured skull in which there is an open surface requiring dressing or in which any discharge exists, by making bacteriological cultures at intervals during life and at the autopsy. Briefly, freedom from sepsis should be definitely and unmistakably proved in any fatal case by the unassailable evidence supplied by bacteriological tests, to clear it from the suspicion of putrefactive infection.

In searching for the source of infection, one is impressed with the invariable freedom with which the immediate seat of injury is now inspected, cleaned, and dressed, relieving in a measure the region of direct violence from the suspicion of contamination. Of the more remote sources, the common association of bloody and serous discharges from the ear and nasal passages suggests possibilities of bacterial infection through the extension of a fracture by fissuring to the internal ear; which, in addition, may supply abundant material through the retained products of chronic disease. By laceration of the membrana tympani, direct connection is made with the outer air on one side, and on the other communication is opened through the Eustachian tube with the cavity of the naso-pharynx, which Paul Raugé terms "the storehouse from which the infective elements passing through the tube into the tympanum are derived." Fissures communicating directly with the nasal cavity are of necessity open to the same infective influences.

A large percentage of those who die from skull fractures have these bloody or serous discharges; also those who survive for more than five or six days and then die. On the other hand, a good proportion of those who recover have the same history; from which it is proper to infer that such discharges are not in themselves necessarily fatal nor the bony fissures associated with them.

Another explanation for fatal cases must be found either in the character of the injury to the brain and its vessels, or that of the fissures through which they escape. A fissure extending through loosely fractured bone would be more likely to supply an avenue for infective material to reach the skull cavity than one that could be barely detected and closely resembled a crack in glass or porcelain. The variations between these extremes are common to all fractures, and may explain a part at least of the differences of results in cases presenting similar symptoms. Should fissuring extend in the direction of the internal ear, the difficulty of making that region aseptic and free from the possibility of dangerously contaminating an opening communicating with the brain is a serious one; especially so in old cases of otorrhœa.

The cavity of the skull is not second to that of the peritoneum in the importance of maintaining perfect aseptic defences. The septic area, after careful disinfection, should be approached from the wound at the vertex by widening connecting fissures with the rongeur to half an inch, until the base can easily be

reached and packed with gauze above and below the fissure extending along the base. The brain can be lifted with a retractor and the auricle dissected up and displaced forward should it become necessary. This packing of gauze limits hemorrhage without undue pressure upon the brain, and provides an excellent drainage apparatus from the vertex to the base of the skull.

As possibilities of infection cannot be estimated before the development of unfavorable symptoms, when too late to institute antiseptic measures, however radical, conservative treatment should include at the first inspection of the wound a most rigid asepsis, the exploration of fissures with the utmost precision, uncovering the whole circumference of the perforation in the skull for that purpose, and providing unlimited drainage by widening the fissures into loosely connected bone that extend in the direction of the base. When nearly fifty per cent. of brain abscesses originate in suppurative ear diseases, the isolation of this region from the brain and its attachments during the repairs of a fractured skull demands the serious consideration of the surgeon. It also suggests the question of a more radical clearing and asepsis of the ear cavities than can be obtained without anæsthesia in cases in which the temperature steadily rises, notwithstanding our precautions. The danger associated with such a plan lies in the possibility of forcing, by washing under pressure, septic material through a wide fissure into the skull cavity, and emphasizes the importance of a competent primary asepsis of the ears in all fractures connected with them.

Reports of cases were given illustrating the practice advocated.

DR. W. L. ESTES, in discussing Dr. Beach's paper, said that the questions involved in this paper, which set forth very clearly the necessity of disinfection, the production of a septic state, and the employment of proper drainage, are important ones and should not pass unnoticed. Too frequently these fractures and the necessity for their proper disinfection are overlooked by the busy practitioner, and in a number of cases which had come under his notice he had found that there had been absolutely no attempt at disinfection of the nasal passages or of the external auditory meatus, although all the symptoms pointed to a fracture involving the base. The speaker's custom is to douche or spray thoroughly the nasal cavities, and when necessary to plug them anteriorly and posteriorly with some disinfectant gauze, after which he usually plugs the external auditory canal. With regard to the drainage of these conditions he said that it is often a very serious matter, although, if the disease involves only the area posterior to the auditory canal, it may not be so difficult. The securing of proper drainage when the area anterior to this canal is involved is the most difficult matter, but this should not be neglected. Hemorrhage is another dangerous factor, and it should receive prompt attention. The meningeal vessels are those especially likely to be involved, while the sinuses need not necessarily be injured.

Brain Surgery.—DR. J. C. OLIVER, of Cincinnati, presented a report of four cases representing injuries and operations upon the brain.

CASE I. was that of a man, aged fifty-nine, who fell through a dust chute, striking upon his head. He presented ptosis on the left side, hemorrhage from the left nostril, and motor aphasia; the pupils were midway between contraction and dilatation and did not react to light. There was no paralysis of the limbs nor of the face. The autopsy showed that the symptoms were each dependent upon separate lesions. There was found rupture of the middle meningeal artery on the left side, a fracture of the left orbital

plate, and also a distinct, separate fracture of the cribriform plate on the left side.

CASE II.—The patient presented Jacksonian epilepsy, the convulsion always beginning in the left leg, then involving the left arm and the left side of the face, and then becoming general. Following the convulsion the patient would have left-sided paresis, which would remain for only a few hours. After the attack he would become maniacal, in which condition he was dangerous to those about him. The convulsions occurred in groups, so that he would have ten or fifteen in a day. Because of the symptoms, trephining was done over the leg centre on the right side of the brain. A varicose vein in the diploe was found to have ulcerated through the internal and external plates of the skull, and had also caused absorption of the dura mater at one point. At this point there was a small hernia or protrusion of the pia and brain. No other lesion was discovered. The course of the vein was bitten out with rongeur forceps and the channel in the diploe plugged with a sterilized match. Following the operation the patient was free from epilepsy for six months. After this he began to experience pain in his left leg, and there was a gradual return of the convulsions. As it was believed that the return of the convulsions was dependent upon the adhesions which had formed, the patient was again operated upon, nine months after the first operation, and a plate of gold foil inserted in the deficiency in the skull. A few months subsequently the patient died suddenly in the night from causes unknown. Subsequent to the operation he experienced no convulsions. An examination of the head after death showed no gross lesion of the brain. The gold plate had very effectually accomplished the purpose for which it was inserted.

CASE III.—The patient in this case had an inflammatory condition in the left upper eyelid which went on to suppuration. This was opened and the patient returned to his occupation, that of a machinist. After being at work for about three weeks he began suffering with pain in the head, which was most marked over the left frontal region. He became stupid. On testing the vision it was found to be $\frac{2}{70}$ in each eye. A choked disc was present in the left fundus. A paresis involving the right side was found to exist. The deep reflexes were normal. Temperature was slightly subnormal, the pulse was irregular and hard. The diagnosis of cerebral abscess of the left frontal lobe was made, and a trephining over this area and exploration of the brain in this region led to the evacuation of an abscess containing three ounces of pus. The patient recovered and is now in his usual condition of mind and body.

CASE IV.—In July, 1895, the patient was treated for an acute otitis media. This condition persisted in spite of treatment. On the 13th of October the patient was found comatose, with pulse of about 90. The pupils contracted, slightly reacting to light, and the Cheyne-Stokes respiration was apparent. This condition continued until the following morning, when he was removed to the Cincinnati Hospital. That evening his temperature was 103° F.; he was delirious and the pulse was rapid; he had divergent strabismus, and there was no evident facial paralysis; pulse, 132; respiration, 26. He became very restless and had to be restrained. The reflexes were present and active; slight trismus was noticed. In view of the fact that these symptoms followed the ear trouble and also in view of the very evident meningitis, it was deemed advisable to trephine over the temporo-sphenoidal lobe for possible abscess. This was done with a negative result. The left lobe of the cerebellum was then opened with likewise a negative result. The patient died within an hour after the operation. Post-

mortem showed diffuse purulent meningitis involving both the base and the convexity. There was no localized accumulation of pus. The infection in this case followed along the carotid canal.

DR. RANSOHOFF, of Cincinnati, said that it having been stated that there was considerable hemorrhage in the case just reported, he would like to mention a method which he had employed to overcome this. We all know that under the older methods much blood was lost, and that very frequently in an operation for the removal of a brain tumor the dura and the cerebral veins were divided, causing such a loss of blood that the operation could not be completed in one sitting. The Esmarch strap has been used considerably, but all know the difficulty of properly applying it, its entire object often being lost through the sinking of the scalp into the orbit. The method which the speaker employs is a very simple one, but he has never seen a description of it. He introduces about an inch from the surface of the tumor a continuous chain suture, which he draws tight around the entire line of the incision. He recently practised this method in a case of sarcoma of the dura mater, in which the tumor was as large as a small orange, and which had been operated on twice before on the supposition that it was a wen. When this suture is drawn tight, which can be done very rapidly, the entire area of the skull is made absolutely bloodless and the incision was made within the line of the chain. One has but to remember the size of incision that is necessary for trephining and the difficulty of grasping the vessels in the tense scalp to appreciate how much blood will be saved the patient by using this suture. The sutures can be clipped and removed at the end of twenty-four hours in order to remove the gauze packing, and the vitality of the flap will be in no way interfered with.

Cholelithiasis and Cholelithotomy.—DR. CHARLES H. DUNN, of Minneapolis, read a paper based upon a study of forty cases of gall stone and a review of the chief literature of the subject. He had been impressed, he said, with the highly overdrawn notion of biliary colic and the misinterpreted view of the symptomatology of cholelithiasis prevalent in the general professional mind, with the mistaken prominence given to jaundice as a symptom, and with the tenacity with which a childlike pathology explaining its presence or absence on the purely mechanical action of the stone is held. Jaundice is a comparatively infrequent symptom, at least in the earlier course of the average cholelithiasis, and cases not rarely run their whole course without icterus. The author reported a case of a young and otherwise healthy woman who died as a result of six weeks' attack of biliary colic with nearly constant pain, tenderness, and vomiting. She had had but one previous attack, of short duration, nearly a year before. A trace of bile was present in the urine, but at no time had there been a trace of icterus observable by the friends, trained nurses, or physicians. At the autopsy five gall stones were found, three in the gall bladder and two in the common duct. The presence or absence of icterus must not have too strong an influence on one in locating the stone. The indications for cholelithiasis should be divided into relative and imperative. If the attacks be frequent, the calculi not passed, and the symptoms not relieved by a reasonable hygienic and medical course of a few weeks' duration, so safe an operation as cholecystotomy at this stage is doubly preferable to further delay, even though no very threatening symptoms have developed; first, as the cheapest escape from present suffering, and second, as a preventive measure against the ever-possible dangers of cholangioitis, duct impactions, etc., which may entail a much more dangerous and trying operation upon a patient. In time the

proper treatment of cholelithiasis, with few exceptions, will be considered to be early surgical interference, although, so long as the patient is in no apparent danger, a rational non-surgical management through one or several attacks, as good judgment may dictate, cannot be condemned, and is to be heartily advised unless circumstances offer very perfect surgical advantages. When, however, after several days' duration only a partial peace is declared, the general health begins to fail, local tenderness, lesser paroxysms recur, jaundice and infection threaten, one is confronted with a far more serious situation and the indications for interference may be termed imperative. The practical distinction between relative and imperative indications in surgery is of the greatest importance and too often overlooked, and it seems a very pertinent question whether or not operation should be advised in the midst of a recent attack of colic, etc. Kehr, having, as he believes, learned to distinguish between gall-bladder colic and gall-duct colic, advises waiting when the latter exists, lest the stone be left in the choledochus or a difficult choledochotomy need to be performed. Many will be quite unable to make this differentiation with any certainty, while to delay long with a calculus in this most dangerous locality will often jeopardize the patient. The diagnosis once positively made, it would appear less difficult for a surgeon to approximate reasonably the burdens and the dangers of the disease in a given case, and to distinguish between when to advise waiting, when to recommend operation, and when to insist upon it, than to formulate rules for others. One prominent authority seems to regard the size of the stone as having an important bearing upon operative indications, but, in the first place, we can foretell absolutely nothing as to the size of the stones before they are removed or passed, and in the second place, however much the theory that a small stone ought to be passed and a large stone cannot be passed may appeal to rational simplicity, the case above mentioned of the young woman proves that the facts fail to follow mathematical fancy. All modern observations go to show that nine times out of ten the gall stones occupy the gall bladder alone, and ninety-five times out of a hundred they occupy the gall bladder alone or it and the cystic duct alone. In the vast majority of cases, therefore, the indication appears to be to open the gall bladder, remove the stones and debris, and temporarily drain the diseased organ. In the author's opinion, cholecystotomy, with temporary fistula, is the operation of election in the average cholelithiasis, and the one to be chosen probably eight or nine times out of ten. Various conditions in connection with the remaining minority will demand a modification in the operation. In certain cases choledochotomy is the choice operation, but it is always difficult, frequently dangerous, and sometimes impossible of practical execution.

DR. DONALD MACLEAN, of Detroit, in discussing Dr. Dunn's paper, said that the surgery of the gall bladder is only in its infancy, but there is always the hopeful and inspiring feeling about operations on the gall bladder that if the patient be saved from great pain and great danger there is everything to be gratified about and nothing to regret.

DR. ALEXANDER HUGH FERGUSON, of Chicago, said that the great question is, When shall we operate? If we examine the gall bladder and find it enlarged so that there is apparently a tumor, it is the time to operate. If the stone be a small one, it may pass through, but if not, it may force its way into the common duct, where it becomes impacted. Cases of one stone are more difficult than those of several stones, and the side of the gall bladder is no indication. If the patient has colic and jaundice, it is imperative to open the gall bladder and not to wait until the development

of pyrexia. By suturing together the gall bladder, peritoneum, and skin, thirty-three per cent. of the cases have resulted in permanent fistulae. In view of the fact that jaundice cases stand operation and chloroform very badly, we should operate as little as possible. As soon as we see bile, our work is finished. There are two ways of getting at the common duct, one internal and the other external to the duodenum, of which the former is the better. If there be jaundice, the incision should be either oblique or transverse; the oblique gives the more room. In order to tell whether or not the common duct is patulous, a good way is to take a glass tube that is bulbous at one end with a rubber bulb attached to the other. This will become impinged into the duct. If water will then flow through the bulb it is well to stop operating.

DR. J. C. OLIVER, of Cincinnati, asked what was found to be the cause of death in the case of the young woman to whom Dr. Dunn had referred as having had two attacks of biliary colic without jaundice.

DR. HUNTER MCGUIRE, of Richmond, said he believed that some day a method will be found of dissolving gall stones, so that operation will not be necessary.

DR. DUNN said that the young lady referred to by Dr. Oliver died of exhaustion. He was of the opinion that too many men have the idea that in these cases there should be jaundice, or tumors or colic resembling the pains of childbirth. What is wanted is more diagnosis and less technique. In none of his cases had he found tumefaction, unless by this is meant enlargement of the liver dulness which is frequently present.

Operative Interference in Abdominal Ailments.

—DR. DONALD MACLEAN, of Detroit, reported several cases bearing on this question. In opening his paper he stated that he desired to raise the question of the advisability of interference or non-interference in cases of abdominal ailments, traumatic or otherwise. The first case mentioned was that of a very obese woman of fifty, who had suffered from absolute obstruction of the bowels for ten days and was in a very advanced state of exhaustion. Upon opening the abdomen, after a somewhat prolonged and careful examination, a large egg-shaped calculus was found, and the intestine both above and below was so constricted that it constituted a perfect obstruction. Although the abdominal cavity was closed with all possible speed, the patient died in twelve hours. The second case was that of a man who gave the history of several well-marked attacks of appendicitis, but who was apparently quite well and engaged in active manual labor when he came for advice, complaining only of a feeling of weakness in the right iliac region. Operation was advised, and the appendix was found distended with pus. On further investigation extensive intestinal adhesions were encountered, and it was found necessary to sew up several large rents in the intestinal walls produced by disentangling these adhesions. Patient made a complete and rapid recovery. The third case was that of a young man of nineteen, who had had repeated attacks of appendicitis. He was a healthy and robust fellow, and on this account postponement of operative interference was advised, but the speaker was compelled the following day to change his opinion absolutely, as the patient was found in a very different condition, with tongue furred, pulse 120, and temperature 101° F. Operation was then advised, and the appendix was found deeply embedded in an immense inflammatory mass which surrounded the caecum. The fourth case was that of a man who was taken suddenly and violently ill with all the signs of appendicitis, and when first seen by Dr. Maclean the patient was in a state of great distress from constant cough, with exces-

sive expectoration of an indescribably fetid character. The temperature was high, pulse rapid, and there was a total loss of appetite with proportionate general weakness. The burrowing of an appendicitic abscess behind the peritoneum was suspected, and an incision was made between the sixth and seventh ribs on the right side, which fortunately tapped the depot of fetid pus. Three years have elapsed since the operation, but when seen recently the patient presented the very picture of manly health and vigor. The fifth case was that of a man, thirty-five years of age, who was thrown from his bicycle and alighted on the asphalt pavement with very great force on his buttocks, between five and six o'clock in the afternoon. He noticed no bad effects from his fall until late the same evening, when he was taken so ill that he was compelled to enter a drug store and telephone for a physician. An anodyne was administered, but during the next day and evening such alarming symptoms developed that the author was called to see him, and, finding him very tympanitic, with pinched and pale face, pulse 120 and temperature 102° F., a laparotomy was advised and performed at 10 P.M. Upon opening the abdomen the following condition was found: An ancient ulcer of the stomach had induced a firm adhesion between the pyloric end of the stomach and the duodenal mesentery. The jar of the fall had had the effect of separating this adhesion and thereby caused a rupture of the stomach at the point of the ancient ulcer and consequent adhesion. This rupture was carefully stitched and all foreign matters which had escaped from the stomach into the peritoneal cavity were washed out with gallons of sterilized hot water, after which the abdominal incision was closed. The whole procedure was conducted with the utmost possible expedition, and, during its performance, every means of stimulation were resorted to, hypodermically and otherwise, but in spite of all efforts the patient died twenty hours after the operation. In addition to the morbid condition of the stomach already described, the left kidney was found situated just below the promontory of the sacrum, and was very small and very imperfectly developed. It is reasonable to suppose that this abnormality may have had some part in the fatal issue, but, at any rate, it is a fact that complete suppression of urine existed from the time of the accident to the end of the patient's life.

DR. THOMAS H. MANLEY, of New York, stated that he recently had a case very similar to that mentioned by Dr. Maclean. He took exception to the practice so prevalent of recommending early exploratory incision in every instance, as in some cases but little will be gained by it. He mentioned the case of a young man who had been kicked by a horse, and who when seen by his family physician was in a state of profound shock, perfectly rational, but cold. Reaction was brought about in twenty-four hours, during which time not a drop of urine was passed. Thorough examination caused the speaker to diagnose peritoneal hemorrhage, although one would suppose it would have been a renal hemorrhage. On the fourth day bad symptoms set in, the most serious of which was fecal vomiting. Operation was recommended, and not being able to find any kidney, he commenced to search for the horseshoe kidney, which he found lying over the caecum. About five feet from the duodenum two large gangrenous patches were found, one of which had just perforated. The patient sank and died. Dr. Manley asked what good a laparotomy would have done had it been performed immediately after the accident.

In response to an inquiry, DR. MACLEAN said he did not think the patient died from hemorrhage. The gall stone was removed from the jejunum.

DR. WHEATON, of St. Paul, said that about four months ago he removed a stone weighing three hun-

dred grains, and the patient died of hemorrhage on the third day.

DR. J. T. THOMAS, of Pennsylvania, said he wished to bring up the question of enteroliths and to ascertain from those present what was their usual result in these cases. A few years ago Dr. Thomas operated on a patient suffering from an obstruction resulting in fecal vomiting. Upon opening the abdomen, an enterolith was found which entirely occluded the lumen of the intestine. The patient died in about two hours, and, in the opinion of the speaker, these cases are more often fatal than is generally supposed.

DR. WINSLOW, of Baltimore, said he wished to add to the list a fatal case of a similar nature. The case was that of a lady who had presented symptoms of obstruction of the bowels for three days. There was no great pain, but vomiting and persistent constipation were present. The symptoms were those of intestinal obstruction and an operation was decided upon. On opening the abdomen, complete intestinal obstruction was revealed, which was caused by a mass which proved to be a gall stone. The patient died shortly after the operation. Another case was mentioned of a man who had been injured by the pressure of a car, but who presented no other symptoms than considerable pain in the abdomen and some vomiting. An operation was performed and a genuine hernia in a sac, which was entirely within the peritoneal cavity, was discovered. This patient also died. The interesting feature about cases of this character is the entirely different conditions that are found to exist from those suspected previous to operation.

DR. PHILIP MARVEL, of Atlantic City, mentioned the case of a lady who had suddenly fallen in a store, and who for some hours thereafter experienced hysterical convulsions at half-hourly intervals. Total suppression of urine existed, and the autopsy showed but one kidney, which was in the normal position on the right side and was not diseased.

DR. McRAE, of Atlanta, said he wished to give the particulars of a case that was of extreme rarity and of important medico-legal interest. The man had received a stab wound between the sixth and seventh ribs six months prior to the time he was first seen by Dr. McRae, at which time he was suffering from intestinal obstruction, which had been diagnosed as cramp colic and for which morphine had been administered. In consultation it was decided that the patient had a hernia of the diaphragm and an operation was agreed upon for the next morning. Upon entering the abdomen, an opening was found in the diaphragm with a band of adhesive tissue extending up to the exact point where the stab wound was. It was evident that the man would die, and the opening in the diaphragm was enlarged until the hand could be inserted into the left thoracic cavity. A small portion of intestine was found in the pleural cavity and the adhesions were very dense. The lung was compressed and the condition of the bowel was one of beginning gangrene. The patient came out of the anesthesia and died shortly afterward. One of the most interesting points about the case was that the man who did the stabbing was declared not guilty.

DR. MACLEAN closed the discussion by saying that the result of his paper and the discussions seemed to be that a surgeon should have the courage of his conviction and advocate an early exploratory incision. Although some patients get well without operation, ninety-nine in every hundred do not.

Some Mechanical Causes of Interference with the Action of the Stomach and Their Surgical Relief.—DR. W. J. MAYO, of Rochester, Minn., presented a communication with this title.

The author divided his subject into two classes: first, those which act from within the cavity of the

stomach or its immediate connections, such as a tumor, cicatrix, or a foreign body which may obstruct its inlet or outlet or prevent its normal muscular action; and second, those which act from without the stomach and interfere either by pressure or adhesion, obstructing its inlet or outlet or fixing some portion of its wall, thus preventing its functions. The history of the case, the physical examination, the distention with air, and the test meal constitute the main diagnostic resources. The diminution or absence of free hydrochloric acid, when taken into consideration with the physical examination and the history, is of some service. The treatment of forms of obstruction due to stenosis as a result of scar tissue is exceedingly trying, but some of the less resistant cases, when seen early, can be dilated by means of bougies used through the mouth. If it is impossible to pass a bougie, retrograde dilatation by means of gastrostomy is a rational procedure, and the olive-tipped whalebone bougies are of most value. Gastrostomy for the purpose of retrograde dilatation is perhaps best done by Fenger's oblique left lateral incision through the abdominal walls, which brings this opening more directly in line with the cardiac orifice. Gastrostomy for the removal of foreign bodies is an operation of great efficiency, while gastrostomy for the purpose of feeding is subject to great annoyance in the way of leakage. For temporary purposes the Witzel method is of the greatest benefit, as immediately after removing the tube the fistulous tract closes, while for permanent feeding Frank's spout method is undoubtedly the best. Obstructions at the outlet of the stomach are exceedingly common, and many cases, especially those of pyloric stenosis secondary to ulcer, are too often pronounced malignant without proper examination. For the relief of non-malignant stricture at the pylorus the Hoenke-Mikulicz pyloro-plastic operation is the one of choice and is wonderfully well adapted to the average case. The author briefly cited a case in which this operation had been done and in which the recovery was prompt and the gain in weight remarkable. For inoperable obstruction, such as advanced malignant disease, gastro-enterostomy is the operation of choice. As a result of three of these operations, in which the Murphy button was used by the author, there were two successes and one death. Of the two patients who recovered, one has gained forty pounds up to the present time, which is one and a half years after the operation. The frightful mortality of pylorectomy in malignant disease without reported permanent cures is not encouraging, and the reason for this great mortality lies in the debilitated and starved condition of the patient at the time the operation is resorted to.

Among the external causes of interference with the stomach, adhesions of the pylorus or duodenum to the gall bladder due to the inflammation excited by gall stones is not infrequent. The most common cause of external interference with the action of the stomach is adherent omentum. Irreducible omental herniæ of any variety are almost always accompanied by gastric distress which disappears after the radical cure of the hernia. The author mentioned a case of a man fifty-four years of age who had suffered for seventeen years from gastric pain and chronic indigestion, and in whom upon dilatation of the stomach an old irreducible omental hernia was found. Radical operation on the hernia with liberation of the omentum promptly relieved the symptoms.

—

Third Day—Thursday, May 7th.

Surgery of the Stomach.—DR. ALEX. HUGH FERGUSON, of Chicago, in discussing Dr. Mayo's paper read at the previous session, said that he approved of Dr. Mayo's methods of treating non-malignant and malig-

nant stricture of the œsophageal end of the stomach and also the palliative treatment that he recommends for malignant disease of this region, discarding curettage and adopting Frank's operation as superior to Witzel's and Fenger's, since this operation, although only palliative, will give the patient considerable trouble. He also agreed with him in advising forcible dilatation in diseases of the pyloric end of the stomach, which can be done in several ways. There are two classes of cases in which gastro-enterostomy can be done: first, those in which the patients are weakened and cannot withstand pyloroplasty, and secondly, those in which it is expected to cure palliatively. In addition to this, dilatation may also be done as a preliminary step to the complete removal of the pylorus. He believes in encouraging pylorotomy, although he fully realizes the gravity of the operation and is aware of its mortality. The medical treatment of cancer of the pylorus has a mortality of one hundred per cent., while within certain limits pylorotomy permits of a cure. In fifty per cent. of the cases in which it was performed recovery followed, and one patient, who went on for three years, is now working on a farm. In nineteen per cent. of over nine hundred cases recorded cancer did not reach the peritoneum.

DR. DONALD MACLEAN, of Detroit, said that he agreed with Dr. Mayo, but was not able to speak very positively on the subject, not having had much to do with surgery of the stomach.

Exploration of the Brain with a Needle and Syringe through Capillary Holes Drilled through the Skull.—DR. EDWARD SOUCHON, of New Orleans, read a paper with this title. The method, he said, is designed to take the place of trephining, *i.e.*, removing a ring of bone before exploring the subdural spaces and the brain. The simplicity of the procedure and its safety recommend it as an easy means within the reach of a greater number than the other comparatively more serious and complicated operation of the trepan. By its ready employment it is expected that many lesions, especially abscesses, cysts, and hard tumors, can be earlier diagnosed and located with certainty after exploring by this means the region suspected from the distant symptoms. It is only in cases of tumors of the same consistency as the brain, that is, soft but not fluid, that the explorations would be of no avail, but this would also be the case if the trepan had been used instead of the drill. Even then, in some cases, the microscopical examination of the particles expelled from the needle might give reliable information. The *modus operandi* is most simple. Spots of the scalp are disinfected; a puncture is made with a sharp bistoury down to the bone. The drill employed is an ordinary stem-watch drill, to which is added an adjustable guard to prevent unlimited penetration of the drill into the brain substance after penetration of the bone. When the inner table is reached the drill is worked more cautiously. The perforation of the skull is easily completed with the point of a No. 1 aspirator needle attached to a syringe. All must be done under thorough asepsis and according to the rules followed in exploring after ordinary trephining. Several holes can be drilled at a distance from one another at the same time. Referring to apprehensions which have been expressed as to the danger of hemorrhage, the writer cited experiments made by himself on dogs whose brains were several times explored at several places at each sitting and which never exhibited any symptoms of hemorrhage. One of the dogs was killed and no trace of hemorrhage worth mentioning was found. He reported also post-mortem examinations by Spitzka, Meinhard, and Schmidt of cases in which the subjects had succumbed from the natural course of the original disease and in whom no traces of hemorrhage were found.

DR. THOMAS H. MANLEY, of New York, said that he could not agree with many of the points mentioned in this paper. If there is an effusion of blood into the brain, there is no reason why that blood should not undergo rapid resorption the same as it would elsewhere, especially on account of the high vascularity in this region. If it is necessary to explore the skull, we should be ready at the same time to go on and operate, and the anesthetizing of the patient should be just as complete as for any other operation.

DR. NICHOLAS SENN, of Chicago, said that the paper was a very valuable one, but he was compelled to disagree with a number of the ideas which it contained, as the operation described had never given any diagnostic information that he felt he could rely upon. A small perforation is attended with more danger than is opening the skull, just as small wounds often give more trouble than large ones. Temporary resection of the skull combined with a puncture with the needle often yields valuable diagnostic information, and when doubtful these may be followed by palpation. The sensation imparted to the finger is also of great value in determining between a solid tumor and a cyst, and increased resistance to the needle will often be of service. In the case of such pathological productions as blood, serum, cysts, or abscesses, the needle may give positive results and may also be utilized as a guide to reach the abscess. The difficulty of sterilizing and properly cleansing the apparatus is an objection to the use of the needle.

DR. ALEX. HUGH FERGUSON, of Chicago, considered Dr. Souchon's paper a valuable one, but in his own experience he had not found the use of the needle a reliable method. In cases of hemorrhage he would prefer to use some other method, as, for instance, gauze packing.

DR. SOUCHON, in closing the discussion, said the use of the needle has frequently proved of great service to him, and if the size of the needle and its thorough cleanliness be attended to, much good may result from its use.

Surgical Shock.—DR. FENTON B. TURCK, of Chicago, read a paper on the treatment of shock. He said that he had performed twenty-three experiments and obtained practically the same result in all of them. The following was the method employed in his experiments upon animals: The abdominal wall was opened for about four inches and the stomach was brought out of the opening and exposed to the air from an open window. The chloroform was pushed to narcosis and in a short time the vessels became markedly congestive, while the gastric vein and the gastro-epiploica were distended and of a bluish color. An empty bag with tube attachment was then introduced into the stomach and hot water at 125° F. was rapidly introduced, with the result that the animal began to breathe and the color of the stomach markedly changed from a dull blue appearance to a bright red color. The author gave a practical demonstration of his method before the section.

Ligation of the External Carotid Artery in Conjunction with Exsection of the Jaws.—DR. WILLIAM PERRIN NICHOLSON, of Atlanta, Ga., read a paper with this title.

The author referred at some length to patients on whom he performed the operation of ligation of the external carotid artery and to the good results which he obtained. The incision employed is from two to four inches long, according to the depth of the neck, though it is better to begin with the former and extend if necessary. The centre of the incision should be at a point parallel with the Adam's apple. After the skin and deep fascia have been passed, the work is largely done with the handle of a scalpel and the finger, and in this way the vessel can be rapidly approached

without danger. The chief obstacle to be encountered is the crossing of the vessel by the facial, lingual, and superior thyroid veins, their combined trunks making, in some cases, an enormous vessel. These can be pulled aside when the division is at the normal point, but sometimes they must be cut between forceps and tied at once. In only two cases did the author see the internal jugular vein, and this was when the common carotid was followed to the dividing-point. It must always be remembered that the external carotid is the one nearer to the median line. The point of ligation varies considerably. The material employed for ligature and sutures in every case was catgut. In five of the cases the only dressing applied was iodoform and collodion scab, and not a single case required a second dressing.

The Technique of Removing the Appendix Vermiformis.—DR. M. M. JOHNSON, of Hartford, Conn., read a paper with this title and gave a report of one hundred cases. He described the method of preparing the patient for the operation which he is in the habit of employing in these cases. He spoke at some length concerning the incision to be made and considered that the statement of Dr. Morris, "an inch and a half and a week and a half," contained a sound surgical principle to go upon. He also strongly advised as little manipulation as possible of the intestines. In chronic recurrent cases he makes an incision one and one-half inches long directly over the appendix, and when the peritoneum is reached a catgut suture is passed through it at the upper angle of the incision, so as to prevent its retraction. In finding the appendix he passes the thumb and index finger through the incision and seizes the colon, which he draws through the incision until the appendix is brought into view. When the cæcum is surrounded with a pus sac, a perforated and sloughing appendix is usually found and should be removed. It should be a fixed rule never to close up the incision without finding and removing the appendix. The treatment of the stump resolves itself into the treatment of an intestinal perforation, and the surgical rule for the treatment of this condition should not be violated in the treatment of the stump, although it is stated by Dr. Robert H. M. Dawbarn, of New York, in the May number of the *International Journal of Surgery*, that there are eleven different methods employed in its treatment. While these methods are popular, they are at variance with correct surgical principles, because they leave a point of infection in the peritoneal cavity which will sooner or later prove a serious complication. In closing the incision we are justified in assuming that the various layers of tissue are arranged in the best possible order, and the work of nature should be respected by leaving them as nearly as possible as they were found. By making gentle traction on the catgut suture passed through the peritoneum at the upper angle of the incision, the retracted peritoneum is brought into view, and with a Martin needle loaded with No. 2 catgut a stitch is easily passed through the free borders of the peritoneum and the edges are drawn together. By removing the original suture and making gentle traction on the last stitch, enough more of the peritoneum is drawn into the incision to allow another stitch, and this is continued until the peritoneal incision is closed by a continuous catgut suture. The transversalis fascia and transversalis and internal oblique aponeurosis are secured by a continuous suture separately. The skin is put hard on the stretch by a tenaculum placed in the angles of the incision and the edges are united with No. 0 catgut in a fine needle. The author has never had a case of hernia following this method of closing the incision. Catgut is used throughout the entire operation, which is sterilized by the author himself. With regard to multiple pus sacs and other complications oc-

asionally met with, there is a great diversity of opinion as to what should be done. Gilbert Barling states, in the *British Medical Journal*, page 1,254, that "if the vermiform appendix is left, little anxiety need be felt as to future attacks of appendicitis, as they rarely occur." This means that little anxiety need be felt when dead, decomposing, highly infectious animal tissue is left in the abdominal cavity. A more dangerous opinion, he thought, could not be expressed, and the author related a case in which Barling's dictum was followed and in which a second operation was necessary. Upon opening the abdomen a perforation in the cæcum was observed and many strong bands of adhesion were present. The appendix was in a gangrenous, highly infectious condition, and was removed, the patient making a good recovery. With regard to the time for operation, this should be decided from the standpoint of the best interests and safety of the patient. In the author's opinion operative measures should be an early consideration rather than the last resort. Of one hundred operations performed by Dr. Johnson, ninety-eight resulted in recovery and two in death, of which number sixty-four were males and thirty-six females.

DR. PARKER, of New Orleans, said that he was much surprised at the large number of cases of appendicitis in the North as compared with the South, as he did not believe half a dozen cases a year were seen in New Orleans. He never saw any in the negro. He could not agree with the author as to the advisability of at all times removing the appendix, and thought that in those cases in which the appendix is surrounded by an abscess all that is necessary is to open the abscess and drain the region. He was in favor of opening the bowel with an enema and saline as a preparatory procedure, but did not believe in the use of opium.

THE SECRETARY said that he fully agreed with the last speaker that the opening and draining of abscesses surrounding the appendix is in the majority of cases all that is necessary, and in the large number of cases which he had observed he had not encountered a single recurrence after this method had been employed. One should no more think of treating every case of appendicitis in the same way than he should think of treating all cases of pneumonia with the same drug, and the same remark applied to the length of the incision. He thought this a matter which should be decided entirely according to the requirements of the case. The result obtained by the author of the paper was, he thought, almost unparalleled.

DR. CARPENTER, of Kentucky, said that each case is a law unto itself and must be treated in that way. He believed many patients are lost by meddling surgery and also that excision, irrigation, and drainage are all that is necessary in the majority of cases.

DR. McRAE, of Atlanta, said that, as regards the question of appendicitis in the negro, he had operated on two patients, one male and one female, both of whom recovered. He was firmly convinced that it would be a very dangerous practice to state that every appendix should be removed when it is contained in an abscess wall, and he agreed with the other speakers that simple drainage is usually all that is necessary. He was satisfied that the appendix could be removed at a later sitting with less danger to the patient.

DR. ALEXANDER HUGH FERGUSON, of Chicago, said that in his opinion the most favorable time to operate is between the attacks, and he considered it dangerous to operate during the height of inflammation, particularly when there is a tumor. The second most favorable time to operate is early, say within twenty-four hours, and the patient's chances are much better than if left until the fourth or fifth day. In ninety-nine

per cent. of the cases an inch and a half and a week and a half is wrong. Upon entering the abdomen, as soon as pus is found a drain should be employed, and the best way of doing this is with gauze and a glass tube.

DR. HAINES, of Omaha, said that he did not believe that it is always necessary or advisable to remove the appendix; in fact, he considered that such routine practice should be condemned.

DR. JOHNSON, in closing the discussion, said: "When the appendix is situated in the wall of the pus sac, I think it should always be removed. Although there are good authorities against this procedure, my experience is that it is the best thing to do. I have never yet had a case of peritonitis resulting. You have a highly septic matter which, in my opinion, it is dangerous to leave behind. As to the length of the incision, I do not think a seven-inch incision should be required in any case, as it not only prolongs the operation but weakens the abdominal wall, which is a serious matter if your patient be a laboring man. Experience soon enables one to perform the operation through a very small incision. The Dawbarn method, when it can be employed, is an excellent one and by it the operation can be done in five minutes after you get used to it. Fecal fistulæ will usually take care of themselves. As to the preparation of the catgut, I do this myself by placing it in ether, changing the latter until all the fat is taken out. I then boil it continuously at a temperature of 173° F., and put it away in sterilized glass jars until I wish to use it, when I resterilize it."

Illumination of the Sigmoid Cavity.—DR. J. G. CARPENTER, of Stanford, Ky., made a few remarks on his method of illuminating the sigmoid cavity which he has employed for a number of years, and drew diagrams of the instruments used. He stated that Dr. Kelly, of Baltimore, claims to have been doing a similar operation for many years, but no account of the work can be found in medical literature previous to 1894.

Fourth Day—Friday, May 8th.

Gastrostomy for Stricture of the Œsophagus.—DR. HUNTER P. COOPER, of Atlanta, related the history of a young man who one year ago took one swallow of pure nitric acid by mistake, causing corrosion of the entire mouth, lips, and œsophagus. The mouth and lips healed about three weeks after the sloughs separated. The author first saw the patient in January, 1896. Several months previous to this an increased difficulty in swallowing was appreciated, but at that time this symptom was considerably worse and the feeling existed that small particles of food were stopped before reaching the stomach, apparently low down in the œsophagus. Liquids could be swallowed slowly and with difficulty, but half an hour was occupied in drinking a glass of milk. For two or three days at a time swallowing was impossible, and then relaxation occurred. When first seen, the pulse and temperature were normal, the tongue was clean, the appetite good, and the pulse regular. Examination of the stomach revealed three strictures, seven and one-half and eight inches from the edge of the incisor teeth. No more were discovered until the instrument had passed thirteen and one-half inches down the œsophagus, when an obstruction was met which would not allow any instrument to pass. The largest instrument that would pass the stricture seven inches from the teeth was of the size of a No. 22 French urethral bougie, and nothing would pass lower than thirteen and one-half inches. Gastrostomy was decided upon, and the Shanijew-Frank method was selected, which the author briefly described as follows:

An incision is made about a finger's breadth below the costal cartilages on the left side over the stomach. The first incision, three and one-half inches in length, goes down to the muscles, and the muscles are then divided in the direction of their fibres by blunt dissection. The peritoneum is opened in a line parallel with the edge of the costal cartilages. The stomach, having been withdrawn from the wound, is drawn strongly outward by a ligature passed through its walls, and traction is then made on this ligature by an assistant until a cone of the stomach three or four inches long is drawn out of the abdominal incision. While the assistant holds this cone in position by means of the ligature, the base of the cone is sutured to the parietal peritoneum all the way around. The next step consists in making an incision through the skin, superficial fascia, and areolar tissue down to the deep fascia. This incision is placed one inch above the margin of the costal cartilages, and its direction is parallel to that of the primary incision. By blunt dissection communication is made underneath the skin and superficial tissues between this incision and the primary incision, and through this communication the apex of the cone formed by the stomach is drawn. The wall of the stomach is then sutured to the skin and the stomach is opened. The primary wound is closed, the muscles being sutured seriatim and the skin incision sutured last. The advantage of this plan is that it brings the stomach through the abdominal wall in an oblique direction, and a part of the stomach is included between the edge of the costal cartilage and the skin, forming as it were a valve. This device prevents leakage of the contents of the stomach during digestion, and is a great advantage over the old method of making a direct communication between the stomach and the abdominal incision.

The subsequent history of the case is uneventful, the patient gaining in flesh and strength and being perfectly nourished by means of feeding through the artificial opening. Since the operation a small bougie has been passed eighteen inches from the edge of the teeth, No. 15 on the French urethral scale was passed twenty inches, and No. 22 of this scale has been passed through the strictures at seven and seven and one-half and eight inches from the edge of the teeth. On account of the large amount of cicatricial tissue present, it is doubtful whether it will be possible to thoroughly divide it so that recontraction will not take place. The valve does its work very well and there is practically no leakage. A little gastric juice exudes from the opening, but none of the stomach contents.

DR. ROSENTHAL, of Philadelphia, said he had seen this operation performed by Dr. Thomas S. K. Morton, and the only point about it upon which Dr. Morton laid great stress was the advisability of getting the patient up as quickly as possible.

DR. THOMAS, of Pennsylvania, said that, in employing the Abbe ligature in this operation, there might be the danger that the stricture will recontract and necessitate a repetition of the operation.

DR. COOPER said that he agreed with Dr. Morton as to the necessity of getting the patients up as early as possible.

DR. FERDINAND C. VALENTINE said that he had had considerable experience in dealing with strictures of the urethra, but not of the œsophagus. He thought that somewhat the same methods would apply in each case, and he believed that the method suggested by the author is a good one.

DR. W. J. MAYO, of Rochester, Minn., said he was of the opinion that Fenger's operation is the best for this particular class of cases, although it causes great annoyance from leakage. He thought Dr.

Cooper's operation very complete and in cases of lingual stenosis the one of choice.

DR. COOPER, in closing the discussion, said that one good point about the wound is that if you divide the strictures and they recontract, you will simply have to open at a certain point and turn in the edges.

The Abortion of Gonorrhœa and Treatment of Other Urethral and Vesical Diseases by Hydrostatic Irrigations.—DR. FERDINAND C. VALENTINE, of New York, read a paper with this title. He said that he desired to submit some modifications of his usual method of performing hydrostatic irrigations, and mentioned: 1, the substitution of a cast-iron ring to hold the irrigator; 2, a rubber tube with a lumen one-fourth inch in diameter, made especially for this apparatus, which enables the operator easily to overcome any sphincter vesicæ; 3, a stopcock nearly thrice as large as its predecessor, which prevents cramping of the hand when frequent irrigations are required; and 4, the enlargement of the shield's neck, which facilitates its being slipped over the nozzle when attached to the hose and also attaches it firmly to the stop-cock.

The apparatus of the author of which the above are modifications was fully explained in a paper entitled "The Technique of Urethral and Intravesical Irrigations," which was published in the *Clinical Recorder* for February, 1896.

In Dr. Valentine's opinion, the difficulty of obtaining statistics of gonorrhœa is very great and its serious nature is far too lightly viewed by the laity. In those cases which he has observed from the beginning of the muco-serous discharge and in which gonococci were present, every one of the patients has entirely recovered within thirty-six hours, and in those in which the discharge had grown distinctly purulent, when not complicated, all the patients have recovered within ten days. Chronic cases which have lasted for months and years recover in varying lengths of time, and in one case (that of a physician who had persistently treated himself for twelve years) the copious, yellowish-green blood streaks discharged grew watery in two days, the gonococci disappeared in five days, and the discharge was entirely gone in eight days.

The following is the method of treatment employed: "After the discharge ceases, the patient is not treated for a week or ten days, when, no discharge reappearing, he is ordered to drink at least twice the quantity of beer to which he has been accustomed. No discharge resulting, after another lapse of ten days he is given a strong irritating injection of nitrate of silver. If the resultant discharge, which lasts from eight to thirty-six hours, contains no gonococci, all restrictions are removed, except that the patient is requested to bring the next seminal emission resulting, coitus condonatus, in the same condom. If this contains no gonococci and anterior and posterior urethroscopy show a healthy urethra, the patient is discharged.

According to statistics compiled by Berthold Goldberg, of Cologne, of patients treated by systematic intravesical irrigations, sixty per cent. recovered in less than ten days, thirty per cent. in from two to three weeks, and ten per cent. mischanced. One-half of this ten per cent. was attributable to avoidable causes—disobedience of patients, repeated excesses, etc.—while the remaining five per cent. distinctly resisted treatment. Goldberg's experience and that of others lead him to conclude that carefully systematized irrigations with potassium permanganate (1) are indicated when gonococci are present; (2) are contraindicated in acute inflammatory conditions; (3) permanently removed the gonococci in ninety-five per cent. of far more than half the cases within one to two weeks, in any stage of the disease; (4) are reliable as a means of aborting gonorrhœa; (5) the successes are due to coincident mechanical and chemical effects.

Dr. Valentine agreed with Goldberg in all but one of his conclusions, viz., the second one, for he thought that the pain of an acute local inflammatory condition could easily and quickly be overcome by an injection of cocaine.

Although the author follows Oberlaender's methods of treating gonorrhœa, he never fails to add irrigations, as this combination invariably yields the most satisfactory results. If this method is correctly followed (1) the disease is cut short; (2) pain is stopped; (3) no complications ensue; (4) no hand injections are used, with their unreliability; (5) no drugs are given by the stomach; and (6) the patient cannot peddle prescriptions.

In referring to a number of advantages which the author claims for his method, he mentioned as the most important the fact that a larger proportion of complete cures have resulted from it than from any other method with which he is acquainted.

Dr. Valentine concluded his paper by referring to the relation various diseases bore to the use of his apparatus, and stated his experiences as follows:

Catheter fever. He has never seen a case after use of the apparatus.

Cowperitis, folliculitis, and seminal vesiculitis do not contraindicate irrigations.

Cystitis and posterior urethritis. Irrigations are exceedingly well borne and yield excellent results.

Epididymitis and orchitis. If the case is one-sided strap the testicle and irrigate at once. If both testicles are involved use Wossidlo's method, which consists in applying the galvanic current, two to eight milliampères, for from three to fifteen minutes daily, after which apply suspensory bandage and irrigate at once.

Neurasthenia. Irrigations render surprising results.

Prostatitis does not contraindicate careful irrigations of the anterior urethra.

Retention. Irrigations should be used.

Secondary syphilis. Patients have not been found to bear the irrigations badly.

Strictures. The Oberlaender method combined with irrigations yields brilliant results.

Tuberculosis. Tuberculous patients when not very low or in fever can be treated as other patients.

Skin Surgery.—DR. F. W. EPLEY, of New Richmond, Wis., reported a case in which he transferred fifty-two square inches of skin in six large pieces from five different persons and three hundred smaller grafts from four other persons to repair an injury to a man's foot, all of which transfers were successful. After a brief description of the method employed, he laid special stress upon the necessity of using antiseptics freely, cocainizing fearlessly, and making the donor's wound boat-shaped.

A New and Original Method of Obtaining Material for Skin Grafting.—DR. Z. J. LUSK, of Warsaw, N. Y., reported a number of cases of skin grafting, and stated that he employed two methods in the work. The first method is that of raising epidermis by cantharides, and the second is the employment, after proper softening and sterilization, of exfoliated epithelium. In all cases in which these methods have been employed excellent results were obtained.

DR. J. MCFADDEN GASTON, of Atlanta, said he would like to mention two methods with which he is familiar and which he considers superior to those mentioned. The first is the employment of traction with adhesive strips to bring the edges of the torn skin together and thus cover up the injury, and the other is the use of the inner membrane of the egg for granulating-purposes. He did not think the use of corrosive sublimate, which was mentioned in Dr. Epley's paper and also in Dr. Lusk's, should be advised.

DR. EPLEY, in closing the discussion, said that he had found the use of corrosive sublimate very advantageous. One great advantage of his method of skin grafting was the preservation of the elasticity of the skin.

The Therapeutic Value of Oxygen in Combination with Ether, Chloroform, and A. C. E. Mixture.—DR. J. N. DEHART, of Brooklyn, N. Y., dwelt at some length on the details employed in his methods, described cases in which they have been used with excellent results, and stated that he considers the administration of anæsthetics in the way he suggests perfectly safe.

Treatment of Cancer of the Rectum.—DR. LEWIS H. ADLER, JR., of Philadelphia, read a paper on this subject. He said that the four recognized operations for this affection are extirpation, colotomy, posterior linear proctotomy, and curettage. The ideal method is extirpation, but unfortunately it is not often that the rectal neoplasm is discovered in time to permit of the entire removal of the growth and of all glandular involvement. Colotomy is quite practicable in a large number of instances and the benefits derived from its performance were minutely described by Dr. Charles B. Kelsey, in the *New York Medical Journal* for November, 1892.

The author described at some length a case in which he performed the operation of inguinal colotomy and secured excellent results, although at the present time (three years since the operation) the patient has suffered considerable distress from pain over the sacrum and has not been able to work.

Dr. Adler has never attempted to relieve malignant trouble affecting the rectum by means of a linear proctotomy, but has found it an excellent plan of treatment when combined with the subsequent use of bougies in benign stricture. He called particular attention to the value of curettage in those cases of cancer in which the disease is within the lower three inches of the rectum, and its character of such a nature as to permit of its more or less complete removal by the curette. In certain cases the combined operations of colotomy and curettage afford the patient more relief than where one or the other procedure is individually adopted. At the present time all that can be offered patients under any plan of treatment in the majority of cases is temporary relief. Of seven cases of curettage of the rectum for the relief of malignant trouble, performed during the past few years, only one was deemed unsatisfactory. In this case after the curettage the patient was unable to leave her bed, her appetite failed, emaciation followed, and death from exhaustion ensued in a little over two months. Even in this case, which for several reasons was a most unfavorable one for operation, the patient was much relieved of pain, and the two months she lived were certainly passed with more comfort than would have been the case had no operative interference been attempted.

Dr. Adler described a case in which he performed the operation of curettage and secured such excellent results that four months after the operation the patient was in such good health that he married. His gain in flesh was very marked. A short time after his marriage the growth in the rectum was noticed returning and the discharge reappeared. Other symptoms developing, he was subjected six months afterward to a similar operation. A month later marked tympanites suddenly appeared and the patient was unable to pass either wind or feces. Various laxatives were employed and several enemata administered before the bowels were made to move, which was not until the third day. Finally the patient became confined to his bed through sheer weakness, and death occurred from exhaustion about nineteen months from the time Dr. Adler first saw him. The autopsy revealed cancerous involvement of the liver and intestines.

In conclusion, the author summarized the indications for the operative treatment of rectal cases as follows:

Extirpation, to be considered only in those cases in which the disease admits of the hope of obtaining a permanent cure.

Colotomy, when the rectum is involved above the lower three inches of the bowel and the disease has produced an appreciable obstruction.

Curettage, or a posterior linear proctotomy, or the two combined, for those cases in which the disease occupies the lower three inches of the rectum.

Surgical Sterilization and Sterilizers in Private Practice.—DR. EDWARD BOECKMANN, of St. Paul, Minn., referred to an address which he read before the Association of Military Surgeons of the United States, on "Asepsis in Military Service." He strongly recommended the 120° F. warm and one to two per cent. strong solution of lysol for combined mechanical and chemical disinfection of the operator's hands and the patient's skin. Provided with lysol, absolute alcohol, and ethereal solution of sterilized lanolin, we are enabled to disinfect the skin, the most dreaded bearer of infection, as safely as is possible at this time and with as few and as simple agents as can be demanded in operations in private practice.

All sterilizers for streaming steam must necessarily be constructed for oversteam. Dr. Boeckman does not favor combination sterilizers, because boiling and steaming are different processes requiring an unequal time.

He uses a combination portable sterilizer, consisting of four parts: the boiling-pan, the hood, the instrument tray, and the steam chamber. The boiling-pan is filled with a sufficient quantity of water, care being taken to fill the groove at the same time; the hood is adjusted, and the whole placed over a good fire. While the water is heating the instruments are arranged on the tray, and the dressings, etc., in the steam chamber; needles, drainage tubes, ligating and suturing materials are put (separately) in a small metal box (sterile catgut is brought along in hermetically sealed envelopes). When the water boils the hood is removed and the steam chamber put in, whereupon the hood is replaced with a cork in the upper tube. The steam will now ascend between the hood and the steam chamber to the top. The cork at the top and the water in the groove and the pan acting as locks, the steam is forced to work its way through the opening in the cover into the steam chamber, through the articles contained, and out through the tube in the boiling-pan. In the course of five minutes the instruments are surgically sterile.

Dr. Boeckmann urged all surgeons to consider every wound at the end of an operation of some duration as slightly infected, and therefore to combine their asepsis with a judicial antiseptis. Thus, he is in the habit of repeatedly dipping his hands in a weak, sterile solution of lysol (one to two per cent., or even less). This small amount of antiseptic he has yet failed to find objectionable, and he uses lysol because it is at hand and because it is alkaline. When the operation is completed he applies next to the wound an antiseptic dressing, not exactly the customary iodoform gauze, because its preparation requires unusual facilities; but anhydrous lanolin, first sterilized, mixed while cooling with two-per-cent. lysol, and run into sterilized tubes, this being first expressed over the wound, whereafter the ordinary dressing is applied.

Laminectomy.—DR. JOHN A. WYETH, of New York, reported a number of cases of this operation. After a detailed description of each of the cases of injury to the spinal cord which have come under the personal observation of the author in recent years, he briefly summarized them as follows:

In Case II. there was compression of the cord with paraplegia due to the presence of a tuberculous neoplasm. This paraplegia had existed a little over six months. After the removal of the tumor the functions of the cord were restored. While the conductive power of motion and sensation was suspended for six months, the ascending and descending degeneration of the cord evidently took place in so slight a degree that the conductivity of the cord was restored after the removal of the source of compression.

In Cases III. and IV. there were no external evidences of fracture, and while extradural hemorrhage occurred in both cases from rupture of the venæ basis vertebræ there was no direct compression from displaced bone. In all the other cases either a projection or depression of bone pointed directly to the seat of injury. In both of these cases the cord was very much reduced in size at the point at which the dura was incised, was pale, and more anæmic than the others. The paraplegia and the ultimately fatal results in both cases were due either to traumatic pachymeningitis or to general concussion and myelitis resulting in degeneration of the cord. Both of these patients were injured by falling directly upon the back. Of the eleven cases of fracture of the vertebræ only two were due to direct violence, one of which was a gunshot injury and the other the result of impact of a heavy stone. Two cases were in all probability caused by *contre coup*. The remaining cases were due either to falls from a height, diving, or blows upon the back of the head.

As to the results of the treatment: Three were not operated upon. Of these one was greatly improved by extension and counter-extension, as the fracture occurred in the dorso-lumbar region where this plan of treatment can be satisfactorily carried out. The same treatment was undertaken in the other two cases, but with no improvement in their condition. Both patients are living, but their condition is decidedly hopeless.

Of the eight patients operated upon, one was entirely cured (after the removal of a tuberculous tumor); another (a young man who was thrown in front of a locomotive) was greatly benefited by the operation, as he is still living and able to get about with a cane and crutch. In the latter case the operation was performed eight months after the receipt of the injury. The other cases were not benefited in any way by the operation. Of the eight patients operated upon one died six days after operation, and his death may have been hastened somewhat by the interference, but, on the other hand, destruction of the spinal cord at the level of the fifth cervical vertebra could not have continued without interference with the roots of the phrenic nerve. In none of the other cases could a fatal result be charged in any way to the operation. The operation of laminectomy involves so slight a risk to life that the surgeon should be encouraged to resort to this method of exploration in all cases in which the symptoms point to compression of the cord. Great depression of the pulse, respiration, or temperature may be taken as a contraindication to the operation. In one of the above cases, however, the temperature was as low as 91° F., and did not go above 96° F. in twenty-four hours. The method of operating which Dr. Wyeth employed is as follows:

With the patient in the prone position, reclining somewhat upon one side in order to interfere as little as possible with the movements of respiration, an incision is made with its centre corresponding to the seat of the lesion, seven or eight inches in length, directly over the spinal processes. Strong hooks are used as retractors, which also assist in controlling the hemorrhage. The attachments of the muscles should be cut or scraped from the bones in order to avoid wounding any vessels. In this way the laminæ are finally exposed, and

with a small rongeur divided and removed one after another, until the dura is sufficiently exposed. Oozing of blood may be controlled by pressure with sterile gauze. After the wound is entirely dry the dura is opened by a sharp-pointed knife in the middle line. Through the primary puncture a grooved director should be introduced and the dura divided exactly in the middle line as far as necessary. When the fluid escapes the edges of the dura can be held apart by mouse-toothed forceps and the cord inspected. A light probe should be passed up and down from the point of opening to determine if any compression of the cord exists at those points. The dura should then be closed by fine interrupted catgut sutures about three-sixteenths of an inch apart, and the muscles of the two sides stitched together with strong catgut sutures. Silkworm-gut sutures are used for the skin. It is always wise to leave a twist of catgut projecting from the level of the dura at the inferior angle of the wound, as some oozing is apt to occur which may exercise compression on the cord. Most careful asepsis should be practised. The patient should remain upon the back for the first week or ten days after the operation. The wound should be dressed so that the patient suffer no material inconvenience from the removal of the laminæ of two or three vertebræ.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

J. TABER JOHNSON, M.D., OF WASHINGTON, D.C.,
CHAIRMAN.

Second Day—Wednesday, May 6th.

Gauze Drainage in Pelvic and Abdominal Surgery.—DR. MILO B. WARD, of Topeka, Kan., urged the importance of drainage in a large number of cases following operation. He said it was idle to contend that drainage is necessary only when the operation is imperfectly done. The only consideration is what is the best kind of drainage. While no one kind can meet all cases, yet his own experience led him to urge the claims of gauze drainage in the large majority of cases, as it meets two indications, viz., the control of hemorrhage and drainage at the same time. Of course drainage is not necessary in every case, but where there is any septic condition he thought drainage should always be used. The objections to the use of gauze were the facts that a large opening is necessary in order to remove the gauze and the pain caused by the removal. In his experience he had never seen any ill effects from the use of iodoform gauze, though others had reported cases of poisoning. He had nothing new to offer in regard to technique except to say that the gauze should be used freely. In answer to the question as to what kind of cases required drainage, he would say that it should be used in almost all seriously complicated cases or when the intestine is involved, and in all cases in which an opening is made in the vagina. In conclusion, he thought many patients would recover by means of drainage who otherwise would not survive.

DR. KELLY, of Baltimore, in opening the discussion, said that now he very rarely drains, and that his work has improved very much since he has ceased using drainage in the majority of cases. In the first four hundred out of fifteen hundred abdominal sections he used drainage in seventy-three per cent. of the cases, in his last one hundred in only eight per cent., and the mortality decreased in proportion. When drainage is necessary he thinks the gauze drain the only one to use. He condemns the glass drainage tube, because it does not drain properly and because it introduces sepsis. He no longer uses drainage in cases of tuber-

culous peritonitis, for he has found that the patients all get well; but those cases in which drainage is used required an average of fifty-nine days for convalescence, while those in which no drainage is employed recover on the average in thirty days.

He thought drainage should rarely be employed for hemorrhage, and then only when it is excessive. He limits drainage to the septic cases or those in which the intestine has been wounded. He advocates gauze drainage because it covers a large area—any quantity can be used, and because it can be used in curved and angular spaces, and because a constant capillary action is kept up. The disadvantages are that the drainage is apt to stop after a while unless watched, and the pain of removal. It is his plan to remove the gauze very soon if it has been used for hemorrhage; if for sepsis, to leave it in for five or six days.

DR. NOBLE, of Philadelphia, said that in the beginning he drained a larger percentage of cases than Dr. Kelly, but the longer he operates the less he drains. In his early cases he thought the recoveries were due to the tube, but he has since seen his mistake. According to his experience gauze ceases to drain after a few hours. The serum collects in the gauze and is retained. He, therefore, is in the habit of inserting a glass tube in the middle of the gauze. In his opinion the chief function of the gauze is to pack off the infected area. He has never found it necessary to use drainage for hemorrhage, and thinks that with the patient in Trendelenburg's position it can always be controlled. In a case in which it is necessary to employ drainage for this purpose he would prefer a glass tube for twenty-four hours.

DR. H. O. MARCY, of Boston, said that for many years he stood alone on this question of drainage, and he was glad to see others coming to his views. He has laid down two rules for his own guidance. If the case is aseptic, no drainage; if septic, drainage. The reason, he thought, gauze sometimes ceases to drain is because the operator tries to drain up hill. The proper place to drain is not through the abdominal wound, but through the vagina, and a large opening should be employed.

DR. NEWMAN, of Chicago, said he has lately employed iodoform wicking instead of gauze and has found it more satisfactory. The capillary action is better and it is easier to introduce and remove.

Degenerative Changes that Occur in Uterine Fibro-Myomatous Growths.—DR. AUGUSTUS P. CLARKE, of Cambridge, Mass., began his paper with the statement that the belief that fibroid tumors are always benign, and that if a patient suffering from these growths once passed the menopause she would have no further trouble, is erroneous.

The same is true of the statement that degeneration of a fibroid is favorable. Later investigations have shown that these growths frequently become harder, and may press upon the ureters and cause renal complications. In addition to the dangers from hemorrhage and pressure, suppurative changes may take place, endangering the life of the patient from septic poisoning. He has seen several cases of this character. He doubts if a fibroid tumor ever wholly disappeared spontaneously. It may remain stationary for a long time, but there is constant danger of degeneration and the development of malignancy. These changes are not rare, and they may occur at any time, even after the menopause. This change is usually insidious in onset, and the early signs and constitutional symptoms of primary cancer attacking the cervix are not present. The patient may appear in perfect health until the growth has become very extensive and involves the lower portion of the uterus. Fatty degeneration is another degenerative change which may take place in fibroid tumors. It may occur under the

influence of pregnancy. It is more likely to take place when the growth is myomatous. The liquefied portions may become absorbed and cavities formed, which give it the appearance of a fibro-cystic tumor, but it is not, as the cavities are not lined with epithelium.

The other degenerative changes liable to occur in fibroid tumors are inflammation leading to obliteration of the vessels and consequent sloughing and gangrene, colloid degeneration, melanotic growths, calcification, contraction, and atrophy.

In consequence of these various changes, many of them fraught with so much danger, he advises the removal of all fibroid tumors as soon as they are discovered.

Drainage versus Radical Operation in Cases of Large Pelvic Abscesses.—DR. CHARLES P. NOBLE, of Philadelphia, said that the object of his paper was to call attention to drainage in large pelvic abscess and to contrast the results with those of abdominal section. He wished to state at the outset that the method is applicable only to a specific class of cases, viz., those in which there is a large collection of pus in the pelvis and the patient has become very weak and ill from a long-continued septic process.

Previous to July, 1895, he always performed abdominal section in these cases, and while he had obtained some excellent results, yet the mortality was somewhat high, being at least twenty-five per cent. This would be fairly satisfactory in this class of cases if there were nothing better, but simple drainage has revolutionized things.

Since July, 1895, he had operated in eight cases of this nature without a single death. Seven of these patients were very septic, and he thought at least six of them would not have survived the shock of an abdominal section. A detailed report of the cases followed.

Dr. Noble then added that his experience was too limited to predict the number of cures by this operation, and that probably some of his cases would require a second operation. What he claimed was that in desperate cases it was a life-saving operation; that it permitted the patient to recover strength and get into a condition which would permit a radical operation if necessary. He also thought that in a certain percentage of cases the operation would bring about a permanent cure without further interference.

Some Suggestions on the Prophylaxis and Management of Puerperal Eclampsia.—DR. H. D. THOMASON, of Albion, Mich., stated that the pathology and etiology of puerperal eclampsia are still undetermined and unsettled and that it is necessary therefore to fall back upon our clinical experience. The various causes which have been given are: 1, albuminuria; 2, renal insufficiency; 3, cerebral irritation; 4, obstruction to the portal circulation due to cirrhosis; 5, peripheral nerve irritation; 6, pressure on the renal vessels; 7, pressure on the ureters. Probably no one cause can be assigned for every case.

He has been accustomed, therefore, to make for clinical purposes three groups:

1. Toxæmia from some cause.
2. Peripheral nerve irritation.
3. Hysteria.

Whatever may be the cause of eclampsia, the important thing to bear in mind is to keep a close watch on the patient. Rarely are convulsions unheralded. In the vast majority of cases there were prodromal symptoms. Frequent urinary analyses, both qualitative and quantitative, should be made, and if albumin is found or the amount of the solids greatly diminished, suspicion should be aroused. Any abnormal symptoms, such as headache, disturbances of vision, or œdema, should put us on our guard. When

such symptoms appear the patient must be put on a milk diet with large quantities of sterilized water; hot baths should be employed, and the bowels kept active by catharsis and saline enemata. If there seems to be pressure on the ureters, the method of catheterization advocated by Dr. Kelly may be used. In the majority of cases this treatment will remove the unpleasant symptoms, but if there is no improvement then the induction of premature labor must be considered. The continuance of these symptoms threatens the life of the child by toxæmia, and, therefore, if the child is viable, labor should be brought on both for its sake and for that of the mother. If a convulsion does occur and the child is viable, labor should be at once induced. If the child is not viable, then there may be delay unless the mother's life becomes endangered. In post-partum eclampsia the treatment varies with the subject. If the patient is plethoric and vigorous, venesection is the best remedy; if anæmic and weak, veratrum accompanied by the transfusion of the salt solution is indicated.

—
Third Day—Thursday, May 7th.

Vaginal versus Abdominal Section for Small Tumors and Pus in the Pelvis.—DR. R. S. SUTTON, of Pittsburg, who opened the appointed discussion on this subject, said that the whole question hinges upon the disposition of the uterus in cases of bilateral purulent infection of the appendages. If the uterus is to be removed, the vaginal route should be selected, and if the uterus has become a pathological organ it should be removed in all cases. He accepts the statement of Jacobs, that seventy-five per cent. of all cases of pus in the tubes were due to gonorrhœa; he thought tuberculosis accounted for ten per cent., and cancer and other causes for fifteen per cent. Gonorrhœa first affects the vagina, then extends along the uterine canal and into the tubes. The tubercle bacillus will produce pus if lodged in the tubes. We may also have a pelvic cellulitis and abscess in the broad ligaments due to infection, starting in abrasions and travelling along the lymphatic system. If, therefore, the uterus is thus infected, we should remove it. When both ovaries are taken out the uterus has no further function, and it is liable to cause further trouble from hemorrhage, discharges, chronic poisoning, and its susceptibility to malignant disease. The question has been asked, Does it add to the danger of the operation? Judging from his own experience and that of his colleague, his opinion was that it does not. Therefore the vaginal route is to be chosen, because it gives absolute and perfect drainage, shortens the convalescence from a period of from twenty-one to twenty-eight days to seven or eight days, and settles the question of future trouble both as to infection and uterine disease. In the case of small fibroids Dührssen's operation of anterior colpotomy should be employed and only the tumor removed, saving the uterus and appendages. When the tumor is too large for this method then morcellement may be employed. This operation is better than abdominal section, for it leaves no external marks and the convalescence is shortened.

DR. W. E. B. DAVIS, of Birmingham, Ala., thought the choice of operation depends largely upon the individual; that the man who has done a great deal of successful work by the abdominal incision will be loathe to change, and *vice versa*.

DR. SUTTON rightly emphasized the fact that the choice of method depends largely upon the decision as to removal of the uterus. But he himself did not agree with the conclusions of the last speaker. In his opinion the uterus should be left in the great majority of cases. He believed that it did have some function, and he knew that women feel better if it is

not removed. He also doubted the statement that such a large percentage of cases of pus in the tubes was due to gonorrhœa; the puerperal state is responsible for a great many. Many writers have stated that their patients were cured when the uterus was left behind, and it is a reflection on them to say that no case was really cured unless the uterus was also removed. A slow convalescence, or even a second operation, is preferable to removal of the uterus unless absolutely diseased. It is doubtful if the uterus is so much affected by gonorrhœal pus as has been stated. The conservation of organs is in his opinion of great importance.

The objections urged to the abdominal operation, viz., hernia and the scar, are not well founded. If the operation is properly done, there will be no hernia and very little scar. The advantages are that one can see what he is doing, and in the Trendelenburg position every facility is offered for doing what is necessary.

DR. KELLY, of Baltimore, stated that in every case in which both tubes were diseased the uterus should be removed. The abdominal operation is the best. The operation is much more rapid than the vaginal and the chances of shock no greater. It also gives an opportunity for conservatism by allowing inspection. It is never advisable to remove the uterus for a fibroid as large as a lemon or even as large as a fetal head. He has removed large fibroids by making five or six incisions into the uterus. An abdominal drain is never needed. Abscess of the abdominal wall rarely occurs, and hernia never, if the wound has been properly closed. The mortality from the abdominal operation is no greater than from the vaginal. He considers the vaginal operation a bad one on account of the liability of frightful hemorrhage, the danger of injuring the bowel, prolapse of the bowel, and because it does not provide for the dense adhesions which sometimes occur. Neither does it provide for appendical trouble, which complicates these cases in a considerable percentage.

DR. BOVEE, of Washington, said that he had been doing work by both methods, but he did not think it advisable in the majority of cases to remove the uterus with the appendages. Perhaps his experience is unique, but all of his patients who recovered from the operation got well with the uterus left behind. In many cases he curetted the uterus thoroughly before operating. He thought the abdominal method simpler than the vaginal. He believed that the tubercle bacilli came from the abdominal cavity, and infected the uterus later through the tubes. At the present time he employed drainage rarely. Fair-sized fibroids could be easily removed by anterior colpotomy, but if they were large he thought the abdominal route the better. In all cases where it was possible, he left a portion of one ovary.

DR. L. S. McMURTRY said that the real point of discussion is whether the vaginal or abdominal route is to be preferred, and everything else was subsidiary. He wished to announce that the first object to be attained in pelvic surgery is the greatest preservation consistent with thorough surgical work. It is a crude idea that the easiest way is to get rid of an organ. It is a much higher idea to attempt to preserve it. The vaginal route and vaginal drainage are not new ideas. What must guide us are the results of a very large amount of work by both methods. He did not think that the statistics of expert operators should be taken as a guide. The French surgeons have become phenomenally skilful in the vaginal method, but they have never done very good work by the abdominal. Hysterectomy at present is being overdone, and the impression is abroad that the vaginal route must be chosen. In his opinion the uterus

should not be removed unless diseased. On the other hand, where five or six incisions are necessary to remove a tumor, he would not leave the uterus. That is the other extreme. Everything points to the advantages of the abdominal route, for the aid of positive sight is given. Moreover, the results of the abdominal operations covering a long period of time are before the profession and can hardly be improved upon.

DR. JOSEPH EASTMAN, of Indianapolis, thought the question of accurate diagnosis in these cases had been overlooked. It was very important; we must deal with facts and not fancies.

He was surprised that Dr. Kelly advocated the partial removal of the uterus in these cases, whether done from above or below. If it is diseased, the whole of it should be removed and nothing left to carry infection. The decision as to the method to be employed must depend on the history of each individual case. He agreed with Dr. Kelly that a diseased appendix is frequently associated with these cases of diseased tubes, probably in ten per cent. and possibly in twenty-five per cent. He was also fully in accord with Dr. McMurtry that everything possible should be left.

The vaginal route has some things to recommend it in individual cases, in which the uterus is diseased as well as the tubes. But he wished to utter an emphatic protest against patients going home as soon as the eighth day. He thought there is an analogy between the opening of the pelvis by either route, and much the same precautions should be used. There is no excuse for such extensive packing with gauze in the vaginal method as had been recommended. In many cases the wound could be closed as perfectly as in abdominal section, and that was the plan he had adopted with great success.

DR. F. E. MONTGOMERY, of Philadelphia, wished to say that the aim and object of all surgical procedures should be conservative; that nothing which has a function should be sacrificed. He claimed that the abdominal operation is a conservative one, since an opportunity is given to examine both sides. When both tubes are diseased he is in favor of removing the uterus. It has no functional value and may become the seat of disease. The infection involves the uterine mucosa and walls, and gives rise to hysteroneurosis. If the tubes are removed the condition of the patient will not be the same as if the ovaries were present and healthy, but by removing the uterus we take away the chances for many new symptoms. The change which the uterus undergoes after removal of both ovaries may cause compression of the nerve filaments in the uterus and consequent neurosis. Hemorrhages and purulent discharges are also frequent. In his opinion the time of both operations is about the same. The necessity for separating adhesions in the vaginal operation is not so great, on account of the perfect drainage. He thought that the danger of injuring the intestines and ureters is just about as great and occurs as frequently in the abdominal method, but there is more opportunity to repair the damage.

DR. I. S. STONE was surprised that attention had not been called to the selection of cases. Where the patient is very ill, suffering from sepsis, and cannot endure the shock of an abdominal operation, a simple incision through the vagina, as advocated by Dr. Noble, was the only thing to do. He thought there is less shock in the vaginal operation. He thought the time would never come when the abdominal operation for fibroids would be given up.

DR. HALL, of Cincinnati, thought that only a very small proportion of cases of double pyosalpinx requires the vaginal operation and the removal of the uterus. In his experience the hemorrhages, discharges,

etc., were readily cured. In fact, he has seen many patients get well without any treatment.

DR. CORDIER, of Kansas City, Mo., was surprised that no reference had been made to the difficulties of the vaginal operation. He had found that it is not so easy to do a vaginal operation as an abdominal. The difficulties are many. In a recent case an omental vessel was adherent, and it having been torn in the midst of the operation the bleeding could be controlled only by an abdominal section, though the patient had already been some time on the table. Drainage is not necessary by the abdominal method, we are told, but very necessary by the vaginal. Why is this? By the vaginal method it is impossible to discover adhesions. If the intestine is injured it is either not discovered, or if discovered cannot be repaired without an abdominal section. It is possible for a hernia to occur if the mesentery is long, and if patients should be examined in the upright position after a vaginal operation, doubtless many cases of hernia into the vagina would be discovered.

Intestinal Obstruction Following Laparotomy.—DR. H. O. MARCY, of Boston, Mass., stated that he was led to present this very important subject to the section because seven cases occurred recently in his own practice, five of which were fatal, and he hoped to derive some information on the subject. On account of the short time at his disposal he was obliged to omit the description of his cases and also the consideration of the anatomy of the subject, which he had written out fully. In his opinion the obstruction always occurs in the small intestine near the seat of the operation, and most frequently quite near the junction of the small and large intestine. This is important to bear in mind in connection with the treatment. The important thing is the diagnosis, for the prognosis depends largely upon the early diagnosis. But this is extremely difficult, for there are no clear-cut, positive symptoms. There is a wide difference in the symptoms from those which indicate the usual acute intestinal obstruction. In none of his cases was the integrity of the intestine involved, and he was inclined to think that the operation had so lowered the vital forces that paralysis of the bowel took place, peristalsis ceased, and septic poisoning occurred through accumulation of the secretions of the bowel. The prominent symptoms in these cases are persistent vomiting, which is of much more significance when it comes on several hours after the operation and is not due to the anæsthetic; pain which might be local or general, and frequently was not severe. The temperature is not usually marked, but the pulse is rapid and there is a peculiar, anxious expression of countenance which is quite characteristic. In the treatment we are prohibited from using remedies by the mouth, since there is an accumulation of everything above the obstruction, and drugs will only aggravate the trouble. Enemata are of no use, as the obstruction is in the small intestine.

A careful examination of the intestine should be made at the site of the operation, then in the region of the appendix, and then of the omentum, and the obstruction will usually be found. If done early the difficulty can be corrected. In desperate cases an incision may be made in the abdomen, the first inflated coil of intestine seized, attached to the wound, and opened, establishing an artificial anus, and thus the patient be carried along until a thorough and radical operation can be performed. As a prevention of this complication he believes that careful suturing of every abrasion of the peritoneum and the covering of all stumps, etc., by peritoneum is of great value.

Puerperal Sepsis, Its Prophylaxis and Treatment was the title of a communication by DR. E. E. MONTGOMERY, of Philadelphia, Pa. He said this is

a fruitful subject for discussion on account of the mysterious way in which it frequently appears and the mortality which it causes. Opinions as to the etiology have been numerous and widely divergent, but he thought the best authorities are now agreed. There are two forms: One a putrid infection, due to decomposing material in the uterus, local, non-communicable, and yielding readily when the cause is removed; the other septic, due to special forms of micro-organisms coming from outside, strongly infectious and communicable. This latter form was the subject of his paper. The micro-organism in the vast majority of cases is the streptococcus, which is identical with the streptococcus of erysipelas. In some few cases the disease seems to be due to the staphylococcus. The entrance of these organisms is favored by wounds and abraded surfaces. The infection proceeds along the uterine canal through the tubes to the peritoneum and also by means of the lymphatics. These organisms always produce pus and septic poisoning. The symptoms will vary with the individual and the amount of infection. At times only local suppuration is produced; at others, points of suppuration appear at a distance from the seat of primary infection; in still other cases the system is so overwhelmed with the poison that there is no time for suppuration. The prophylaxis consists in absolute cleanliness on the part of the physician, nurse, and patient. When symptoms of infection appear, the first thing to determine is the nature of it. If the finger reveals the presence of decomposing material in the uterus, prompt removal and one or two washings will usually be sufficient. If, however, it is a case of microbic poisoning, more time and more active measures will be necessary. The system must be sustained by nutritious food and tonics, of which strychnine is the best, and the uterus must be kept thoroughly cleansed and drained. He also strongly advocated the use of the streptococcus antitoxin, as he has seen some excellent results follow from it. Curettage should rarely be done, but if at all, very early. Hysterectomy is rarely indicated, for, by the time so grave an operation can be considered, the infection has spread beyond the walls of the uterus, rendering its removal useless.

Puerperal Infection, its Pathology, Prevention, and Treatment.—DR. R. R. KIME, of Atlanta, Ga., presented a paper with this title. He accepted the same pathology of puerperal infection that has been given by Dr. Montgomery, viz., the putrid infection, or sapræmia, and the septic. It is possible, of course, to have a mixed infection. His rules for prevention are much the same, and consist in absolute cleanliness and the immediate closure of all tears in the genital canal. In the treatment he laid special emphasis upon drainage of the uterus by means of a tube kept constantly in position and washed out every six to twelve hours. He thought this much better than gauze drainage, and felt that he had saved the lives of many patients by its use. He also advocated the stimulation of the patient, the use of fresh air, and a large amount of nutritious food.

Gonorrhœa in the Puerperium.—DR. ALBERT H. BURR, of Chicago, said that puerperal infection is justly dreaded by all physicians, and when it does occur both the profession and laity are inclined to think that a blunder has been made by some one. But this is not always the case. The infection may have preceded the labor or even the pregnancy, and no one who has had much experience in obstetrics can fail to have been impressed with the fact that gonorrhœa is responsible for many cases of puerperal infection. He had come to feel a decided sense of insecurity in every case in which there was the slightest suspicion of gonorrhœa. He was able to present the

histories of six cases of this character, three of them fatal, in which he demonstrated positively the correctness of the diagnosis by the presence of the gonococcus in the pus cell. All were primiparæ, in good health, and every aseptic precaution had been taken. He brought this subject up both to show that puerperal infection may result from a cause entirely independent of any carelessness on the part of doctor or nurse, and also to make a plea for prophylaxis. Gonorrhœa is very prevalent, and young men marry at a time when they can communicate the disease to innocent young women and bring untold misery and even death to those whom they have chosen to love and protect. Frequently this is done through ignorance, and he thought every physician should lay down the law in every case coming under his observation and stand between the source of infection and those who might become its innocent victims.

Hysterectomy as an Accompaniment to Bilateral Removal of the Appendages.—DR. REUBEN PETERSON, of Grand Rapids, Mich., opened his paper by a discussion of the change of sentiment which, he said, had taken place in regard to the treatment of inflammatory diseases of the appendages during the past five years. Many operators have found that the patients from whom they had removed both ovaries and tubes for disease did not get well. The uterus formerly was thought to be the offending body and it was curetted and treated by various means, until in 1893 Dr. Polk, of New York, announced that in all cases of bilateral tubal disease the uterus should be removed at the same time, no matter what its condition. The pendulum has swung clear over, and this axiom has been accepted in many quarters as a universal law. Against this he wished to protest.

Have the pathological conditions found borne out the clinical phenomena? The mortality is no greater than when the tubes alone are removed; but the treatment must be based upon pathological grounds and the uterus should not be sacrificed unless it is so diseased that it cannot be cured. If it is not enough that it is diseased, it must be beyond help by other means. He agreed with the statement of a distinguished writer who said that many uteri have been removed which could have been saved. It is possible that the gonococci might penetrate below the mucous membrane into the deeper tissues of the uterus, though only one observer had ever found them, and he was willing to grant that twenty-five per cent. of cases of salpingitis were gonorrhœal; but he did not believe that every case of gonorrhœal infection of the uterus is incurable. If the disease is tuberculous in character he thought the uterus should be removed, as the nature of the disease makes it incurable. It is necessary to bear in mind that there are two classes of cases of bilateral disease of the appendages. The first variety is chronic, with large pus sacs and many adhesions and characterized by recurrent attacks of pain. Here the indications are to remove the uterus. In the other variety the tubes and ovaries are purulent or cheesy, the attack is acute, and the uterus is perhaps a little large, but freely movable. In these cases it is a grave question whether it is advisable to remove the uterus.

In conclusion he wished to emphasize the fact that there can be no universal law in these cases, that each must be studied by itself, and that the condition of the uterus at the time of the operation should be the guide as to its removal or not.

Vaginal Fixation.—Among two hundred and seven patients operated upon by Dr. Dührssen for vaginal fixation twenty have had children. Of these three, or fifteen per cent., have had difficult labor.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

EXHIBITION OF CASES—MAMMARY ABSCESES—THE MIDWIVES QUESTION—THE LIVERPOOL LYING-IN HOSPITAL DEADLOCK—A JUDICIAL SCANDAL—SMALL-POX—THE LATE W. SQUARE, E. D. M'NICOLL, AND A. F. WOOD—THE PLAYFAIR CASE SETTLED.

LONDON, May 1, 1896.

AMONG the cases exhibited at the Clinical Society last Friday were two of deficient development, of which it would be interesting to study the results in the light of the new photography. One patient was a little boy of five years of age, in whom three ribs (eighth, ninth, and tenth) on left side were absent. The eleventh rib on this side was also smaller than on the opposite, though the twelfth was larger. The movements of the spleen and diaphragm were visible. The other was a lad in whom the deficiency was in the lower end of the tibia occurring after transverse fracture. There was marked curving outward, throwing the internal malleolus into prominence. The lower end of the fibula was hypertrophied and bony ridges were formed. The line of fracture was some distance from the epiphysis. A delicate-looking boy of three, with an enormous sacro-coccygeal tumor, was also shown. The tumor seemed to be a cyst with some solid matter round the base. The sacrum and coccyx could be felt over the tumor, which commenced between the rectum and coccyx. In contrast with this case was that of a woman, aged twenty-six, with spina bifida, the position of this being of course outside the sacrum. It was remarked that operations on these cases were always fatal before the antiseptic era. Since then some cases had been successfully operated on. It was also suggested that the mortality of the earlier cases was the result of operating at too early an age. A girl, aged fourteen, was shown as a marked example of pseudorickets. She had been under observation two years and submitted to the new photography, which had shown the exact state of the joints. She did not seem to have had rickets as a child, and the bony lesions were not accompanied by the usual sweating, restlessness, and painful sensations.

Sequels to cases previously exhibited were also shown, among them a lad, aged thirteen, with a curious defect of speech. It was suggested that such cases could be well recorded by the phonograph, and verbal descriptions are certainly of little use.

At the Medical Society meeting on Monday Mr. Shield read a lengthy paper on "Abscess of the Breast." He thought most of the cases were due to infection through sore nipples and were therefore preventable. When fully formed, he advocated thorough operation. He makes an incision through which he passes the finger to explore the whole cavity, and, having found the most dependent part, makes there a second incision. The abscess cavity is then evacuated and cleansed, and the original incision closed with horse-hair sutures, over which collodion is applied to prevent scarring as much as possible. Should a sinus form and prove intractable to scraping, he would excise a wedge of gland tissue, including the sinus and the surrounding dense fibrous tissue.

Mr. Wallis spoke of the tendency of these abscesses to form in the hourglass shape, and said in many cases it is only on squeezing the breast that the communication between the superficial and deeper collections of pus can be demonstrated. Other speakers pointed out the great success that had attended antiseptic preventive measures in various institutions, and

Sir James Crichton Browne, president, said he had often seen puerperal mania of an acute type associated with mammary abscess. This he thought might be due to traumatism or might be a part of a general septic process.

The midwives question is as hotly discussed as ever. The registration bill indeed has no chance of passing this year, for the government has obtained all the time at the disposal of members for its own measures. Nevertheless, the opponents of the bill are active, and rightly urge that efforts must not be relaxed to educate the public and the House of Commons on the danger of setting up uneducated women as a lower order of practitioners, and thus virtually repealing the medical acts. Still a few consultants are upholding at fashionable drawing-rooms a scheme condemned by the great majority of the profession. A nice ethical position this and advertising at a discount! They may have cause to repent.

The deadlock at the Lying-in Hospital at Liverpool continues. The board seems determined to place the matron midwife in full authority over all normal cases, and the members of the staff decline to withdraw their resignations until she is placed under the direction of the medical officers. They are supported by the Medical Society, and I hope for once we may see that no one will accept a position on the staff to enable the board to carry out such a proposal. The board must have a medical staff, but it would be degrading to the profession to subordinate the staff to the matron midwife.

In the last two numbers of the *Westminster Review*, Mr. H. H. L. Bellot, B.C.L., has traced the history of the oppression suffered by Dr. Anderson at the hands of colonial judges. It is well that the case should be thus once more brought before the reading public, and that in an organ of such weight as the *Westminster Review*, which was edited for so many years by a member of our profession, who gathered round it such a galaxy of eminent writers, including J. S. Mill, George Eliot, Lewis, Spencer, and a host of leaders of politics, literature, and art.

Your readers may remember the case of Dr. Anderson, for whom a British jury found a verdict with £500 damages against the colonial judges who had oppressed him, and even ruined him, out of personal malice. Yet judgment was entered for defendants on the ground that no action can lie against a judge for acts in his judicial capacity. The civil rights defence committee arose from this case, and they intend to carry it to the House of Lords. Meantime, the wrongs of Dr. Anderson remain unredressed. But Mr. Bellot takes up the great public question thus brought into prominence and passes all the decided cases in review in the two articles I have mentioned, which he entitles "A Judicial Scandal." From his statement it appears that the doctrine that no action lies against a judge, whether he acts within his jurisdiction or outside it, "is barely thirty years old, and is not only opposed to common sense and the plain meaning of words, but to the distinction between judicial and extra-judicial acts laid down by leading judges." It seems, too, that American law maintains the old rule so eloquently laid down by Senator Clinton in *Vates v. Lansing*, the result of which he said was to decide "whether ministers of justice may oppress with impunity! Whether the habeas corpus act shall any longer dispense its blessings, and whether the law shall bend to the judge, or the judge bend to the majesty of the law."

It is hoped that our highest court will pronounce in favor of this older doctrine and sweep away the more recent decisions that have permitted the disgraceful injustice to Dr. Anderson, who still remains without redress.

Small-pox is spreading in the country and attack-

ing towns nearer to London than Gloucester. That unhappy city has now had about fifteen hundred cases. There is some decline in the number attacked during the past week, and vaccination and revaccination are being carried out. Above twenty-five thousand of the inhabitants are said to have sought the protection of the operation. Among them is one of the leaders of the anti-vaccinationists, who says he did so in deference to others, but we may be sure he wanted to save his own skin, though some of his misguided followers professed to prefer the disease and caught it.

William Square, F.R.C.S., of Plymouth, died lately, aged fifty-two. He was for many years identified with the medical institutions of Plymouth, having been hospital surgeon, president of the Medical Society, and occupied other prominent posts in the town. He was also widely known in other localities. He was fond of travelling and botany and horticulture, an enthusiastic athlete, especially devoted to swimming and lately to cycling. A thorough surgeon and oculist, he had the confidence of his brethren and the esteem of his fellow-townsmen. He was an alumnus of the Baptist College, Regents Park, and of St. Bartholomew's Hospital.

Edward Day McNicoll, F.R.C.S. Edin., of Southport, also died lately, aged fifty-one, of sarcoma. He had a large practice at Southport, where he had lived for twenty-three years, and was honorary medical officer of the infirmary.

Andrew Fleming Wood, M.B., died at Edinburgh, of pneumonia, at the age of forty-eight. He was the superintendent of the Hospital for Infectious Diseases, a post in which a correspondent says he gained universal esteem. The streets were lined with crowds when the large and influential funeral procession passed.

The Playfair appeal case came on yesterday, but counsel stated that an arrangement had been made. The case was therefore withdrawn. The terms of the settlement were not stated in court.

OUR PARIS LETTER.

(From our Special Correspondent.)

HYPNOTISM—THE VOYANTE OF THE RUE DE PARADIS AND THE ANGEL GABRIEL—HYSTERIA AND SOMNAMBULISM—CHARCOT AND BERNHEIM—THE DIFFERENT STAGES OF HYPNOTISM, RULES FOR THE ADMINISTRATION OF—AN HYPNOTIC WAVE SWEEPS OVER PARIS—SEROPTHY IN ALCOHOLISM.

PARIS, May 1, 1896.

THE thirst for a knowledge of the "beyond," the influence of the mystery pervading not only death itself but what may come thereafter, is implanted in every human breast. It is for this reason that spiritism, hypnotism, and somnambulism are so deeply interesting to the laity as well as to the medical profession. To the former, because they are awed and mystified; to the latter, because they are not only able to study metaphysics more profoundly, but also have in them valuable therapeutic measures with which to treat, often successfully, certain forms of nervous disease. The spiritualistic and hypnotic fever has been raging in Paris for several months past, and a certain Mlle. Couédon, living with her parents in a modest home in the Rue de Paradis, has contributed in no small way to throwing the great city into its present psychological state. This modest young girl, about nineteen years of age, with her black hair and eyes, claims to be in communication with the angel Gabriel during the catalepto-somnambulant sleep into which she puts herself. Of course it is the angel Gabriel whom her

dupes wish to consult, and if he had need of money before Mlle. Couédon appeared upon the scene, he certainly does not need it now, unless Mlle. Couédon keeps it all for herself, which is probable. This *voyante*, as she is called, has been so overrun with clients that she can no longer be seen except by written appointment, and numbers among her callers the highest and wealthiest in the land. Only a few days ago Henry, Prince of Orleans, consulted her, and weak-minded persons believe that he will soon ascend the throne of France in fulfilment of her prophecy. Emile Zola was not enthusiastic about his visit to her, and thought that she said well only what she knew well. As might be expected, official notice was soon taken of this case by the Society of Psychical Science, which appointed a medical commission to examine Mlle. Couédon. The report has just been read before a large audience at the Hôtel des Sociétés Savantes. Dr. Hacks, the reporter-general for the commission, examined the *voyante* from both an anthropological and pathological point of view. Her general condition he found satisfactory. Is she hysteric? No, he affirms. Is she epileptic? She may have sudden absences, vertigo, but that is all. Dr. Hacks denies absolutely that the *voyante* has a double personality. As regards her mental condition, he adds, let us for the moment put an interrogation point. He concludes his report as follows: "If Mlle. Couédon is not insane for the instant, as I suppose, she is a pretender. Her attitude is one of defence, her ecstasy is only a feint; she is continually on her guard, and could not support the prick of a needle nor the burn of a hot iron." However, Dr. Hacks admits that there exists with Mlle. Couédon a mental state that diminishes her responsibility, and ends by declaring that she is a candidate for dementia.

Dr. Encausse, one of the examining commission, demurred, giving it as his opinion that Mlle. Couédon presented two conditions: the normal state and the second state. He considered her case one of the most complex problems and one of the most troublesome, and thought it better that the commission should avow its ignorance rather than formulate such categorical conclusions. Another commission of twelve members was then appointed to re-examine Mlle. Couédon, this time from a purely psychical standpoint.

Dr. Fleury, one of Charcot's favorite disciples and whose opinion is almost law in neuropathology, has no hesitation in pronouncing Mlle. Couédon a neuropath; while Dr. Seglas, physician at the Salpêtrière, affirms that she presents all the signs of a precise disease and one that has been minutely analyzed during the last few years—a typical hysteric degenerate, and submitted to all the suggestions flattering her delirium of grandeur, thinking herself the angel Gabriel.

It would, perhaps, be too much to say, in view of the diversity of opinion regarding this remarkable personage, the bulk of which seems to be that she is mentally unsound—it would, perhaps, be too much to say that if Mlle. Couédon is weak minded, she is certainly stronger than those who consult her, and the shower of gold that is falling about her is evidence of the gullability of the human race, even at the end of the nineteenth century.

We are here brought on to the old scientific ground of contention between the schools of Paris and of Nancy, into which it is impossible for us to enter. Both Charcot and Bernheim, the chiefs of the two schools, have divided hypnotism into different states or conditions, Bernheim into nine and Charcot into three. As they are essentially the same, we will give Charcot's division, as being more concise; also the rules for the application of hypnotism, as upon this point they really agree. The first is the lethargic state. It is obtained either by the fixation of an object or by pressing gently

upon the eyeballs through the lowered lids. The lethargy thus obtained is characterized by the appearance of a deep sleep, muscular relaxation, anæsthesia, often complete, with abolition of the intellectual life. In this state suggestions are impossible. There exists a muscular hyperexcitability and contractions are readily obtained by slight pressure or friction. The second is the cataleptic state. In order to make a subject pass from the first to the second state, it is sufficient to raise the eyelids. If only one eye is open that side only enters into catalepsy, the other remaining in lethargy. The cataleptic remains fixed in every attitude given to him or her; the muscular hyperexcitability has disappeared. In this stage suggestions can be produced in the muscular sense; for instance, if the hand of the subject is approached to the lips as if to send a kiss, the face becomes smiling; if the hands are joined together as if in prayer, the subject kneels. By a retrograde process it is possible to pass the subject back again from the cataleptic to the lethargic state by closing the eyelids. Finally, this state can be produced at once and directly, without the primary lethargic period, under the influence of nervous shock caused by an intense light or violent noise. The third is the somnambulistic state. This also can be produced primitively by fixation of the look or by different procedures. Lethargy or catalepsy can be transformed into somnambulism by exercising gentle or prolonged and repeated frictions on the vertex of subjects. This state is characterized by an habitual anæsthesia more or less decided, by a sensorial acuity, and above all, because the subject is essentially amenable to all suggestions, the neuro-muscular excitability no longer exists. This state can also by a retrograde process be transferred back to the cataleptic state by opening the eyes of the subject, or into lethargy by closing them and compressing mildly the eyeballs.

These three stages comprize what is called the grand hypnotism or the grand hypnotic neurosis.

In dealing with so dangerous a therapeutical measure as hypnotism—dangerous morally and physically in almost every respect—the physician, in order to safeguard his conscience and professional honor, ought to adhere strictly to the following rules:

1. Never put to sleep any patient without his or her formal consent or the consent of those having authority over them.
2. Never provoke hypnotic sleep except in presence of an authorized person—father, husband, brother, etc.—who guarantees the hypnotizer and the hypnotized.
3. Never give to the subject without consent other suggestions than those necessary for the cure. The physician should limit himself to therapeutic suggestion only.

Dr. Berillon, medical inspector of the public lunatic asylums and director of the *Revue de l'Hypnotisme*, has begun a course of lectures at the practical school of the Faculty of Medicine on the clinical applications, psychological and medico-legal, of hypnotism, and will continue them during the summer semester on Tuesdays and Saturdays.

The Société d'Hypnologie is always actively at work on the subject, and just now especially so. The next report is looked forward to with much interest. What with the increase in the use of hypnotism by the profession at large, the many books and pamphlets on somnambulism and clairvoyance, theatrical pieces representing the same, to say nothing of the daily newspapers and all kinds of séances in private houses among the laity and spiritualistic amateurs, the *jam satis est* has been reached. If these facts are coupled with the alarming increase in the number of cataleptics admitted into the hospitals, it will be seen how vast are the proportions of the hypnotic wave that is sweeping over Paris.

Another therapeutic method that is not likely to suffer for want of use is seropathy.

Dr. Toulouse conceived the idea that the serum of an animal deeply alcoholized might have a happy action in the treatment of human alcoholism. Let us hope that his novel experiment may prove of some value in diminishing this ever-increasing evil.

Dr. Toulouse made two dogs absorb forty grams, or about one and one-third ounces, of ethylic alcohol every day for one week. After this he bled them and gathered their serum, which he employed in a case of acute alcoholic delirium, with tremor, profuse sweats, and violent hallucinations. Three times in twenty-four hours he injected twenty-four cubic centimetres (thirty cubic centimetres representing an ounce). The next day, eighteen hours after his first injection, the fever fell and the patient became calm and lucid.

The case, of course, is only an experiment, but as such highly successful, and if this treatment stands the test of time and general practice it will be a great improvement on the old method of the bromides, chloral, morphine, and champagne.

SHALL WE GIVE THE APPENDIX A REST?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The somewhat incisive and sarcastic reply of Dr. Morris to the communication of Dr. McArtney is in accordance with the well-known views of the latter gentleman and as keen as his scalpel. However, it may be that the article of Dr. McArtney may provoke some views from foemen worthy of Dr. Morris' steel. Many of us who have been fortunate enough to be so situated as to spend our time and money in sitting under the droppings of the Eastern sanctuary for a limited time and have seen the skill of Wyeth, Gers-ter, Meyer, McBurney, Dawbarn, and other of "the lights," when confronted by results in actual practice of intelligent and honest country practitioners and conservative city surgeons have been led to question seriously whether "the appendix should be removed as soon as the diagnosis of appendicitis is made," or, according to Dr. Hawley (?), whether it might not be better if every one should have the appendix removed. The idea has occurred to some of us that after a time the appendix might receive the same surgical rest that the ovaries are now receiving from conscientious men, or that it might lie down with the rectum, which now no longer retracts at the sound of Whitehead, or might eventually receive the treatment now accorded a tubercular knee-joint, which is now less frequently æsthetically carved and spiked. It is now, I believe, several years since Dr. Fenger, in an article which will bear perusal to-day, said: "In these days, when surgery or rather surgeons are claiming the treatment of appendicitis to the exclusion of internal medicine, it is well to remember that appendicitis is on the whole a benign affection, with a mortality of about nine per cent." (I quote entirely from memory.)

It is somewhat refreshing also to some of us, who after a moderate amount of success in operative procedures have adopted conservative views from the inevitable logic of the facts presented by observation of many of the severer types of the disease when patients refused operation, to read the following from Dr. N. Senn: "The removal of the appendix should be limited to those cases in which during the first attack symptoms arise which portend danger to life and relapsing appendicitis. Some cases of appendicitis yield to medical treatment, and *in a large percentage of such cases* [*italics mine*] the patients remain free from a second attack." What we desire to know, and from unbiased observers, is whether the latter assertion is true. It would seem to be in line with my experience, for I can

recall but one relapse in a large number of cases seen in the past five years; that was a rapidly fatal one occurring after an operation and was wilfully brought on by hard labor before convalescence was completed.

Dr. Emory S. Lamphear, now of St. Louis, formerly of Kansas City, told me one year ago that he had ceased to operate in the majority of cases of appendicitis; that he found patients would get well without, and he evidently has no such fear of "tuberculosis of the appendix, large enteroliths, strangulating adhesion bands, portal embolism," and other spectres that Dr. Morris fears. To those acquainted with Dr. Lamphear it is unnecessary to refer to his skill as an operator or to his judgment.

I never could understand how the indiscriminate operators in appendicitis could interpret the figures of Fitz Hektoen and others, who find that thirty-five per cent. of all bodies in the dead-room show traces of appendicitis. Certainly the type of the disease is different in New York City, the recuperative power less, or, what is more probable, only the worst cases seek or are sent to the surgeon—at least the observation of intelligent country observers like Dr. McCartney is more in accordance with the statements of Fitz Hektoen and others.

I hate to "lower the caste of this article" by reference to the fee. There is no doubt that those of us who are conscientious are all perfectly honest and that we all do plenty of charity work, the majority of us without the reward of signing ourselves professor to a diploma or even a mineral-water certificate. However, I cannot forbear to quote what has passed into comic history here and is a local slang medical phrase. It is the remark of a noted consultant to the attendant: "Will she stand a laparotomy?" which referred, not to the pathological condition, but to her financial standing.

As this is written away from home while awaiting a train, my references and statements are from memory.

J. H. GREENE, M.D.

DEBUQUE, IA., May 11, 1896.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 16, 1896:

	Cases.	Deaths.
Tuberculosis.....	295	135
Typhoid fever.....	5	1
Scarlet fever.....	98	12
Cerebro-spinal meningitis.....	3	6
Measles.....	368	23
Diphtheria.....	291	33
Small-pox.....	0	0

The Passing of Antitoxin.—The Paris correspondent of the *Cincinnati Lancet-Clinic* writes under the the above caption that it seems that the enthusiasm manifested last year for Behring's antitoxin serum has commenced to diminish. Official statistics published by Bertillon give thirty-three deaths as the enormous weekly mortality from diphtheria, figures that have never been attained during any preceding year before the discovery of this celebrated so-called specific. Like the rest of serious maladies to-day treated by serum therapy, it is necessary to recognize the fact that such medication no longer keeps the promises made in its name. Besides, Drs. Sevestra, Gaucher, and Legendre have been courageous enough to make

known to the Société Médicale des Hôpitaux the serious and frequent accidents to which the antidiphtheritic serum gives rise even when applied to very simple cases of angina. But all this does not discourage the Pasteur Institute and its purblind disciples.

TO HIS DELINQUENT PATIENT.

If I should die to-night—
And you should come to my cold corpse and say,
Weeping and heart-sick, o'er my lifeless clay;
If I should die to-night—
And you should come in deepest grief and woe,
And say, "Here's that \$10 that I owe,"
I might arise in my great white cravat
And say, "What's that?"

If I should die to-night—
And you should come beside my corpse to kneel,
Clasping my bier to show the grief you feel;
I say, if I should die to-night—
And you should come to me, and there and then
Just even *hint* 'bout paying me that ten,
I might arise a while—but I'd drop dead again.
—*Gross Medical College Bulletin.*

Alleged Safe Method of Inhaling Chloroform.

According to Dr. A. Guerin, of Paris, death from chloroform may be avoided if it is inhaled exclusively through the mouth. When death occurs from stoppage of the heart, the cardiac muscular fibres cease to contract under the influence of a reflex action exerted by the nasal nerves on the pneumogastric, stimulating the inhibitory power of the latter on the heart. He further shows that when a rabbit is subjected to tracheotomy, and then made to inhale chloroform directly through the trachea, the drug has no effect whatever on the heart. On the contrary, when chloroform is held before the nose of the rabbit, the heart immediately stops. The trachea being cut transversely, it is obvious that the chloroform inhaled by the nostrils cannot reach the heart through the bronchi. Dr. Guerin therefore assumes that the anæsthetic agent exerts its injurious action upon the movements of the heart through the intervention of the nasal nerves and the cardiac branches of the pneumogastric, the former acting reflexly on the latter. Dr. Guerin therefore advises that the nose of the patient should be held by the fingers until general anæsthesia is produced, when there can no longer be any reflex action of the nasal mucous membranes anæsthetized like the rest of the body.—*The General Practitioner.*

A Prison as a Health Resort.—It is the one aim and object of some people to find the most healthy spot to live in. The latest health resort *The Hospital* has heard extolled is Pentonville Prison where during the past year, among eleven thousand four hundred and ninety-five prisoners, there has only been one death. Whether the argument is most in favor of limited diet and plenty of work, or of the healthiness of the locality, or all three combined, it is not possible to state definitely.

Women Doctors in India.—From an official report of the National Association for Supplying Female Medical Aid to the Women of India we learn the following: In eleven years since its organization, under the name of the Lady Dufferin Fund, the number of women and girls annually relieved and cured has risen in 1895 to above a million (1,054,387), and in the last three years the number has doubled itself. The movement has a pathetic history. After suffering for years from native quacks, the Maharanee of Punnah, the diamond-deposit State of Central India, was cured by an English lady—a medical missionary. Her Highness wrote to Queen Victoria, inclosed the letter in a gold locket, put the jewel round the doctor's neck, and charged her not to take it off until she gave it into the Queen's hands. Her Majesty sent a

kind answer, and laid on the next new Viceroy, when dismissing him, the "special injunction" to launch a scheme for the improvement of the medical treatment of her Indian female subjects. With Irish impetuosity and Scotch thoroughness combined, Lady Dufferin organized the fund all over India, and in London also, for training native women doctors, as well as healing the suffering. The invested funds amount to £129,000 at par, and the income from all sources last calendar year was £115,545. With this a million of suffering women were cared for, in addition to the many who came under the ministrations of the medical missionaries, American as well as British. Were progress more rapid, especially among the high-caste ladies, who must be attended in the *zanana* and harem, there would not be women doctors enough. Lady Elgin, Lady Elliott, and other governors' wives have brought about the foundation of hostels for native women studying medicine, obstetrics, and nursing. The Hon. Mr. Woodburn, an experienced civil servant, declared at the annual meeting in Calcutta lately that "the rapidly growing and now enormous attendance at the Dufferin hospitals is the best possible evidence of the trust of the people in the treatment they receive there." As the general education of women in India rises, the number of female candidates for the higher grades of hospital assistants and assistant surgeons will increase, however slowly. It is sixty years since Dr. Duff induced some of his best students to learn to dissect the human body, and now the Indian Medical Service has many native members, while the cities of India are flooded with fully qualified native practitioners. The same will be true of the women half a century hence.

Cetrarin.—According to Kobert, cetrarin, the active principle of the lichen *cetraria islandica*, stimulates the peristaltic action of the stomach and the bowels, increases the number of the blood corpuscles in cases in which they have diminished in the course of disease, and is a general tonic for the nervous system. Cetrarin, therefore, is indicated in chlorotic, anæmic cases in which there is constipation and loss of appetite. Dose prescribed: one-eleventh gram.—*Progrès Médical*.

Physiology of the Primary Schools.—Physiology is to study about your bones, stomach, vertebry. Occupations which are injurious to health are car-bolic acid gas, which is impure blood. We have an upper and lower skin. The lower skin moves all the time and the upper moves when we do. The body is mostly composed of water and almost one-half avaricious tissue. The stomach is a small pear-shaped bone situated in the body. The gastric juice keeps the joints from creaking. The chyle flows up the middle of the backbone and reaches the heart, where it meets the oxygen and is purified. The salivary glands are used to salivate the body. In the stomach starch is changed to cane sugar, and cane sugar to sugar cane. The olfactory nerve enters the cavity of the orbit, and is developed into the special sense of hearing. The growth of the tooth begins in the back of the mouth and extends to the stomach.—MARK TWAIN, in *West Virginia Medical Journal*.

A Good Pavement.—With reference to the agitation as to a new pavement for Fifth Avenue we would call the attention of those in the city government who have charge of the matter to the experiments lately conducted abroad with cork to obtain a new and superior pavement. The pavement used in Vienna consists of granulated cork mixed with mineral asphalt and other cohesive substances, compressed into blocks of suitable size and form. Among the numerous advantages set forth in its behalf are cleanliness, noiselessness, durability, elasticity, freedom from slipperi-

ness, whether wet or dry, and moderate cost. Unlike wood, too, it is non-absorbent, and consequently inodorous. It presents the minimum resistance to traction, and, being elastic under passing loads, does away with the vibration caused by heavy teaming. The blocks are embedded in tar, and rest upon a concrete base six inches thick. When taken up for examination they have exhibited, when compared with new ones, a reduced thickness by wear of less than one-eighth inch—this in the case of a section of a London street leading to the Great Eastern Railway station subjected to continuous heavy traffic, the blocks having been in use nearly two years.

Abnormality or Madness?—Perhaps it is too much to hope that the wit of man will ever be able to devise a strict criterion which shall mark off sanity from madness. Yet the fog in which we are involved as to the extent to which man is responsible for what he does is becoming denser every day. It is a misfortune that this question has chiefly arisen and been discussed in regard to grave and serious cases—cases of murder, in which the alternative of insanity has been death, for it can hardly be denied that in many such cases the plea of insanity would hardly have been invoked, and certainly would not have been listened to, but for the knowledge that a bald verdict of guilty involved an irrevocable sentence. Two very recent cases have shown on what very slight evidence of insanity, other than that derived from the crime itself, it is possible to escape the extreme penalty and it becomes a matter of much interest to inquire to what extent the doctrine of irresponsibility which is urged in murder cases is to be taken as applicable to the little crimes and peccadilloes met with in daily life. We all know that such a malady as kleptomania exists, yet how sceptical we are when a case occurs, and how the people grin with satisfaction when they find a magistrate refusing to listen to such a plea. Kleptomania, however, is none the less a fact, and if sudden impulse be admitted as an excuse at all we may well question whether it has not been the real cause of many crimes which nevertheless have received the punishment due to wilful malice. It is, however, in matters of ordinary conduct rather than of crime that the question of responsibility becomes of interest in our social relations. Clearly, so far as oddity can be taken as explaining and excusing crime, it should be admissible also as proof of that insanity the presumption of which is accepted as the crime's excuse. The doctrine is growing up that to be abnormal is to be irresponsible. But what a field of abnormality there is around us! Surely these odd people are not all insane! We have amongst us those who believe in the supernatural, and profess that in their comings in and goings out they are surrounded by spirits who influence them and guide them in their daily life. Are they mad, and, if not, how shall that man be excused, who, urged on by spirit voices in his ears, is driven with uncontrollable impulse to slay his neighbor? What, also, about immorality and defiance of custom: how far may man or woman outrage the social rules prevalent at the moment without risking the asylum? Every one laughs at "The Woman Who Did," and says she was cracked upon her one idea. But how about her imitators in the flesh? Are they also mad? Are socialists mad, or is it only that a rich socialist is crazy while a poor one is a clever fellow? Who, indeed, is mad—the idle tramp who wanders o'er the country the summer through, no doubt suffering many discomforts but still enjoying life, or the honest worker who slaves in a mill, and lives in a slum, and dies in the workhouse? Normal man is often but a mean fellow, and we must be careful how we accept mere abnormality of conduct as proof of irresponsibility.—*The Hospital*.

THE PROPAGATION, PRESERVATION, AND USE OF VACCINE VIRUS.¹

By FRANCIS C. MARTIN, M.D.,

BOSTON, MASS.

MR. PRESIDENT, LADIES, AND GENTLEMEN: During the twenty-five years that have elapsed since the introduction of true animal vaccination in this country in 1870, the many mooted points regarding it have been thoroughly disposed of by careful observation and experience, so that to-day we can fairly say that we have quite as exact a science in this as we can ever hope for in any branch of medicine. Many observations have been confirmed, many theories have been exploded, but the grand result that has been obtained is this—that all earnest students of the subject now agree that pure animal vaccine virus, transmitted uninterruptedly from one young bovine animal to another, is far superior to all other forms of vaccine. This is true both of the results in individual cases and of the protection afforded to large communities on the advent of an epidemic of small-pox. The large proportion of active practitioners to-day have had but little experience with any form of vaccine other than that taken directly from the animal, or perhaps a few removes from this through human subjects.

To understand clearly the present status of vaccine production, however, I hope that some of you to whom it may be an old story will pardon me if I glance briefly at the various sorts of vaccine that have been employed during the century whose completion we celebrate to-day.

First of all, we have the Jennerian vaccine, viz., the virus taken by Jenner and his contemporaries directly from animals in whom the disease occurred spontaneously, inserted into the arms of human subjects, and carried from arm to arm through a succession of infants down to the present time. This virus is still used in England to some extent, although in recent years, since the establishment of a government institution for propagating calf lymph and of a number of private establishments for the same purpose, it is rapidly going out. In America, this was the vaccine in general use prior to 1870, and when the infants vaccinated were carefully selected and healthy, it was superior to any other sort of virus employed before the systematic production of pure animal vaccine.

Secondly, in several countries there have been cases of cow-pox discovered at different dates during the last sixty years, from which virus was taken and propagated thereafter from arm to arm. This gave a vaccine nearer to the animal than the Jennerian lymph, but in a few years it became indistinguishable from the latter in the vesicles produced and other symptoms.

The great objection to these "stocks" of vaccine has always been that in the course of years their vigor has steadily deteriorated, producing less and

less constitutional effect and more and more short-lived vesicles. To counteract this in the case of the Jennerian lymph, more insertions were made in the arms of the patient, often as many as nine in each arm. Even now, from three to six insertions are customary with many European physicians. This is entirely unnecessary with animal virus. My custom is to make two scarifications on the left arm or leg, but one typical vesicle is quite sufficient.

I will not weary you with a long dissertation on the dangers of a third form of vaccine, obtained from the variolation of kine, or the serious defects of retro-vaccination—that is, the vaccination of animals with humanized virus. These different forms of virus will always have great scientific interest to experimenters, but we have happily arrived at a stage of vaccine production where we can ignore them as having any important bearing on the practical part of the subject.

Not one of all these varied forms of virus can compare in practical value to-day with true animal vaccine. Perhaps this statement seems rather *ex cathedra*, but I have ample reason, begotten by many years of experience, for affirming its truth. Unfortunately, however, there is no time to enter upon a statement of it here.

True Animal Vaccination, as we now understand it, originated in this way: On March 28, 1866, a case of spontaneous cow-pox was discovered in a heifer thirty months old, at Beaugency, Department of Loire, France. From virus derived from inoculation from this animal, Professor Depaul, directeur de la vaccine, continued the propagation of pure animal vaccine by inoculation of one young heifer directly from another, at Paris, under the auspices of the Academy of Medicine. Various other cases of spontaneous cow-pox have been discovered from time to time, and with virus from such animals vaccination is now carried on in almost every country in Europe.

The Beaugency stock of virus produced by Professor Depaul was the one introduced into this country by my father, Dr. Henry A. Martin, in 1870. He wrote most indefatigably and used all his efforts unsparingly to secure the adoption of this new method of vaccination; but the results exceeded his most sanguine hopes. Within two years the profession had adopted the method enthusiastically and almost universally.

Since that time results have only strengthened the favorable reception accorded to true animal vaccination, and to-day physicians who use humanized virus, even of a few removes, are so rare as to be remarkable. I acknowledge, as regards these gentlemen, that animal vaccine, carried through one remove, viz., through a perfectly healthy child, is an excellent virus. But with every further remove comes greater and greater risk of some imperfection in the child, and so danger to the character of the virus. This danger is by no means so great as is popularly supposed, but it is real and demands consideration.

With ample opportunity to-day of securing pure animal vaccine, I can see no excuse for the use of long-continued humanized lymph. Any serious complaints against animal vaccination can be traced to improper methods of producing or keeping the virus,

¹ An address delivered before the General Session of the American Medical Association, at the Jenner Centennial Celebration, Atlanta, Ga., May 7, 1896.

but can never be fairly made against pure virus, produced honestly and scientifically, and in the best manner.

True Animal Vaccination is the inoculation of a young selected animal of the bovine species from an original spontaneous case of cow-pox, from this others, and so on, in continuous and endless series, as the source, and the only source, of virus for the protection of the human race against variolous disease. This is the definition given by Dr. Henry A. Martin in his report to this association in 1877, and I cannot improve upon it. It is in accordance with this definition that the Beaugency stock, brought here in 1870, has been continued constantly up to the present time. I am sure of one point, however, that was still in doubt during my father's life. There is no fetich or charm in any particular "stock" of virus, provided the original case of cow-pox is unquestionable, and provided, too, that the virus is propagated properly and on animals of the right age, continuously from the start. This last matter is of essential importance.

The Propagation of Animal Vaccine, as at present carried on, may be broadly divided into two varieties, viz., the European method, which now obtains very generally throughout Europe, and the American method, or that introduced here by my father and still practised with some modification by myself.

Various so-called "improvements" of the latter method have been devised by persons of more ingenuity than ingeniousness, which are doubtless "labor saving" and pecuniarily profitable, and which I must presently refer to, but only to warn you against them.

First, then, let us consider the European method. A young bovine animal, from six weeks to six months old, according to the ideas of the different institutions, is strapped upon its back with its legs distended, on a specially adapted table. The entire abdomen is then shaved and washed, and the operator takes a rather heavy instrument, shaped like a bleeding-lancet at the point and flattened at the sides, with which he makes a series of rows of line cuts, about one inch long and one and a half inches apart, through the cuticle, merely deep enough to draw a slight tinge of bloody serum. On the flat surface of the instrument are the crushed particles of the crust of a matured vesicle from another animal lying on an adjacent table. As the operator cuts with the point of the instrument, he turns the flat side to the cut, and quickly rubs in the bits of vesicle. This is done very rapidly, so that the entire abdomen is inoculated in a very short time. The calf is then released, and returned to the stable. On the maturity of the vesicles, which is about the fifth day afterward, the animal is replaced on the table, when we see, instead of the rounding vesicles to which we are accustomed here, a series of very narrow lines of inflammation, with vesicular edges. The belly is carefully washed, and the operator seizes enough of the loose abdominal skin with a special sort of curved lock forceps, to completely include the whole of the vesicular line. The entire vesicle is then scraped off with the edge and carefully preserved on the flat side of the vaccinating instrument. This crushed vesicle is immediately inserted into other animals and into the arms of patients. To preserve the virus for future use and to send out to physicians at a distance, a number of the vesicles scraped off as I have described are put in one mass in a sterilized agate mortar, and immediately mixed with absolutely pure glycerin and filled into tubular glass bottles. These are carefully corked, dipped into paraffin, and put away in a cool, dark place. They are kept thus for several weeks, and it is claimed that by this process all the extraneous micro-organisms present in the lymph are destroyed, while the activity of the virus is in no way deterio-

rated for a long time. After this period of purification, the contents of the bottles are thoroughly triturated with a little sterilized distilled water. This is done by means of a special triturating machine, of elaborate construction, which reduces the mass to a fine homogeneous emulsion. This is filtered and then put up in capillary tubes, "lymph squares," and vials. These are merely different forms of putting up the lymph, but the substance is the same in all of them. The use of ivory points in Europe has been almost entirely superseded by these tubes and "squares."

I will reserve any criticism of this process, gentlemen, until I have described to you the American method, which is as follows:

I take a young bovine animal, about eight or ten months old, selecting perfectly healthy, clear-skinned animals that are thoroughly weaned and can live entirely on hay and meal. The younger the calf the better, so long as it answers these requirements. I place the animal on its side on a special table, and have portions of the escutcheon and belly shaved and carefully washed. I then vaccinate in precisely the same way as in the human subject, by transverse scarifications, drawing a little blood-tinged serum, but making a scarified surface about two-thirds as large as the thumbnail and nearly circular. I use a square portion of the abdomen, anterior to the teats, and place the scarifications in rows of four or five, about two inches apart. My object is to produce a vesicle as nearly as possible to resemble the natural eruption of the disease. I vaccinate directly from another animal.

Up to this point, you observe the differences of procedure from those in Europe are rather of detail than of important essentials. But here comes in the radical difference of the two methods, which lies in the collection and preservation of the lymph. Having scarified the fresh animal, I turn to one on which the vesicles have matured, and selecting a typical vesicle. I carefully remove the crust *in toto* and throw it away. Lying under the crust is a thin layer of cheesy pus, perfectly innocuous perhaps, but still pus. This is carefully washed away, leaving a bare, raw surface. Thorough cleanliness is used in all these steps, but no antiseptics are employed, as they would simply destroy the virus. As a rule, I apply no pressure to the denuded surface but leave it severely alone, and at the end of several minutes small drops of a sticky, amber-colored fluid are seen oozing out all over the vesicle. These coalesce and constitute the fluid vaccine lymph, which I use to rub into my scarifications on the fresh animal. To secure lymph for future use and to send away, I have the ivory points dipped carefully by hand, one by one, in this same lymph, dried in rows upon shelves, and then immediately packed in small bundles covered with cotton and silk paper, and hermetically sealed up in gutta-percha tissue. These packages are shut up in air-tight glass jars, away from the light and packed in ice, and always sent out with a caution to keep the vaccine cold, dry, and dark. The best practice is to keep them in a corked vial in a dark refrigerator.

This, gentlemen, in brief, is my method of producing animal vaccine, and an experience of over twenty-five years with it has convinced a large portion of the profession of the country, as well as myself, that it is by far the best, most scientific, and most reliable method. Certainly it is the one best adapted for the climatic conditions of America. The essentials of dryness, darkness, and cold, which are requisite to keep the virus properly, are easily obtained here, where our climate is, in general, dry; and where the use of ice and refrigerators is so universal. In many parts of Europe, the damp climate and the extreme rarity of ice, makes a strong argument in favor of the

tubes, which are not so easily affected by climatic conditions.

Vaccine virus produced in the manner employed by myself secures typical vaccine vesicles, without any undue severity of symptoms, and affords perfect protection against variola. It is very important to bear in mind the fact that a very sore arm is no proof of proper vaccinal effect.

But it must be remembered that a very large percentage of the vaccine in America is produced by men who, under the guise of some "vaccine company" or "vaccine farm," look entirely to the commercial side of the matter, and, although utterly unheard of in the scientific world, are keenly alive to any method of making more money.

To these persons my method has these very serious objections, viz., that it takes constant care and skill, that it is expensive, and that the supply of virus from one animal is so limited. In other words, to supply a large number of vaccine points, a large number of calves must be employed.

Now, it has long been known that the greater the age of the animals vaccinated, the more marked and severe are the symptoms produced; and, further, it was found that by increasing the size of the vesicles a very much larger quantity of serum, "virus" by courtesy, could be obtained, although much thinner and more dilute.

From these facts the brilliant theory was evolved that an ideal virus could be obtained by using full-grown cattle, three or four years old, and making deep scarifications two inches square or larger. These scarifications in no wise resemble a vesicle, but make a large angry sore, and when ruptured an enormous quantity of thin serum is poured out.

But, argued these *sarans*, by this means we can get a large amount of virus from one cow and the dilution of the lymph will be counteracted by the greater vigor obtained from the full-grown animals. This idea appealed with great force to the commercial mind, and in accordance with it millions of vaccine points have been produced. The method is labor-saving and cheap, but the theory is utterly wrong, the fact being, it is true, that the larger the animal used the more vigorous the vaccine germ and the more violent the effects on the human subject, but the change from a small vesicle to a large angry sore only increases the flow of inflammatory serum, tending in no way to lessen the vigor of the vaccine germ, but very much diluting the amount of these germs in the so-called virus. In other words, the amount of true virus is not increased, but it is obtained adulterated with a large amount of serum. The practical results frequently obtained from such virus are either very sore and troublesome arms or no vaccinal effect whatever.

Another labor-saving improvement which I must warn you against is the method of fixing the ivory points between two strips of rubber-covered wood, in rows of fifty to one hundred, so that they resemble a picket fence. The operator then ruptures the vesicle, dips a camel's-hair brush in it, and paints the pointed ends of the points over rapidly with the brush, leaving an almost invisible coating of vaccine on them. This can be done so rapidly that an ordinary day's work by the proper method is nominally accomplished in fifteen or twenty minutes. Some of the points prepared in this way will take. A great many will fail. There is no possible excuse for this method of charging the points, nor for the method of large scarifications on full-grown animals, except that they are "labor-saving" and "money-making." On all scientific grounds they are unqualifiedly bad and objectionable.

During the past year I have investigated the reasons for the preference in Europe for tubes rather than for points. From conversations with the authorities

there and a careful observation of their methods, I am convinced that the modern tube, prepared as I have described above, is much more reliable than the old-fashioned tube of clear virus taken directly from the vesicle.

Our method, however, of charging the ivory points is much more simple, economical, and reliable, and we certainly obtain a far purer virus at the start. The vesicle which they grind up and use is not the old-fashioned vaccine crust, with which many of you are familiar. That was the dried covering of the vesicle, which was allowed to remain undisturbed until it dropped off naturally at about the twentieth day. It was then cleaned thoroughly and scraped, and was perfectly dry and almost odorless. The European crust is taken at the height of the disease, when its reticulations and under surface abound with pus cells, and these are all included in the mass that is combined with the glycerin. I am not prepared to deny that this combination renders all the germs present, except the vaccine germ, inert and innocuous. I only say that, if true, it is an extraordinary fact, and that certainly the pure, clear virus that is collected on the points, after all the pus is removed, is a very much purer lymph, as it is taken from the animal.

The real reason, as it seems to me, for the adoption of these tubes in Europe lies in the difficulty of preserving the points in a moist climate and of obtaining ice with which to keep them. We have no such difficulties here, and with us the ivory point will long keep its supremacy as the best form of preserving and using vaccine.

I will only detain you, gentlemen, with a few words regarding the use of the vaccine points.

Every one of you has his favorite way of vaccinating. My way is to make two sets of scarifications about two inches apart. I cut with a dull bleeding-lancet about half a dozen short lines close together, just deeply enough through the skin to draw a tinge of serum and blood. These I cross with a similar set of cuts at right angles. I thoroughly dissolve the virus on the point with a little water, then wipe the cuts thoroughly, and immediately rub the virus into the cuts for about ten seconds with the flat side of the point. Then I expose the arm for one minute to the air. No plaster or subsequent dressing is necessary. The arm should be washed at bedtime. In three or four days the vesicle will begin to appear and will be at its height in about eight or nine days, after which it will decline. Unless the crust is broken there will be no severe symptoms with good virus, and indeed there should never be bad and sloughing arms if the patient is in any reasonably healthy condition at the time.

Antivaccinationists Getting Vaccinated.—Gloucester, in England, sixteen miles from Berkeley, where Jenner made his discovery of vaccination, has been visited with an epidemic of small-pox. The "antis" in the place have for years been vociferous in their opposition to vaccination, but when the outbreak of the disease began to assume alarming proportions, almost every one of them hastened to get vaccinated. Some of these had the honesty to confess that they had been in error, but the majority said nothing at all, being vaccinated quietly, some even going to towns at a distance from Gloucester in the hope that the fact of their apostasy from the holy cause of the antis might escape publicity. The editor of the paper which had led in the antivaccination crusade could not get away, so he published a card to the public, announcing that he had been "influentially urged" to get vaccinated, and hence he had sacrificed his "personal convictions" in the hope of contributing to "the public good." The rôle of martyr in a bad cause is evidently not to the liking of this little man.

THE VALUE OF FORCED ARTIFICIAL RESPIRATION (FELL METHOD) IN SAVING HUMAN LIFE IN CHLOROFORM, ETHER, AND NITROUS-OXIDE NARCOSIS, TOGETHER WITH THE ACCOUNT OF A REMARKABLE CASE IN WHICH IT WAS USED FOR FOUR DAYS AND THREE NIGHTS UPON A PHYSICIAN, RESULTING IN SAVING HIS LIFE.¹

BY GEORGE E. FELL, M.D., F.R.M.S.,

LATE PRESIDENT OF THE AMERICAN MICROSCOPICAL SOCIETY, ETC., BUFFALO, N. Y.

First Cases.—The first attempt I made to save life by forced artificial respiration was July 23, 1887, the subject a human being, and the operation resulted successfully. The laboratory apparatus used at that time merely demonstrated the value and safety of the principle which, previous to this and my following cases, had been universally condemned as not only unreliable but dangerous to use. The prevailing opinion at that time was that the air vesicles of the lungs would not resist forcible mechanical measures in artificial respiration. The medical world had accepted the views of the celebrated English physician, Marshall Hall, to "avoid the use of bellows or any forcing instrument" in his ready method in asphyxia. In this first case it was found that no lesion or interference with the pulmonary tissue had been produced, although the case came near being a failure through the laboratory apparatus used being unsuitable in its application to man. In my second case, a much more difficult one, I succeeded in saving my patient after breathing for him fourteen and one-half hours, which I could have accomplished only through the new apparatus which I had specially devised for use upon human beings. Since then, December 10, 1887, some one hundred² human lives, which would certainly have been sacrificed by the methods at the command of the profession at that time, have been saved through forced respiration. Most of these cases have been saved at my hands with few exceptions in the city of Buffalo, where I reside. It may be truthfully asserted that the manner in which I have utilized forced respiration is the only one in which it has been systematically demonstrated to be of value in saving human life.

Author's Method with Face Mask.—The introduction of the use of the face cup or mask has also overcome the prevalent idea that the epiglottis would fall and close the glottis in forced respiration. Many lives have been saved by it without necessitating the operation of tracheotomy, and its use has demonstrated that intubation is seldom needed, although its value must not be lost sight of in forced inspiration, as I intimated in my first writings upon the subject. My work has also demonstrated the uselessness of double-bellows and double-cylinder schemes, which had long been advanced and had failed as measures for artificial respiration. They will never be utilized in forced respiration when the same work can be more thoroughly and more easily applied and at less expense by the measures I have utilized.

Many believe forced respiration to be of value only in cases of opium narcosis, the field in which I first systematically utilized it.

This is far from the truth, as many cases have demonstrated, so that the broad assertion may be made without fear of contradiction that it will keep up the respiratory action in man better than any other method

of artificial respiration now known. These statements are all borne out by cases fully recorded by the author in various medical journals, and it may be stated that in all cases of asphyxia or superficial respiration from any cause in which artificial respiration may be needed, it is the most easily applied and most reliable method now known. One of the cases detailed to-night goes so far beyond the expectation of any one acquainted with the subject as almost to surpass belief. It is, however, so well authenticated as to do away with any question of doubt.

Cases of Chloroform and Ether Narcosis in which the Patients were Saved.—We will first look into a few cases, heretofore unreported to a medical body, which affect the everyday experience of the medical and dental practitioner. Within some months I was called in council to attempt the reduction of a strangulated hernia. The anæsthetic was chloroform. Thorough anæsthesia was produced slowly and carefully, but the method by taxis failed to reduce the hernia. Deeper narcosis was produced and the patient stopped breathing. I applied forced respiration by the face mask for five minutes and auto-respiration ensued.

The anæsthetic was used again, the respiration ceased the second time, and again the apparatus was used with similar results. Operation revealed an omental hernia which could not have been reduced by taxis. However, under the chloroform, what a weight of anxiety was lifted from our minds by the satisfactory working of the forced respiratory apparatus! I did not use the Sylvester method, because I had no faith in it as compared with my own method and wanted to take no chances, the method of forced respiration being much easier in application and more effective.

Another everyday case occurred in this city, in which ether was used as the anæsthetic—a case of a young lady being prepared for a surgical operation. The respiration ceased, the Sylvester method failed to establish auto-respiration, the patient was taken to the Fitch Accident Hospital, where the apparatus was used for about half an hour, and the patient's life was saved. Thus, in cases of chloroform and ether narcosis we do not require to merely present an opinion upon the efficacy of this method of artificial respiration over all others, but give you facts which, connected with the results of this work in the past, are worth a multitude of dissertations founded, as generally is the case, upon experimentation on animals. Right here I might say that I have not made progress by such methods, and it is an interesting fact, which a remarkable array of circumstances has brought about, that all of my experimentation in the saving of human life by forced respiration has been made upon living human beings. My first attempt to save life by this means, as stated, and in which I succeeded, was made upon a human being.

Value in Nitrous-Oxide Narcosis.—But let us relate the value of the method with that other most frequently resorted to anæsthetic used in dental operations, nitrous oxide, and note the results. Here in this city of Buffalo we can present contrast cases of a most interesting nature, through which the value of forced respiration is made to stand out with great clearness. There is no subterfuge under which you can dim its value. To it alone must be given full credit for the saving of these human lives, and these cases cannot be obscured by the petty jealousies of professional life. The results of my labor in this line may be dimmed temporarily, but will eventually shine all the brighter when its true magnitude comes clearly to the light of the fullest investigation.

Dr. Longnecker, of this city, a dental practitioner, had administered nitrous oxide thousands of times. About one year ago a young married lady was taking

this anæsthetic at his hands in the presence of her husband. She ceased breathing. Sylvester's method of artificial respiration was resorted to. Dr. Marcel Hartwig, one of our most able Buffalo practitioners, a surgeon of experience and repute, was summoned, and with assistants worked faithfully to save the patient's life. Her heart kept on beating for fifty-five minutes, and yet death stepped in, when, as we will show, her life might have been saved had proper appliances been at hand. Dr. Hartwig stated to me that he did not think of my work or apparatus at the time, and he believed it would have saved her life. The following case would appear to justify this belief. I am indebted to Dr. F. W. Low, of this city, for the facts here stated:

"Report of Case of Nitrous-Oxide Narcosis Threatening to Result Fatally, Resuscitated by the Use of the Fell Forced-Respiration Apparatus. Occurred July 31, 1894.

"Patient, Mrs. G—; nationality, Irish; age, twenty-six years; occupation, trained nurse. Anæsthetized for extraction of right inferior *dens sapientie*. The gas was exhibited to the amount of six or seven gallons. No unusual pallor was noticed during inhalation. When the pupillary reflexes indicated complete anæsthesia, the tooth was extracted. The patient sat quietly in the operating-chair, apparently able to recommence respiration, and inasmuch as it is my habit to allow a moment to intervene after extraction before attempting to arouse one to consciousness, no alarm was felt at first. When I attempted to arouse her, however, it was found to be impossible. I then unhooked her corsets and cut all waistbands, and attempted to induce respiration by telescoping the short ribs and then suddenly letting go. Previously, during eighteen years' experience with nitrous oxide, this method had always resulted in the re-establishment of normal respiration. After several attempts of this character had proved unavailing, I dispatched my assistant for my neighbor, Dr. Charles S. Butler, who practised dentistry in the same building, and told her that after summoning him she should go to the nearest telephone and call the Fitch ambulance, with the request that the hospital surgeon should bring with him 'the Fell forced-artificial-respiration apparatus.'

"Dr. Butler came immediately to my assistance, but before he arrived I had opened the mouth and drawn the tongue well forward to open the air passages, and had again attempted several times to start respiration by telescoping the short ribs. Upon his arrival the patient was placed on her back on the floor, a pillow first being placed under her shoulders, and artificial respiration was attempted by the Sylvester method. Some slight amount of air must have been forced into the air passages, inasmuch as the patient did not become badly cyanosed, but still no voluntary respiratory effort could be induced, and Dr. Butler discovered that the radial pulse had become very indistinct. Applying his ear to the region of the heart, he reported its action as being both very feeble and irregular. I resorted immediately to a hypodermic injection of from fifteen to twenty minims of brandy in the arm. The heart's action was soon observed to be somewhat improved, but the patient appeared to become if anything more cyanosed, in spite of our efforts at artificial respiration.

"Upon arrival of the ambulance surgeon probably fifteen or twenty minutes had elapsed since the case had become alarming. The Fell apparatus was immediately brought into use, and hypodermic injections of fifteen minims of digitalis and one-thirtieth grain of strychnine were administered.

"I was not present when it was finally discovered that the patient could breathe for herself, but I judge that it must have been nearly or quite thirty minutes after the arrival of the ambulance surgeon.

"The patient was now removed to the hospital, where I visited her an hour later and found her convalescent. She was able to be about her duties in the afternoon of the same day, though feeling very much 'out of joint,' as she afterward told me, probably the result of my heroic effort before the arrival of the ambulance surgeon.

"I have recently learned that the patient reported in the above case had, during the early morning hours of the day of operation, resorted to hypodermic injections of morphine at different times, in all amounting to three-fourths of a grain. This was for the purpose of allaying the intense pain which she was suffering, not only in the offending tooth, but still more so in the regions of that side of her head.

"F. W. Low."

Will any one, I ask, question whether Dr. Longnecker's patient could have been saved in the face of Dr. Low's recital of his most important and interesting case? In the latter the previous administering of the morphine added difficulty to the work of the apparatus, but renders the result more important. Have we not now the right to ask who will be the next to let their patients die when they may be kept alive by the exercise of a little right-minded forethought? Thousands of physicians and dentists are as placed to-day ignorantly ready to take their chances in dealing with the lives of patients entrusted to them. It would seem from these cases and others similar in nature which might be reported, that forced respiration might prove almost a specific in such cases.

The Case of Dr. Henry J. Williams.—The patient in this case had been a student in the medical department of Niagara University, Buffalo, N. Y. He had passed the general examination of the faculty of the school and taken the regent's examination to enable him to practise medicine in the State. During the entire course of his studies he had been employed as night out-door collector in the work of the Buffalo Post-Office Department. He was overtaxing his mind and body to a marked degree. During the last few months of his medical course he had resorted to tincture of nux vomica, twenty minims, three times daily. Owing to the inconvenience of carrying the liquid, he had resorted to strychnine, one-fortieth grain, three times daily per stomach. On the night of July 2, 1894, he had been without sleep and needed rest for five days and nights; in fact, was a thoroughly exhausted man.

About 1:30 A.M., July 3, 1894, under these conditions, he administered to himself hypodermically two one-fortieth-grain tablets of strychnine. He did not obtain the bracing-up effect desired so soon as he expected, and in a short time repeated the dose. He then took another one-fortieth, when the drug manifested its toxic effects in twitching of the muscles and tendency to opisthotonos. At this he became frightened and gave himself a hypodermic injection of one-fourth grain tablet of morphine and atropine as an antidote, and repeated the dose twice at short intervals, as the convulsions had continued to increase. He stated that he did not believe his life to be in danger at any time—did not think it necessary to call a physician. The truth is that he was dazed and stupid, and was fast losing control of his faculties. He subsequently stated that he had the dreamy recollection of repeatedly administering the morphine hypodermically until he became unconscious. There is thus no certain evidence of the amount of morphine and atropine administered. It was about 2 A.M. when the last drug was administered, and about seven o'clock next morning when his father discovered him on the floor of the bathroom, unconscious and cyanosed.

Dr. Archie Drake near by was summoned. He was

followed by Drs. Wesley C. Earl and Thomas Bagley. The latter on consultation administered hypodermically a dose of strychnine. Dr. Sydney A. Dunham next came upon the scene. He wisely proceeded to perform Sylvester's method of artificial respiration, which was beneficial in a degree, as it held the life of the patient until my arrival at 8:30 A.M.

First day, Tuesday, July 3, 1894. Condition of patient on my arrival: Unconscious, reflexes absent, cyanotic, pulse at wrist weak, with difficulty to be detected. An occasional gasping respiratory effort was made. With a hasty glance at these different features, I immediately applied forced respiration with the face mask. Whether it did any good or not, I felt that the case was so desperate as to warrant the operation of tracheotomy, which was immediately done. Hemorrhage persisted, so that it was 9 A.M. before the forced respiration was systematically under way.

In a short time the pulse improved at the wrist, but the cyanosis passed slowly away. At 11 A.M., after two hours of forced respiration, the patient opened his eyes and in a startled manner asked, "What is the matter?" and immediately relapsed into unconsciousness.

The desperate condition of the case being evidenced by the unusually slow response to the efforts being made, it was thought best to administer oxygen gas with the forced respiration. A supply was obtained and connected with the oxygen tube of the apparatus. It was used throughout the case, but it was found that the oxygen alone was not sufficient to retain the life of the patient.

During the whole of Tuesday afternoon and night, July 3, 1894, the first day and night, the apparatus was in continual operation.

Second day, Wednesday, July 4th, Independence day. I had arranged to visit my family and take part in the festivities away from the city, and at 11 A.M., with this object in view, I removed the tracheotomy tube from the neck, expecting that the auto-respirations would ensue and that with the aid of the oxygen gas continuously administered the patient would be enabled to exist without the aid of the respiration apparatus. Then, again, Dr. Williams had now been kept alive by these special artificial means for a longer period of time than had ever occurred previously in the history of forced respiration. We had been continuously at work with him for twenty-six hours. I left the patient in the hands of Dr. Earl Lothrop and Dr. R. R. Taylor, and nurse Mrs. Edmunds, and left for my office to take the boat for Crystal Beach. On arrival at my office I was summoned back with the unpleasant news that the oxygen supply had given out. I gave instructions to have the supply renewed, and hurried back to the patient. He was breathing with considerable exertion, but was somewhat relieved by the renewal of the oxygen supply, so that I made another attempt to get away. I had not reached my city office and residence before a telephone message was sent again, urging my immediate recall, with the admonition that the patient was breathing with great difficulty and had become cyanotic. On again reaching the patient I found that in addition he had relapsed considerably. I then gave up all hopes of having a vacation, and replaced the tracheotomy tube in the neck.

2 P.M., July 4th. I again renewed the forced respiration with varying proportions of oxygen gas, and kept it under way continuously until 9 A.M., July 5th, or the second long-continued period of forced respiration, viz., twenty-one hours.

Interesting Influence of Forced Respiration in Reducing Temperature.—At the beginning of this second long-continued respiratory effort the temperature in the mouth registered 104.5° F. At the close

it was 101° F., or a reduction of three and one-half degrees. Nothing in the line of antipyretic medication had been utilized, and the decrease in temperature had not taken place under the administration of the oxygen gas. Or, in other words, all agents utilized were of no avail without the mechanical respiration; it alone was the necessary factor in the life of the patient; and, owing to the perfectness of the method and its similarity in influence to physiological respiration, its tendency was toward the toning up of the system and the overcoming of the abnormal condition existing.

This speaks volumes for the perfect working of the simple apparatus and for the complete and instantaneous control the physician has over the character of the inspiration, he having it in his power to shorten or lengthen an inspiration or expiration, to change instantly from one to another, and thus to aid the auto-respiratory effort when attempted on the part of the patient. This is effected by the arrangement of the air-control valve, which is simple and yet does its work entirely at the option of the manipulator. Other methods recommended will not accomplish this so readily.

Third day. On the third day of the case, Thursday, July 5th, the question as to the probability of the patient ever being able to breathe for himself was becoming, indeed, a serious matter. It was with a view of giving him an opportunity to do so that the interval between 9 A.M. Thursday and 7:30 P.M. was devoted to auto-respiration. As the afternoon wore away, it became evident that a serious mistake had been made in not early renewing the forced respiration or in discontinuing it at all. The patient relapsed into unconsciousness where before a semi-conscious condition prevailed; the respiration became shallow, cyanosis set in, and the case appeared more hopeless than at any time previously, so that many of the doctors present ridiculed the idea of saving the patient. The pulse became weak, thread-like, and frequent, so that continued hypodermic treatment with brandy and caffeine and rectal alimentation became necessary to sustain the fagged-out system.

7:30 P.M., Thursday, July 5th. Forced respiration was again resorted to, as it had been conclusively proven in this, as in many other cases, to be the only agent which could with certainty be regarded as a life sustainer. I made up my mind to keep it under way until the end came, "be it what it might."

The result was marvellous, although improvement came slowly. The temperature, without other treatment than the forced respiration and oxygen with sustaining measures, came down from 104.25° to 100.8° F., the cyanosis passed away, and the pulse improved in force and lessened in rapidity just so long as we kept our breathing-apparatus under way.

Fourth day. Toward the middle of the afternoon of Friday, the fourth day and third night since my method was used, we again gave the patient an opportunity to attempt his own breathing. The apparatus was used for five minutes and then the patient was allowed two or three minutes at auto-respiration. This was kept up for a short period, as it was evident even at this late time that the respiratory centres were not in sufficiently vigorous condition to control and keep up auto-respiration. It was very fatiguing for the patient to make these efforts, and he would hail with satisfaction the relief afforded by the forced respiration; being perfectly conscious he could not with all his energy keep up auto-respirations.

After a time the working of the apparatus became unpleasant to the patient; the rushing of the air into the trachea appeared to bother him. The fact, however, began to dawn upon us that he was getting into condition to breathe for himself, and at ten o'clock on

the evening of Friday, July 6th, we gladly relinquished to Dr. Williams his undoubted right to do his own respiratory work.

The third and last continued period of forced respiration in this case began Thursday at 7:30 P.M. and terminated finally at 10 P.M. Friday, or twenty-six and one-half hours. The total time during which the apparatus was in constant use was nearly eighty hours.

The tracheotomy tube was removed from the neck, the wound closed antiseptically, and the patient made as comfortable as possible. For some time during the use of the apparatus nutrient enemata were used, the urine was drawn by catheterization, and food and medicine were administered by the mouth.

The following physicians, all engaged in regular practice, were present during the active continuance of the case. Many had not before witnessed a case of forced respiration, and all were interested in watching the progress in so unusually prolonged and valiant a fight for the life of a brother practitioner: Drs. Archie Drake, W. C. Earl, Thomas Bagley, Sydney A. Dunham, Barrick, Dwight G. Hubbard, Charles Albertson, Francis M. Rich, Benjamin Lothrop, Clinton A. Sage, George W. T. Lewis, Earl Lothrop, Taylor, Frederick Preiss, Kaiser, Hoffman, Walsh, Nash, John Cronin, ex-president of the New York State Medical Association, and others whose names I did not obtain; also Mr. Thomas Stoddart, of Stoddart Brothers, druggists, and Mrs. Edmunds, nurse. Members of the family and friends from the neighborhood assisted in working the bellows. To Dr. Earl Lothrop, Dr. Talyor, Mr. Stoddart, and Mrs. Edmunds I am particularly indebted, as they stood by and assisted, hour after hour and day after day, when it seemed a useless task. Hardly one of them thought it possible that the patient could recover or that the means adopted would prove so efficacious. The result was, indeed, an interesting revelation to the medical world.

As stated in the first part of this paper, the Fell method of forced respiration has saved many lives. That it has not saved more has been owing entirely to the difficulty of introducing new methods, to unjust and unreasonable conservatism in a progressive age, when old things are passing away and a new and better, based upon truer knowledge, are taking their place. The value of the method has never before received so severe a test as in the case of Dr. Williams. It offers possibilities never before contemplated in surgical procedures, such as the opening up of the thoracic cavities under conditions which we dare not consider without the possibility of systematic forced respiration, and in conditions of shock, in drowning, and in many other contingencies.

The longest time during which the method was used prior to this case was at the Continental Hotel, Buffalo, in my practice. The respirations were kept up continuously twenty-one and one-half hours and in all twenty-four, before the patient could breathe for himself.¹ He is now living in Pittsburg, Pa. Numerous cases have taken place in which the respirations have been under way for from eight to fourteen hours with favorable results, and in which the face mask was used instead of tracheotomy. Nothing like Dr. Williams' case had ever been reasonably contemplated as a possibility. That a human being, by the administering of poison accidentally or with a mistaken knowledge of its effects, could place himself in such condition that the respiratory centres could be inhibited for days in the performance of their functions, and that it might be possible to respire by mechanical methods in such a condition for days at a

time, would appear preposterous. All this has been accomplished in the case I have presented, and it may be cited as one in which verily "fact is stranger than fiction."

Further Application of the Method.—The inhibition of the respiratory centres in the case of Dr. Low's patient, in which it was of a comparatively temporary nature, and in that of Dr. Williams, in which for days their function was paralyzed, make the remarks of Dr. Horsley, of England, reported in the *Quarterly Medical Journal*, of special interest in connection with forced respiration. He calls attention to the fact that in cases of cerebral compression, such as arise, for instance, from cerebral hemorrhage, tumor, or depressed fracture, as well as from sudden and violent concussion, especially when applied to the region, death is due to failure of respiration.

From experiments on animals he determined that a use of pressure in the skull always causes slowing and diminution of the respiratory movement, and later arrest of the same; and, furthermore, after release and re-establishment of the pressure has been carried out once or twice, the respiration becomes periodic, exhibiting the characteristics of Cheyne-Stokes breathing, or simply becomes irregular in force or in rhythm. Both these effects may be due to direct pressure and secondary anæmia caused thereby.

The practical application is that under such conditions in many instances it is as important to perform forced respiration as if the case were that of a drowning man. Horsley sums up his communication with the statements that the respiratory centre is more sensitive to mechanical pressure and shocks than any of the lower vital nerve centres; that where death threatens from intracranial pressure artificial respiration should be performed and the skull opened freely; and that in cases of sudden shock artificial respiration should be instituted immediately and heat applied to the head frequently by migration. In fact, I believe that in many cases of brain surgery altogether too little attention is given to support by artificial respiration, and now that forced respiration can be carried out in these cases another important field in which to use it is opened up, in addition to many reported in my former papers. Had I the hospital service presenting the opportunities, I should long ago have demonstrated the practicability of these opinions.

Discussion.—In the discussion Dr. Henry L. Williams, whose life was saved, took an active and appreciative part. He gladly gives all the credit to Dr. Fell and Dr. Dunham, who most directly were responsible for his presence on earth.

Dr. Sydney A. Dunham said he would like to change the saying "While there is life there is hope" to "While there is hope there may be life"; i.e., if the hope is so persistent as it was on Dr. Fell's part, life may result where death would have taken place without it.

Dr. Herman E. Hayd commended Dr. Fell's persistency in demonstrating to the world the possibilities and practicabilities of forced respiration. Dr. Stockton stated that in the earlier days of Dr. Fell's work he did not appreciate its value. A number of cases of such a positive nature have, however, changed his mind, and he is now willing to concede the great value of the method. Dr. Stephen Y. Howell thought that Dr. Fell should now begin to reap the reward he is entitled to, and deserved commendation for his unwavering appreciation of the value of his work. Dr. Allen Y. Jones detailed a case in which the life of a patient was saved by Dr. Fell's method. Dr. Hayd suggested that the society call the attention of the United States government to the value of Dr. Fell's method as a life-saving appliance in cases of drowning. Dr. Henry R. Hopkins thought it might be done through the American Medical Association.

¹ Dr. Wm. P. Northup in British Medical Journal, September, 1894, reports a case which required twenty-five hours of forced respiration.

A VERY SIMPLE AND RELIABLE PLAN FOR BLADDER DRAINAGE, WITH AN ILLUS- TRATION.

By ROBERT H. M. DAWBARN, M.D.,

PROFESSOR OF OPERATIVE SURGERY, NEW YORK POLYCLINIC COLLEGE AND HOSPITAL.

IN the February *Annals of Surgery* appeared a description by Dr. Keen of a simplified form of drainage device, the original idea of which he attributed to Mr. Charles W. Cathcart, an Edinburgh surgeon, who published it in October, 1895.

In the interests of truth and in justice to American ingenuity, it seems but right to say that the distinguished surgeon, Dr. Keen, is for once in error. The principle of intermittent siphonage upon which the method depends was first demonstrated by Dr. Snow, an American dentist, of Buffalo, N. Y., very nearly a quarter of a century ago. It has been in use among dentists ever since then the world over, in the siphon instrument used by many of them to keep the mouth continually free from saliva during dental operations.

The extremely simple modification of this same tool, which some five years ago it occurred to me to apply to bladder work, and which I have repeatedly shown to classes ever since, I should not have thought of publishing, it being only a very old idea with a new application, had not Dr. Keen's simplified form of

Mr. Cathcart's drainage seemed to me not so simple as my own

modification of dentist's drainage.

By reference to the accompanying sketch, it will be seen that the essential parts are only a fountain syringe and several feet of additional small rubber tubing.

A is the clamp which comes with every fountain syringe. It has been removed from the end and snapped upon the side of the tube, so as almost to close it, permitting flow only drop by drop.

B is the joint between the two pieces of rubber tubing. That going to the bladder is preferably rather smaller in calibre than the other. The simplest way, if one has a glass, metal, or vulcanite T-tube, is to use that to make the connection. But if not, the joint is made as follows: Cut out a circle from the side of the exit tube from the bag. Sew the end of the other tube to the edges of this small hole. Make tight with rubber cement (made by dissolving gutta-percha tissue in chloroform to saturation). Strengthen by wrapping with narrow strips of rubber adhesive plaster.

C is a trap which is absolutely essential. It is not of the usual shape of the traps to which, under sinks, we are accustomed: but upon reflection it will be seen that it is still a trap, and made in the simplest way, so as to be self-retaining. Either as a knot (as in the sketch) or held in a circle by snapping on an elastic band, the exit tube is thus made into a small trap; and the smaller the better. A circle three inches across is large enough.

We must not permit additional traps, by bends in the exit tubing from the reservoir at any other point.

D is a small piece of glass tubing, say a couple of inches long. Now as to the working of this drainage

device: From the reservoir the water trickles down until the trap becomes filled. As soon as overfilled, it siphons off with a little rush. This in turn makes a partial vacuum above the trap and the urine in the bladder is drawn up to fill this vacuum. Thus a second siphon is created, the fluid running freely from the bladder until it is empty.

This process of intermittent siphonage repeats itself at regular intervals of any desired frequency. As a rule, if the flow from the reservoir be no faster than from one to two drops per second, this will suffice to prevent a bladder from overfilling. And at this rate of flow, it is not necessary to replenish the bag of the fountain syringe oftener than once in several hours.

It makes no difference in the working whether the bag be hung above the patient or lower. As a rule (though this is not essential), I run a large size of soft catheter to the bottom of the bladder through the suprapubic wound. This catheter, like a stomach-tube, should have two openings below; say a second eye cut opposite the original one. Thus, there cannot be obstruction from sucking in a fold of mucous membrane.

The catheter is used because its walls are thicker than those of ordinary rubber drainage tubing, and hence the catheter is less likely to become flattened if accidentally flexed sharply at the wound or elsewhere. Where it escapes from the bladder, pin its side with a safety pin to the dressings. Connect it with the siphon apparatus by a piece of glass tubing at D.

Should we wish to wash out the bladder, this is easily done without disturbing the wound. Take off the clamp, A, and pinch it on again tightly at E.

Now the contents of the fountain syringe will run freely into the bladder. Cease pinching at E, and the fluid will run as vigorously by siphonage out of the bladder and into the bucket below.

Sometimes it is desirable to know the exact amount and the appearance of urine drained away; also we may wish to analyze that urine undiluted by fluid from the reservoir.

To permit this, I insert in a break at any point in the tube leading to the bladder a wash bottle with its usual equipment of tight-fitting rubber stopper and two glass tubes.

In conclusion, it hardly seems necessary to discuss other methods of automatic suprapubic bladder drainage. As every surgeon knows to his annoyance, these are not reliable. But in the simple plan just described, if carried out as detailed, the profession will find something that can be depended upon. It ought, I think, to do away in great measure with the necessity for a double cystotomy—the lower or perineal of which is made for drainage purposes only.

A brief description of this device I published in the *Annals of Surgery* for April.

Philadelphia County Medical Society.—At the stated meeting of the Philadelphia County Medical Society on May 13th, Dr. Silas Updegrove read a paper on "The Necessity for the State to Demand the Adoption by the Colleges of a More Uniform Standard of Educational Requirement for the Degree of Doctor of Medicine." Dr. J. Solis-Cohen exhibited a tongue-depressor, by means of which the interior of the larynx and trachea can be inspected directly without the aid of a laryngoscopic mirror. By invitation of the directors Dr. B. Alexander Randall demonstrated by means of lantern views the "Surgical Anatomy and Pathology of the Mastoid."

BACTERIOLOGY OF THE NORMAL CONJUNCTIVA.¹By CHARLES J. FOOTE, M.D.,
NEW HAVEN, CONN.

THE object of reporting the few bacteriological experiments which are recorded below will be better understood if they are taken in connection with and as supplementary to the paper of Dr. Wilson.

Our purpose in making the experiments was, if possible, to throw some light on the causes of suppuration after cataract extraction.

Our method of examination consisted in smearing over the surface of a slant tube of agar a particle of conjunctival secretion which had been removed with a sterilized cotton swab or a loop of platinum wire.

Agar was used as a culture medium, because we desired to study only those bacteria which grow at 37° C. After sowing the agar tubes they were kept in the incubator for several days at a temperature of 37° C. According to this method ninety-two eyes were examined, one tube culture being made from each eye. Of these ninety-two tubes, fifty-three showed one or more colonies of bacteria, while the rest of the tubes (thirty-nine) were sterile. By this I do not mean to imply that the conjunctivæ of thirty-nine eyes were sterile, but only that such small portion of the secretion as was removed by the platinum loop was sterile. In the fifty-three tubes containing bacteria, some eight or ten different kinds of bacteria were found. In twenty-two cases the staphylococcus epidermidis albus was present; in five cases pyogenes citreus; in one case pyogenes aureus; in one case the bacillus subtilis; in eight cases a large bacillus growing with small delicate translucent colonies on agar, kind not identified; in one case streptococcus pyogenes. The sources from which these bacteria infected the conjunctivæ may perhaps be named as follows in the order of importance:

1st. The edges of the lids and the mouths of the Meibomian glands.

2d. Uncleanly hands.

3d. The air.

4th. Infected nasal fossæ.

In the case of the normal conjunctiva the last is probably not an important source of infection, since the current of secretion is constantly downward into the nose. Bach, after injecting cultures of bacteria into the nasal fossæ, was unable to find that they ever made their way into the conjunctival sac.

Of the many kinds of bacteria (twenty-six species) which have been found in the normal conjunctiva, only three have been proved to be pathogenic to man. These are the staphylococcus pyogenes aureus, the staphylococcus albus, and the streptococcus pyogenes. It is obvious that the mere presence of even these in the normal conjunctiva does no harm. A bouillon culture of the staphylococcus aureus has been dropped into the conjunctival sac of man without producing inflammation (Bach), and even in injured eyes these bacteria often seem to do no harm, as may be seen from some later experiments in which the staphylococcus aureus was found in considerable numbers in the dressings of eyes which had been operated on for cataract and yet no suppuration occurred after the operation. But in spite of these facts it is well to remember that a purulent infiltration of the cornea and panophthalmitis result when the staphylococcus aureus is inoculated upon the surface of the cornea of a rabbit by scratching it with an infected needle; and also that after paracentesis of the cornea of a rabbit with an instrument infected with the staphylococcus

aureus, panophthalmitis develops in thirty hours. The same result occurs also at the end of seventy-two hours even with the staphylococcus albus. Moreover, in man the staphylococcus aureus and albus seem to play an important part in many disastrous processes occurring in the eye. Thus, the aureus seems to be a very important if not the sole factor in many cases of panophthalmitis and phlyctenular conjunctivitis.

These two series of facts illustrating the harmfulness and harmlessness of the staphylococcus aureus and albus can be harmonized only by referring them to a varying vitality of tissues in different patients or to a varying virulence of the bacteria.

Next an attempt was made to determine whether age influenced the kind and number of bacteria in the conjunctiva. For this purpose the eyes of twenty old people, ten children, and forty-six young adults were examined. Thirty-three per cent. of the tubes from young adults were sterile; thirty per cent. of the tubes from old people were sterile; fifty per cent. of the tubes from children were sterile. The percentage of sterile tubes from adults and old people was about the same, while there seemed to be somewhat less infection in children's eyes.

Cultures were also made from the conjunctiva as soon as possible after rising in the morning and again at evening. The eyes of eighteen persons were examined in the morning soon after rising and the same eyes were examined again at night. In this way it was found that of the morning tubes only two were sterile, while of the night tubes nine were sterile. It would seem probable, then, that the natural cleansing of the eye by the lachrymal secretion is more efficient during waking hours. An attempt was then made to sterilize the eyes of six patients. The process of sterilization consisted merely in washing the eye, in three cases with boric acid (one drachm to one ounce) and in three other cases with bichloride of mercury, 1 to 5,000.

After cleansing, the eyes were bandaged with sterilized cotton for twenty-four hours. The bandages were then taken off and cultures made from the conjunctivæ.

Of the three eyes washed with boric acid, all tubes showed colonies which were nearly all of the staphylococcus albus. Of the tubes obtained from those eyes washed with bichloride, one was sterile and the other two infected. The colonies present in these cases were also of the staphylococcus albus. Thus, in an attempt to sterilize the conjunctivæ in six cases, only one case proved successful.

Inasmuch as a certain proportion of tubes remain sterile after inoculation from the normal conjunctiva without sterilization, it seems doubtful whether the attempted sterilization was of any value at all. Bach's results were somewhat more favorable than mine, he rendering sixteen cases sterile out of forty-two attempts. Washing the conjunctiva cannot be depended on as a means of sterilization. A boric-acid washing probably has no more value than washing with sterilized salt solution. The process is merely a mechanical cleansing, and not a sterilization with a germicidal fluid. Inasmuch as the orifices of the Meibomian glands and the edges of the lids are fruitful sources of infection to the conjunctivæ, these especially should receive a cleansing either mechanical or germicidal before an operation.

Dressings over the eye furnish the necessary heat and moisture for bacterial growth. To determine how far an aseptic dressing placed over the eye affords a good breeding-place for bacteria, twenty dressings were examined. Nine of these came from eyes that had been operated on and eleven from eyes that had not been operated on, but had been merely bandaged with sterilized dressings for twenty-four hours. All

¹ Read before the section on ophthalmology of the New York Academy of Medicine, October 21, 1895.

of these dressings contained large numbers of bacteria. Those in the dressings from the operated eyes differed little in respect to the number and kind of bacteria from those in the non-operated eyes. The staphylococcus albus was present in thirteen dressings in large numbers, and in four of the dressings the aureus was also found in considerable numbers; yet in none of the operated eyes was there any suppuration after the operation. The aureus was present in three of the bandages from operated eyes and in one of the bandages from non-operated eyes.

Aseptic dressings should be applied only where the wound or area of application is aseptic. Antiseptic dressings would seem better to use over the eyes, as the dressings are applied to an infected area.

Incidentally, while making these examinations, cultures were also made from six cases of phlyctenular conjunctivitis, three cases of catarrhal conjunctivitis, and four cases of ulcerative keratitis. Three tubes from the cases of phlyctenular conjunctivitis were sterile, possibly because the cases were in the later stages of the disease. The three remaining tubes gave pure cultures of the staphylococcus aureus.

Of the cases of catarrhal conjunctivitis, one showed a few bacilli of a kind not identified, one was sterile, and one gave a culture of Fraenkel's diplococcus.

Of the four cases of ulcerative keratitis, tubes from three were sterile. Cultures of the staphylococcus albus developed in the remaining one.

BACTERIA AND OPHTHALMIC SURGERY.¹

By F. M. WILSON, M.D.,

BRIDGEPORT, CONN.

THE relation of bacteria to operative eye work is a question which none of us can avoid. Not only are bacteria in the air, but facts and theories about them are "in the air" also, and this question is too practical to be ignored.

The introduction of bacterial theories into surgical practice more than twenty years ago found ophthalmic surgeons standing upon the vantage ground of successful operative work, a position not favorable for the acceptance of new theories of any sort. In addition to this, the early antibacterial measures were of so irritating a nature as to practically exclude them from ophthalmic surgery. So that ophthalmic surgeons have a valid excuse for being somewhat slow to adopt the measures which proved of such signal advantage in general surgery.

The investigations which concern us to-night have during the past twenty years been going on along three lines, which overlap each other but are in the main separate:

First, along the line of laboratory work.

Second, along the line of practical surgical work, not ophthalmic.

Third, along the line of practical surgical work upon the eye.

The rise and growth of the bacteriological laboratory is, without any doubt, the most potent and far-reaching influence which modern medicine and surgery have felt, and though "micro-organisms and their place in nature" is a field of which the extent even is unknown, yet so much has been done that the record is one of almost uninterrupted progress. No recent year has passed without definite, positive additions to our knowledge of bacteria and their habits, due directly to laboratory work.

One little corner of this field belongs to ophthalmology, and though it was not one of the earliest to be

cultivated, the work has been varied and extensive. Gonorrhæal conjunctivitis, acute catarrhal conjunctivitis, trachoma, phlyctenular conjunctivitis, phlyctenular keratitis, serpentine ulcer, many forms of superficial keratitis (unclassified), destructive ulceration of a cornea, hypopyon pus, foreign bodies in the globe, sympathetic inflammations, have all been the subjects of laboratory experiments with reference to bacteria; and while we may not agree with all the theories which have been evolved, the large number of recorded facts cannot but have a permanent influence upon future opinion. It is, however, the quiet and not the inflamed eye with which we are principally concerned in operative work. This also has been studied with reference to bacteria. The skin of the lid is found to be about like skin elsewhere, *i.e.*, the staphylococcus epidermidis albus of Welch is constantly present, with other cocci and bacilli in greater or less abundance, especially in the folds. The eyebrows and eyelashes are "catch alls," as hair always is. Dr. Foote has gone a step further to-night, and demonstrated the almost constant presence of this albus in the normal conjunctival sac—a fact in direct line with the experiments of Welch upon the skin. There is, then, no dearth of bacteria. The albus we have always with us, and the citreus and aureus are present in a respectable minority of cases. Bacilli in considerable variety are not infrequent. There is a notable absence of streptococci.

Inoculations of pure cultures of these bacteria into the eyes of animals are among the most important of the laboratory experiments. The aureus has been more frequently used than any other species, and the production of suppuration is uniform by all observers; so far as I know there is not a dissenting voice, though Leber and others have also proved that suppuration can be produced without bacteria. Intensely interesting also are the laboratory experiments upon the eyes of animals illustrating chemotaxis.

From the laboratory evidence, then, we have to accept as facts in ophthalmology:

1st. That the bacteria are present in great numbers and considerable variety.

2d. That the aureus at least can produce suppuration of the globe.

3d. That suppuration can be produced without bacteria, notably by the metals mercury and copper.

Turning now to the second line of work, and principally that of general surgery, no one who did not see with his own eyes what for want of a better name may be called the "old surgery," can ever appreciate to its fullest extent the change which has taken place. To call it "revolutionary" is to use a word we have heard so often that it has lost some of its force; to attempt even a meagre description of it would take us too far afield. But that bacterial theories have borne the most varied, ample, and practical fruit in general surgery is beyond the shadow of a doubt; also that, notwithstanding the many and contradictory changes in methods of dealing with bacteria, the evidence that bacteria cause most of the suppuration in the world has been steadily increasing since the first day that Lister broached the theory.

Turning now to our own special field of work, let us frankly ask this question: What have bacterial theories and what have methods of dealing with bacteria done for ophthalmic surgery? Let us see.

Plastic operations about the eye involving the use of large flaps, either with or without a pedicle, are undoubtedly much more successful now than formerly, and I think no one will deny that this increased success is due in large measure to the more vigorous exclusion of bacteria from the field of operation. Plastic operations of less extent, like those for some of the milder forms of ectropion and entropion, usually heal

¹Read before the section on ophthalmology of the New York Academy of Medicine, October 21, 1895.

kindly whether antibacterial measures are used or not, and even if a stitch abscess forms it does not usually interfere with the success of the operation. Ragged holes in the lids made by scoop operations for chalazia usually heal more quickly than is desirable. Serious infection of a tenotomy wound is and always has been a very exceptional thing. Stitch abscess occurs much less frequently in the conjunctiva than in the skin. The operators of twenty years ago were as much surprised to have suppuration follow iridectomy as we are to-day. And, lastly, the average percentage of loss after cataract extraction is practically the same now as before the introduction of antibacterial measures, viz., about six per cent. This last statement is based upon the results of twenty thousand extractions, ten thousand cases before 1879 and ten thousand cases since that time, and is, of course, the most important item of the list. But if we had only the first table, that of Dr. Noyes, published in 1879, with its average loss of about six per cent, it would hardly be straining a point, standing at this distance with our present knowledge of bacteria and their habits, to infer that the cataract wound is one not especially liable to become infected with bacteria; and if, after sixteen years of greater or less effort in imitating the antibacterial measures of the general surgeon, another table, that of Dr. H. S. Miles,¹ shows the average loss to be still about six per cent., the demonstration seems fairly complete that, so far as actual loss of eyes is concerned, nothing of a revolutionary nature has been accomplished by all our efforts to exterminate bacteria.²

If, then, I have interpreted it aright, the evidence from the laboratory is uniform and overwhelming, not only of the presence of bacteria but also of their power to produce serious suppuration if they are put inside the eyeball or even into the tissues of the eyeball. But we must lay great stress upon that "if," for, with the exception of the gonococcus and the bacillus of Weeks, the unbroken conjunctiva seems very tolerant of the commoner varieties of bacteria. In direct line is the evidence of practical results in many forms of surgery; in fact, the laboratory and general surgery have joined hands, each supplementing the work of the other. But when we reach ophthalmic surgery there is a sudden falling off in the clinical evidence of practical results. Indeed, if one wished to be extreme, it might be said that the evidence of practical results is very slight.

Hence, if we approach this question from what may be called the "laboratory and general surgery" side alone, it is simply impossible not to believe in the great necessity of antibacterial measures. On the other hand, if we approach it from the side of clinical ophthalmology alone, ophthalmic operations are and have been for many years so successful with simply ordinary cleanliness as to furnish no loud demand for something better or that ordinary cleanliness be pushed to that greater cleanliness which we call asepsis.

Assuming, then, that very little has been accomplished for cataract surgery by antibacterial measures, what theoretical explanation can be offered, first and foremost, that the operation was so successful before we knew that the bacteria were there? The strongest force which works against the injurious influences of bacteria upon the eye is probably the natural and not the artificial one, and the natural protec-

tion is probably due to a combination of conditions rather than to any one thing. The risks from hands and instruments are, of course, less than in most of the operations of general surgery. Just why the bacteria of this field of operation do not oftener reach and infect the corneal wound is, with our present knowledge, entirely a matter of speculation. The mechanical conditions surrounding the cataract wound are unique. So long as the wound remains open a gentle stream of aqueous humor flows out, and whatever goes in must swim against the stream; and after the wound is closed, if there is any current of tears it is away from the wound if the suction is upward. Chemically, the influence of both aqueous humor and tears, if not proved to be decidedly adverse, is at least not specially favorable to the growth of bacteria.

A second reason why more has not been accomplished is the difficulty and danger of using the more efficient of the antibacterial measures about the field of operation. Sterilization of the hands and instruments, though not so necessary, can of course be done as thoroughly by the ophthalmic as by the general surgeon. But sterilization of the field of operation in cataract extraction is a practical impossibility. The skin of the lids offers many obstacles to the removal of bacteria from the loose folds. The eyebrows and eyelashes simply cannot be rendered sterile. The deeper recesses of the conjunctival sac can neither be scrubbed nor is it safe to use the stronger of the antiseptic solutions. The solutions used in ophthalmic surgery, while by the laboratory tests they may be within the area of killing power, are never very far within it, the experiments always being to find the weakest solution that will kill. And after all has been done and the dressings are on, the lachrymal passages still communicate with the nose.

From information furnished by Dr. Foote and others, it is my own belief that the following experiment can be repeated indefinitely with the same result: Cleanse the lids and conjunctival sac of a normal eye by any method known to ophthalmic surgery; use the most rigid precautions with hands, dressings, etc.; bind up the eye for forty-eight hours, and when the dressings are removed inoculate tubes of agar from the dressings, from the outside surface of the lids, from the eyelashes and eyebrows, and from the conjunctival sac. Place these tubes in an incubator at the temperature of the body. The staphylococcus epidermidis albus will grow so often as to make it the rule. The citreus and aureus will grow in a considerable number of cases, and occasionally bacilli will be found. In this connection it may also be stated that in general surgery so many bacteria have been found in wounds that heal kindly, that the word "aseptic" has lost its original exact meaning of entire absence of bacteria and has come to mean only that enough of them have been excluded so that the remainder do not interfere with the healing.

In conclusion, thanks to the laboratory, we are in a much more intelligent position in regard to what used to be called dirt. We have become partially acquainted with bacteria and their power to interfere with the healing of wounds. We know that accidental inoculation from the hands or instruments is very likely to produce the same results as intentional inoculation. From the laboratory standpoint it seems impossible to sterilize the field of operation. From the purely clinical standpoint of cataract surgery it seems impossible as yet to demonstrate any great change in operative results due to the introduction of antibacterial measures.

The Bubonic Plague is reported to have broken out afresh in Hong-Kong.

¹ This table was presented at the annual meeting of the American Ophthalmological Society in July last.

² It may be noted incidentally that there are not many operations in which so large an amount of clinical material is available as evidence, and also, as there are so many small collections of cases in Dr. Noyes' table (one hundred and ten items against thirty in Dr. Miles' table), it is, therefore, all the more remarkable that this average percentage of loss should be practically the same in both.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 30, 1896.

ANTI-CIGARETTE LEAGUES.

MUCH has been written for and against the cigarette, but it is really in itself an innocuous little cylinder, admitting that any form of smoking tobacco is harmless. It has often been asserted that the tobacco used in cigarettes is adulterated with opium and other noxious drugs, but this is very improbable as regards the cheaper sorts, for obvious reasons. It has been said that the smoke of the burning paper is injurious to the mucous membrane of the air passages, but many professional singers and not a few laryngologists smoke cigarettes habitually without experiencing any deleterious effects. The truth of the matter is that a given amount of tobacco smoked in a cigarette probably works no more harm than does the same amount in a pipe or cigar. The evil of the cigarette is that it affords a short smoke, and it is often lighted and wholly or partly consumed at odd and frequent moments when there would not be time to smoke a cigar. In this way it offers a temptation and the opportunity for immoderate indulgence in tobacco. If its use were confined to adults, there would be no necessity for any crusade against it, and our duty as physicians would be fulfilled in warning against overindulgence in tobacco as well as in alcohol or ice cream or any other substance which may be injurious to the mass when taken in excess or to certain individuals when taken at all, and in emphasizing the fact that cigarette smoking often leads to such overindulgence.

The evil lies, however, in the abuse (for here all use is abuse) of the cigarette by boys. In the ante-cigarette days it was rare to see a juvenile smoker under sixteen or eighteen years, but now the veriest mites learn to smoke as soon as they do to swear, and are equally proud of and equally addicted to both vices. There is no dispute concerning the injurious effects of tobacco upon the growing child, and the only difference of opinion is as to the best means of repressing the cigarette evil. In various States legislative enactments have been tried, some of the laws merely forbidding the sale of tobacco or cigarettes to minors, others prohibiting entirely the manufacture and sale of cigarettes. We question, however, the practical working of laws of this kind, and believe that much surer results can be obtained by working through persuasion and example upon the boys themselves. In a number of cities "Anticigarette

Leagues" have been organized among the boys in the public and parish schools, and, according to the testimony of both parents and teachers, they have already been the means of accomplishing an incalculable amount of good. A well-informed writer in one of the daily papers some time ago stated that the spread of the cigarette habit among boys had been so distinctly arrested by means of these leagues that there was every reason to hope continued effort would eventually succeed in stamping out the vice altogether. "In many of the schools," he said, "the entire atmosphere has definitely improved. Boys are more attentive to work, are in better health, and are fighting for a better and more rugged young manhood. Organization among themselves with a definite purpose in view has developed an educational value. Within the leagues athletic and literary circles have been formed, and a great force in elementary education availed of—the drawing forth of the best that there is in the boys through one good common impulse, by means of a sentiment created and maintained by the boys themselves."

The members of the league wear badges which remain the property of the particular school league issuing them until each member leaves school in good standing, when, having earned it, he retains his badge as his own property. If he proves recreant to the cause, his decoration is stripped from him, and must be won back by consistent observance of his obligation. These badges are prized as a Frenchman prizes the button of the Legion of Honor, and the possession of one is a very strong force in keeping the boy true to his promise. The leagues are now established in nearly all the grammar schools in this city, and in many of the schools in the cities and towns throughout the country. The same plan is being developed in England with every prospect of success.

Every one appreciates the power of association in keeping a boy or a man true to his ideals. It is far more potent than restrictive legislation, which has often even an opposite tendency among the weak or the obstinate. The establishment of these leagues promises well for the physique of future generations, and they should be encouraged by all who have the mental and physical well-being of the young at heart.

THE BACTERIOLOGY OF DIPHTHERIA.

At this late day it is scarcely necessary to defend the doctrine of the specificity of diphtheria and of the dependence of the disease upon the Klebs-Loeffler bacillus; but a recent investigation by Kossel¹ is so conclusive that it may be worth while here to quote the results in order to remove any element of doubt that may yet remain in the minds of unprejudiced persons. In a study of the throat and membrane in two hundred and fifty-nine cases presenting clinical appearances of pharyngeal diphtheria, this observer found diphtheria bacilli in two hundred and forty-three—ninety-four per cent. The sixteen in which the bacilli were not found proved on closer investi-

¹Charité Annalen, Band 20; cited in the Centralblatt für innere Medizin, 1896, No. 17, p. 428.

gation not to correspond in their clinical course with true diphtheria, and were free from such sequelæ as paralysis, while albuminuria was uncommon among them. These cases further were unattended with fatality, while in the cases in which diphtheria bacilli were present the mortality was twenty-one per cent. (prior to the period of serum therapy forty-two per cent., afterward fourteen per cent.). The diphtheroid affections, which are usually dependent upon streptococci, may present appearances in the pharynx closely resembling those of true diphtheria, and even the larynx may be involved, with slight stenosis: bronchopneumonia is a frequent complication. Failure to detect diphtheria bacilli in a case otherwise typical, cannot, however, be accepted as evidence of absence of the bacilli; for instance, they may be found subsequently in the pus of a complicating condition, such as inflammation of the middle ear. The conclusion must therefore be reached that there is no true diphtheria without diphtheria bacilli, and that bacteriologic examination is the only means of diagnosing this affection from others resembling it.

THE NOISES OF NEW YORK'S STREETS.

NEW YORK is unquestionably in many ways a most desirable place of residence. Years of persistent effort on the part of the health board have resulted in an expulsion of many smells and a banishing of many odors. The streets are beginning to grow clean, although the department having this matter in charge has much yet to learn about the right way of removing garbage, and the proper combining of sprinkling and sweeping so that neither shall remain a menace to the health of the pedestrian or to the happiness of the wheelman.

Far advanced as we are in many matters of comfort, New York is very far behind most European cities in all that pertains to quiet and peace.

If it is true that as a nation we are not more nervous than Europeans, it is no fault of those who regulate the amount of noise to which town dwellers must submit. Every large city must of necessity have its loud and discordant noises, but being unavoidable, we become accustomed to them, and, although the effect upon the system may in time prove injurious, it would appear that the abuse of the tympanum by the unusual and unnecessary noises produces a more immediate and direct result. This is especially true of the noises which occur at times when the system needs repose, and hence applies with double force to that ever-present proportion of the population—the sick. A man in perfect health may go for a long time undisturbed by the piercing street cries, the dinging of loud and harsh-toned traction-car bells, the squeaking of unoiled machinery, and the rattling of vehicles over uneven pavements. Let him once join that great company of the city's sick and lie with nerves on end and listen. Now he cannot escape the street vender with his inevitable hoarseness, nor the false notes of the scissor grinder's *cornet à piston*. When he was upon his feet he could hurry on in the hope that the next

block would be less disturbed. Now he must wait for each succeeding bleat or blast until the regulation number of thirty to the block have been given. Then he must lie and wonder what the next man's yell will be like, and when it comes he finds it more strange and more difficult to bear, and still from the sound he cannot make out whether it be "potted plants" or "bananas, all ripe."

According to the statistics kept by the street-vender license bureau, only one man has applied for a permit so far this season who was not the victim of a severe chronic laryngitis. This one is recorded as having only an aggravated cleft palate. Some of those who are being rendered deaf by the discordant cries may receive satisfaction from the thought that six weeks in the business is the average time for a boy to lose his voice entirely.

While the abatement of the noise nuisance rests in a great measure with the dwellers in the different localities themselves, invalids in institutions must be guarded in their rights to a certain amount of quiet by the community at large. Comparatively few disturbing cries, for example, are now heard in those blocks bordering upon Fifth Avenue, for the reason that in mutual self-protection the occupants of houses refuse to encourage street venders by the purchase of their wares. There would seem to exist no valid reason why citizens living upon any given streets should not enter into compact not to deal with these peace disturbers, and then demand from the authorities that such disturbers be excluded. This would have especial force as applied to quarters in which hospitals are situated. For the comfort of invalids and nervous individuals generally in their homes, there should be restrictions placed upon the hours during which street cries could be engaged in. Then the sufferer could better bear them, knowing that his hour of rest would come.

THE SECOND PAN-AMERICAN MEDICAL CONGRESS.

WE have received from the international executive committee for the United States a notice, printed in another column, of the second Pan-American Medical Congress, which is to be held in Mexico City during the third week of November. It is to be regretted that this announcement is made so late, for the summer is not a favorable time for original investigations or for the necessary research preliminary to the preparation of scientific papers. However, there will be a month of cool weather in this latitude before the date set for the meeting, and this is ample time for one who already knows his subject to write an article that will do credit to American medicine. But doubtless many have long been working in anticipation of this meeting and are even now prepared to assist in its deliberations. There are others again, and we trust many, who will derive pleasure and profit from attendance at the congress although they have no scientific contributions to present. Listeners form as necessary a part of an assemblage of this kind as do speakers, and we can pay no greater compliment to our Mexican breth-

ren than to go in numbers to hear what they have to tell us.

Mexico is an attractive city, the climate of which at all times and especially during the month which has been selected for this meeting is most delightful, and no one who is able to accept the invitation of its citizens will ever regret having done so. As a matter of courtesy, also, there ought to be a generous participation in the congress by physicians of the United States. Many representatives from all the Latin-American republics were present in Washington three years ago, and we owe it to our Mexican confrères, whose interest in the first congress was especially marked, to give a most cordial support to the meeting in their capital. The Mexican government is manifesting a warm interest in the congress, and the success of the meeting, so far as it depends upon the local profession, is already assured.

News of the Week.

Statistics of Diphtheria was the title of a paper read before the New York Academy of Medicine, May 21st, by Dr. C. G. Coakley, who was followed by Dr. Joseph E. Winters, with "Clinical Observations on Antitoxin Treatment of Diphtheria and Report of Personal Investigations of Treatment in the Principal Fever Hospitals in Europe during the Summer of 1895." Dr. Winters held that antitoxin treatment had not decreased the mortality; that in many cases it had produced fatal results which would not otherwise have occurred; and that statistics as to cures were faulty in view of the fact that a large proportion of cases of so-called diphtheria were treated on a bacteriological rather than a clinical basis. Dr. Winter's paper will appear in the *MEDICAL RECORD* soon. The hour was too late to hear from those who believe in the antitoxin treatment, but they are to have an opportunity to reply at a special meeting, date to be announced by the president.

Examination for Marine Hospital Service.—There will be held at Washington, D. C., on June 15, 1896, a competitive examination of candidates for appointment to the position of assistant surgeon in the United States Marine Hospital Service. Candidates are required to be not less than twenty-one years of age and no appointment is made of any candidate over thirty years of age. They must be graduates of a reputable medical college, and furnish testimonials as to character. Successful candidates, having made the required grade, are appointed in order of merit as vacancies arise during the succeeding year. There is at present one vacancy. A successful candidate, when recommended for appointment, is commissioned by the President of the United States as an assistant surgeon. After four years of service and a second examination he is entitled to promotion to the grade of passed assistant surgeon; and to the rank of surgeon, according to priority, on the occurrence of vacancies in that grade. The salary of an assistant surgeon is

\$1,600 per annum, together with furnished quarters, light, and fuel; that of a passed assistant surgeon \$1,800 per annum; and that of surgeon \$2,500 per annum. In addition to the above salaries, after five years of service, an additional compensation of ten per cent. of the annual salary for each five years of service is allowed medical officers above the rank of assistant surgeons, the maximum rate, however, not to exceed forty per cent. When an officer is on duty at a station where there are no quarters furnished by the government, commutation of quarters is allowed at the rate of \$30 per month for an assistant surgeon, \$40 for a passed assistant surgeon, and \$50 for a surgeon. The successful candidates, after receiving appointments, are usually ordered to one of the larger stations for training in their duties. Full information may be obtained by addressing the surgeon-general of the Marine Hospital Service, Washington, D. C.

Paris Academy of Medicine.—Dr. Wardelle Stiles, of Washington, has been elected corresponding member.

Wanted—A Healthy Stool Pigeon.—A Paris journal contains a "want ad." for a robust and distinguished individual to act the part of cured patient and pass the office hours in a physician's waiting-room.

The Supreme Court Sustains the Boston Board of Health.—On April 28th an Italian violinist was found by the Boston board of health to be fiddling in restaurants and other public places, before he had ceased desquamating from an attack of scarlet fever. He was taken to the City Hospital by order of the board of health, there to be confined until he could be allowed his liberty without being a menace to others. A petition was brought before the Supreme Court for a writ of habeas corpus for his release, but was promptly denied by Judge Allen. He will not be allowed to have his "corpus" at large in public places until it is freed from the contagious portions of its outer integument. It is reported that the court, in referring the petition, remarked that a case of this character never ought to have been brought before it, a fact which, it is to be hoped, will discourage counsel who may in future think of presenting cases which are so obviously at variance with common sense and public health.—*Boston Medical and Surgical Journal*.

Malpractice Suit Dismissed.—The suit against Dr. Mollenhauer, of this city, has been dismissed on the recommendation of the district attorney. He was brought into unfortunate notoriety by the death of a pretty waiter girl, Mary Shannon, whom he attended for peritonitis after some one else had performed an abortion.

A Lemon Pessary.—At a meeting of the Lyons (France) Medical Society a lemon was shown which a woman had employed as a pessary for prolapse of the womb. The woman had been in the habit of utilizing this fruit for this purpose for many years, alleging that she preferred it to every kind of pessary.

A Meeting of Sanitarians will be held in Chicago on June 10th.

The Ontario Medical Association will hold its sixteenth annual meeting in Windsor on June 3d and 4th.

The Woman's Medical College of Pennsylvania.—At the forty-fourth annual commencement of the Woman's Medical College of Pennsylvania, held on May 6th, the degree of doctor of medicine was conferred upon twenty-three graduates. Dr. Henry Leffmann, professor of chemistry and toxicology, delivered the valedictory address.

New Hospital at Sharon, Pa.—The Sharon-Sharpsville Hospital was formally dedicated on May 5th by Governor Hastings, who on behalf of the directors changed the name to that of the C. H. Buhl Hospital.

The British Association for the Advancement of Science, which meets this year in Liverpool under the presidency of Sir Joseph Lister, will meet in 1897 in Toronto under the presidency of Dr. Edward Frankland. It was thought that the Prince of Wales would consent to accept the presidency and would attend the meeting, visiting this country also, but he has refused the honor, so the association has had to fall back upon a president who knows something of science.

The Wisconsin State Medical Society will hold its fiftieth annual meeting in Madison on June 3-5, 1896. As previously announced, the entire session will be devoted to the discussion of topics relating to preventive medicine and hygiene.

Dr. J. Forster, of Amsterdam, has been called to the chair of physiological chemistry at Heidelberg, made vacant by the death of Hoppe-Seyler.

The Jenner Centenary.—The memory of Jenner has received but little honor in this centennial year of his discovery of the efficacy of vaccination. The American Medical Association, so it was announced long ago, was to do many things in honor of this great man. A few weeks before the Atlanta meeting it was stated, apparently officially, that an entire day would be devoted to the celebration of the centenary, but the official programme distributed to the members at the time of the meeting contained not a word of Jenner nor mention of those who had promised to take part in the celebration. When the subject was brought up in general session the association flatly refused to give up a day to it, though it gave up the greater part of a day to a barbecue. Finally it was agreed that those who had prepared addresses could deliver them, if time permitted, after the general session. And so the great man was honored by sufferance, but it can hardly be said by co-operation, of the American Medical Association. In England the centenary of vaccination is marked by a destructive epidemic of small-pox in a town only a few miles from the spot where Jenner's investigations were carried out. In Russia, where the celebration was to have been much more elaborate than the proposed ceremonies in this country, the Tsar is being crowned; so Jenner is to wait until October. We have not heard in how far the good intentions of the Germans and Japanese to honor the English discoverer have been realized, but we trust better than those of the Americans and Russians.

The Medical Society of Virginia will hold its twenty-seventh annual meeting at Rockbridge Alum Springs on September 8-10, 1896, instead of at Danville as was previously announced.

The Medical College of Ohio has become the medical department of the University of Cincinnati, though still retaining its old name.

Dr. John W. Williams, recently appointed associate professor of obstetrics at the Johns Hopkins University, is said by the *Maryland Medical Journal* to be the only native Baltimorean among the professors of that university.

Dr. Frances Rae, of Oshawa, Ontario, died in that town on May 8th. He was graduated from Toronto University in 1865. He left a widow and five children.

Professor Ehrlich has been appointed director of the new State institute in Berlin for the testing of therapeutic serum and of the laboratory attached thereto.

Professor Behring has been elected an honorary member of the Imperial Medical Society of Constantinople, of the Imperial Medical Society of Wilna, and of the Royal Italian Society of Hygiene.

Obituary Notes.—**DR. J. B. RAYNES**, of Lebanon, N. H., was drowned on May 22d by the upsetting of his canoe in a squall on Attean Lake, Me.—**DR. CARL PENNINGTON FROST**, dean of the Dartmouth Medical College and professor of the science and practice of medicine, died May 23d at Hanover, N. H., of heart disease. He received the degree of A.B. from Dartmouth in 1852, was graduated from Dartmouth Medical College in 1857, and received the degree of M.D. from New York Medical College in 1859.—**DR. EDGAR H. STEERS**, of Philadelphia, died at Atlantic City on May 17th at the age of thirty-four years. Dr. Steers was born in Maryland, where he received his early education. He was graduated from the University of Pennsylvania in 1884 and became a resident physician in the Philadelphia Hospital, where he served for a year, resigning to take charge of the practice of Dr. T. S. Bartram. A year ago he was compelled to withdraw from professional work on account of ill health.—**DR. SAMUEL B. IRWIN** died suddenly at Manahawkin, N. J., on May 19th, at the age of seventy-four years.

The Waters of Jordan have lost their reputation for healing. Archduke Karl Ludwig of Austria, brother of the emperor, died in Vienna a few days ago, and it is said that the illness which caused his death was ascribed by his physicians to his drinking of the waters of the River Jordan, which he did as a matter of religious devotion upon the occasion of his recent pilgrimage to Palestine. The water of the Jordan resembles that of the Potomac in its tendency to cause diarrhoea in those who drink of it for the first time, and in the case of the archduke it was found impossible to arrest the bowel complaint so produced.

The Second Pan-American Medical Congress.—The international executive committee for the United States has issued the following announcement: The committee on organization of the second Pan-American Medical Congress has elected Dr. Manuel Carmona y Valle, *President*, Dr. Rafael Lavista, *Vice-President*, and Dr. Eduardo Licéaga, *Secretary*, and has announced November 16, 17, 18, 19, 1896, as the date of the meeting to be held in the City of Mexico. The most cordial invitation is extended to the medical profession of the United States to attend and participate in the meeting. Titles of papers to be read should be sent at the earliest practicable date to Dr. Eduardo Licéaga, Calle de San Andres num. 4, Ciudad de México, Mexico. The date selected is in the midst of the delightful midwinter season, when the climate of Mexico is the most attractive to the northern visitor. The occasion should stimulate the medical profession of the United States to a most cordial reciprocation of the generous patronage accorded the Washington meeting of the congress by our Mexican confrères. It should be remembered that the United States is the largest and in many regards the most important of the American countries, and that as a consequence more is expected of it than of any other occidental nation. In no particular is this more true than in the maintenance of position in the realm of scientific medicine on the western hemisphere. It is, therefore, simply essential that in this congress—the most important of all medical congresses in its exclusive, yet broad, American significance—the best thought and the best work of the American profession shall be conspicuous in the proceedings. The zeal and enthusiasm of the Mexican profession and the active interest of the Mexican government are co-operating to make the second Pan-American Medical Congress attractive, important, and memorable. Those who contemplate attending should send their names and addresses at as early a date as possible to Dr. Charles A. L. Reed, St. Leger Place, Cincinnati, that the committee in Mexico may be advised of the probable attendance.

Prof. Germain Sée, of Paris, died in that city on May 12th. He was born seventy-eight years ago, and was graduated in medicine from the University of Paris in 1846. Six years later he was appointed physician to the hospitals, and later succeeded Trousseau in the chair of therapeutics of the Faculté de Médecine. He was elected a member of the Academy of Medicine of Paris in 1869, and was appointed a commander of the Legion of Honor in 1880. Dr. Sée was an original investigator and a voluminous writer.

Carrying Babies on Bicycles.—The officers of the Illinois Humane Society have announced that they will prosecute persons who take young children or infants on the front of their bicycles and ride with them in the streets or on the roads.

The Health of New Brunswick.—At a meeting of the New Brunswick, N. J., board of health, on May 14th, the following reorganization was effected: *President*, Dr. H. R. Baldwin; *Secretary*, Dr. A. V.

N. Baldwin; *Treasurer*, H. B. Willis; *Inspector*, Dr. A. V. N. Baldwin; *Counsel*, H. B. Willis; *Chemist*, Fred. B. Kilmer. In his annual report Inspector Baldwin stated that there had been reported during the year just closed twenty-four cases of scarlet fever, thirty-nine cases of diphtheria, thirty-six cases of typhoid fever, and five hundred and eighty-nine cases of measles.

Typhoid Antitoxin.—Antitoxin serum for the treatment of typhoid fever is to be prepared on a large scale at the laboratory of the Army Medical School at Netley, and the value of the remedy is to be tested in the British army.

New Clothes for the Insane.—The appellate division of the Supreme Court of New York has decided in favor of the Manhattan State Hospital in the controversy with the board of charities in regard to the rule requiring that all insane patients should be fitted out with new clothing before being admitted to the hospital.

The Association of Military Surgeons was in session in Philadelphia last week. At the session on Thursday, May 14th, the following officers were elected: *President*, Medical Director A. L. Gihon, U. S. N., New York; *First Vice-President*, Brig.-Gen. E. J. Forster, M. V. M.; *Second Vice-President*, Maj. John Van R. Hoff, U. S. A., New York; *Secretary*, Maj. Hermann Burgin, N. G. P.; *Treasurer*, Capt. James J. Erwin, O. N. G., Cleveland. Columbus, O., was selected as the next place of meeting.

Dr. John S. Billings has received the honorary degree of doctor of medicine from the University of Budapest on the occasion of its millennial celebration.

The Newark, N. J., Board of Health has been reorganized, Dr. H. C. H. Herold being elected president.

Cold in Pneumonia.—Dr. Thomas J. Mays, 1839 Spruce Street, Philadelphia, requests the publication of the following: "My two collective reports already published on ice-cold applications in acute pneumonia give a record of one hundred and ninety-five cases so treated, with seven deaths, or a mortality rate of 3.58 per cent. Being desirous of making as full a report as possible on this subject, I take the liberty of asking those who have tested this measure to kindly give me the result of their experience. Full credit will be given to each correspondent in the report which I hope to publish. Blanks for the report of cases will be furnished by me on application."

Dr. Charles A. L. Reed, of Cincinnati, has been selected by the European committee on organization of the International Periodical Congress of Gynecology and Obstetrics as honorary president of the meeting of that body, to be held in the city of Geneva, Switzerland, the first week in September of this year.

Dr. C. H. Tebault, of Tennessee, has been appointed Surgeon-General of the United Confederate Veterans, to fill the vacancy caused by the death of Dr. Joseph Jones, of New Orleans.

The Beaven Rake Memorial.—Subscriptions to the memorial to the late Dr. Rake, of Trinidad, have been collected to the amount of about \$400. Of this sum \$250 have been given to Dr. Rake's widow, the balance being expended for a bronze tablet to be placed in the entrance hall of the museum of Guy's Hospital.

Malarial Hæmatobia.—Mr. Laurie, residency surgeon at Hyderabad, is a pronounced opponent of the parasitic theory of malaria, denying the specificity of Laveran's malarial organisms. He announces now in a telegram to *The Lancet* that he has discovered these identical bodies in ordinary pus cells.

The Third International Congress of Psychology will meet in Munich from August 4th to August 7th inclusive. The titles of one hundred and thirty-two papers are announced already, several of them being by English and American writers. The general secretary is Dr. Freiherr von Schrenck-Notzing, Max Josephstrasse, Munich.

Dr. Playfair has had enough of the law, and has compromised his case with Mrs. Kitson, paying her some \$50,000, including costs, instead of the \$60,000 which was the amount of the judgment. The appeal has therefore been withdrawn.

The Cholera in Egypt shows no signs of decreasing. It has recently appeared at Tourah, where is located a prison camp containing over twelve hundred convicts. There was one death there on the 18th and fifteen one week later. The mortality rate is much higher than in most epidemics of cholera, the deaths averaging nearly ninety per cent. of the seizures. There were eighty-three deaths in four of the principal towns on Sunday last.

Venereal Disease in the British Indian Army.—There is a genuine epidemic of venereal disease among the garrison troops in India, the number of admissions to the hospital for that cause having been five hundred and eleven per one thousand. Sixty-three per cent. of the entire garrison of seventy thousand men is reported by the Sanitary Commission to have been infected, and over three thousand men daily were ineffective from that cause.

The Practitioner celebrates the Jenner centenary by issuing a "vaccination number," almost the entire number for May being devoted to historical notes on Jenner and to articles relating to vaccine and the results of vaccination. The frontispiece is an excellent reproduction of one of the Jenner portraits.

The National Association of Railway Surgeons.—At the ninth annual meeting of this association, held at St. Louis the last week in April, the following officers were elected: *President*, Dr. Frank J. Lutz, St. Louis; *Secretary*, Dr. Cassius D. Westcott, Chicago; *Treasurer*, Dr. E. R. Lewis, Kansas City, Mo.

The Late Dr. J. West Roosevelt.—The medical board of the Roosevelt Hospital has heard, with painful surprise and profound sorrow, of the sudden death of Dr. J. West Roosevelt. One of the youngest members of the attending staff, he had the hope and the

promise of a long, useful, and brilliant career. Dr. Roosevelt's buoyant spirit, alert intelligence, and professional acquirements, united to his keen sense of humor and manly character, made him always a welcome presence and a valued counsellor in the wards and in the deliberations of this board. We desire to put on record our high appreciation of his professional merits and his engaging personal qualities. Identified as he was by name as well as by an earnest sympathy and active co-operation with the work of this hospital, Dr. Roosevelt's untimely death must be deplored as a serious bereavement by the managers and by his colleagues in the medical board.

The Twelfth International Medical Congress.—We have received from Professor Erismann a copy of the regulations of the Moscow Congress, containing the new amendments relating to the questions of language and of the division into sections. The following are the sections into which the work of the congress will be divided: 1, Anatomy, including anthropology and normal embryology and histology; 2, physiology, including medical chemistry; 3, general pathology and pathological anatomy; 4*a*, general therapeutics, including hydrotherapy, climatotherapy, etc.; 4*b*, pharmacology; 4*c*, pharmacognosy and pharmacy; 5, internal diseases; 6, pædiatrics; 7, nervous and mental diseases; 8, dermatology and venereal diseases; 9, surgery; 9*a*, odontology; 10, military medicine; 11, ophthalmology; 12*a*, otology; 12*b*, laryngology and rhinology; 13, obstetrics and gynecology; 14, hygiene, including sanitary statistics, social medicine, epidemiology, epizootology, and technical sanitary science. In a note it is stated that supplementary sections will be organized in case of necessity. The regulations as to language have also been modified, French being retained as the sole official language of the congress in all its international relations, but the use of English, as well as of French, German, and Russian, being permissible in the sections. Addresses in the general sessions may be delivered in any European language.

Dr. A. Jacobi, of this city, has been directed by the central committee of the congress to form an executive committee for America, to be composed of representative medical men from different sections.

A New Hospital in Passaic.—Subscriptions are being solicited in Passaic, N. J., with a view of establishing a hospital there, and thus far about two-thirds of the desired sum of \$25,000 has been obtained. The lot on which the hospital will be built is in an elevated portion of the city, and is about two hundred by four hundred feet in area.

Coroner's Physicians.—Dr. H. W. Cattell and Dr. Thomas J. Morton have been appointed physicians to the coroner of Philadelphia, vice Dr. H. L. Sidebotham, resigned, and Dr. W. K. Mattern, deceased.

Wistar Institute of the University of Pennsylvania.—Through the generosity of Gen. Isaac J. Wistar a number of new buildings will be added to the Wistar Institute of Anatomy and Biology, which was founded in 1892 for the preservation of the Wistar and Horner museums and for the promotion of study and

advanced research in anatomy and biology. The most important of the new buildings will adjoin the present one, and will be used chiefly for the accommodation of the large number of specimens that have been contributed to the Wistar and Horner collections during the past three or four years. A second building is designed to furnish heat and light to the institute. When the institute was established General Wistar endowed it sufficiently to provide for beginning the advanced and original work for which it was intended. Every facility will now be provided for the work of original investigators under the supervision of a competent director and skilled assistants. The course is intended for post-graduate and advanced students and not to supersede such elementary instruction of under-graduate students as pertains to the ordinary curriculum of the university. The grading of the ground previous to the erection of the new buildings has already been begun, and it is expected that the work will be completed by the beginning of the fall term.

College of Physicians of Philadelphia.—At the stated meeting of the College of Physicians of Philadelphia on May 6th, the vice-president, Dr. John Ashhurst, Jr., in the chair, Dr. Alfred Stengel related a case of gonorrhœal endocarditis in which organisms morphologically resembling gonococci were found after death in the valvular lesions complicating an attack of gonorrhœa in a young woman. Cultivation experiments proved unsuccessful. Dr. J. P. Crozer Griffith exhibited a heart with perforated septum ventriculorum from a child dead at the age of four years of an attack of pneumonia. The condition had been recognized during life, though unassociated with cyanosis. Dr. F. A. Packard reported a case presenting congenital deficiency of both inter-auricular and inter-ventricular septa, which had existed for forty-five years without giving rise to noteworthy symptoms. Dr. John B. Shober described "An Unusual Thoracic Aneurism" occurring in a young colored woman, and involving either the ascending or the transverse portion of the arch of the aorta. He exhibited photographs and plaster casts showing the successive changes in the external swelling, especially the reduction in size that followed anti-syphilitic medication. Dr. J. Hendrie Lloyd reported a case of tumor of the cerebellum, in which during life forced movements took place toward the side on which the growth was situated. He also exhibited a specimen and photographs of the patient. In the discussion the subject of surgical interference in similar cases was not spoken of with any degree of hopefulness, although it was pointed out that the intensity of the headache could be materially relieved by trephining. Dr. Weir Mitchell emphasized the variability of the knee jerks in cases of cerebellar tumor. Dr. Thomas S. K. Morton, on behalf of himself and Dr. John H. Musser, related briefly a case of carcinoma of the descending colon, in which excision of the neoplasm was practised and anastomosis effected by means of the Murphy button, with maintained recovery of the patient. Dr. J. Solis-Cohen exhibited the Kirstein autoscope, which,

on depressing the tongue and drawing the epiglottis forward, permits of direct inspection of the interior of the larynx and trachea without the aid of a laryngoscopic mirror. He also exhibited a tongue depressor which he has employed for upward of twenty years, and with which he has found he can accomplish almost the same results as with the autoscope.

A most interesting and instructive meeting of the surgical section of the college was held on April 8th, under the chairmanship of Dr. J. William White. Dr. Thomas S. K. Morton related the case of an infant nine months old, from whom he had removed a large angioma of the chest wall almost bloodlessly by means of first introducing a series of deep interlocking ligatures, and after the excision of the mass ligating the divided vessels individually. He also exhibited a large portion of a fibula removed in a case of nephritis on account of partial necrosis; and also a specimen of obliterating appendicitis, obtained from a man who had suffered from attacks resembling gastralgia in conjunction with pain in the left iliac fossa. He further showed an immensely enlarged carcinomatous breast successfully removed by the method of Halsted. Dr. Edward Martin exhibited a woman in whom he had repaired an ununited fracture of the humerus, by means of metallic plates secured to the fragments of bone with ordinary carpenters' screws. He also showed casts illustrating the result secured by means of the chiselling operation in a case of deformity of the nose from fracture. Dr. J. William White and Dr. C. L. Leonard exhibited lantern slides prepared by Dr. A. W. Goodspeed, illustrating the practical application of skiagraphy to surgery. A number of the patients also were shown. Among the cases detailed were the following: Ununited fracture of both bones of the forearm, showing wire sutures in position; ununited fracture of both bones of the forearm, showing union between the proximal extremity of the ulna and the distal extremity of the radius; ankylosis of the elbow after fracture of the humerus and dislocation of both bones of the forearm backward; partial ankylosis at the elbow-joint after old fracture, with partial loss of flexion and extension and pronation and supination; excision of the head of the radius for forward luxation; curvature of the radius due to arrested development of the ulna at its distal epiphysis; diastasis of the distal epiphysis of the humerus, resulting from a fall upon the hand; diastasis of the proximal epiphysis of the humerus, with overlapping of the fragments and union in faulty position; the result obtained in excision of the knee; foreign bodies in the arm; bullet in the forearm. Dr. Goodspeed exhibited also a number of slides illustrating various portions of the normal skeleton. Finally, Dr. T. S. K. Morton exhibited slides showing the normal foot and also the conditions present in the affection known as metatarsalgia or Morton's disease of the foot.

The Blood in Malaria.—A telegram from India received in London a few days ago states that three important observations have just been reported by Dr. Lawrie with reference to the microscopic examination of the blood in malaria: (1) One of his students, who

has been getting fever every two or three months, has had his blood examined every day. Since the last attack up to yesterday Laveran's bodies were entirely absent from the blood. After yesterday's examination he had fever and ague, and to-day the blood contains them in abundance. (2) The characteristic swarming movements of Laveran's bodies, already detected by Dr. Lawrie in normal leucocytes, have now been found in aseptic pus cells, and these are known to be also leucocytes. These facts prove that Laveran's bodies are the effect, not the cause, of malaria, and establish their close relationship to the white blood cells. (3) Dr. Lawrie has shown that aseptic pus swarms with the same small cells and granules found in the liver and spleen of frogs, in normal leucocytes, and in Laveran's bodies, and these are not micrococci. Cocci have automatic movements, but the granules and small cells of aseptic pus have only the swarming movements seen in leucocytes and Laveran's bodies, which movements are produced by intra- and extracellular circulation.—*Medical Times and Hospital Gazette*, May 9, 1896.

Antitoxin Treatment of Diphtheria in Glasgow.—In the May number of the *Glasgow Medical Journal* Dr. Ernest L. Marsh publishes some tables showing the influence of orrhoterapy in diphtheria. The cases admitted to the City of Glasgow Fever Hospital during 1895 numbered 179, and of these 137 were treated by antitoxin, the remaining 42 being either mild infections (38 cases) or profound toxæmias (4 cases) moribund on admission. The fatal cases numbered 25, giving on the admissions a percentage of 14 deaths. In the five years previous to 1895 the cases of diphtheria had never given a less percentage than 35.5 deaths in any one year. Of the 179 patients in 1895 tracheotomy was needed in 29, and of these 10 died, giving a mortality of 34.5 per cent. Dr. Marsh contrasts this low death rate with the high mortality of the tracheotomy cases in previous years—viz., 76.2 per cent. (42 cases) in 1893 and 86.9 per cent. (23 cases) in 1894.

Pennsylvania Training-School for Feeble-Minded Children.—Splendid work is being done by the Pennsylvania Training-School for Feeble-Minded Children at Elwyn, near Media, Delaware County, Pa., where nine hundred and eighty-two children are under observation and care. The institution is a private one, being maintained primarily by voluntary contributions, although it receives additional support from the State, to an extent inadequate, however, to meet the demands upon its resources from those unable to pay and in need of just such care, discipline, and instruction as the school can and does most excellently give. Attention is paid to both intellectual and manual training, and not a little of the work about the place is done by pupils. Within the last six months a good deal has been accomplished by means of instruction in articulation. From the forty-third annual report just submitted to the members of the State legislature, to the State Board of Public Charities, and to the contributors, it appears that of two hundred and one applications made during the year eighty-five were

rejected—the majority from failure to meet the requirements, many of the applicants not being residents of the State. A considerable number could not be accepted because of lack of accommodations. It appears that of nearly nine thousand idiots in the State of Pennsylvania, almost a thousand are cared for at the school at Elwyn.

The Bayonne, N. J., Board of Health has re-elected Mayor Seymour to the presidency for a second term of one year.

The American Gynecological Society held its twenty-first annual meeting in this city during the past week under the presidency of Prof. W. T. Lusk. The sessions were well attended and the papers presented were of high merit. A full report of the proceedings will appear later. The social programme comprised luncheon at the Holland House by the entertainment committees and in the Metropolitan Club by the New York Obstetrical Society; also receptions at the residences of Professor Lusk and Professor Polk respectively, and a banquet at Sherry's. Dr. James R. Chadwick, of Boston, was elected president, an honor worthily bestowed.

Berliner Aerzte-Correspondenz is the name of a new German bi-monthly publication devoted more particularly to the business interests of the medical profession.

The Maine Medical Association.—The forty-fourth annual meeting of this association will be held in Portland, Me., Wednesday, Thursday, and Friday, June 3, 4, and 5, 1896. The officers of the association are: *President*, Dr. L. W. Pendleton, Portland; *First Vice-President*, Dr. D. A. Robinson, Bangor; *Second Vice-President*, Dr. C. E. Williams, Auburn; *Treasurer*, Dr. August S. Thayer, Portland; *Recording Secretary*, Dr. Charles D. Smith, Portland; *Corresponding Secretary*, Dr. W. T. Goodale, Saco.

Medical Students in Germany.—According to the latest edition of the *Universitäts-Kalender* the number of medical students in the several German-speaking universities in the winter semester 1895-96 was as follows: Vienna, 1,727; Munich, 1,466; Berlin, 1,258; Würzburg, 788; Leipzig, 699; Graz, 636; Erlangen, 472; Freiburg, 380; Greifswald, 351; Breslau, 316; Strassburg, 312; Zurich, 309; Bonn, 270; Kiel, 264; Halle, 252; Marburg, 226; Göttingen, 225; Königsberg, 223; Jena, 207; Tübingen, 206; Heidelberg, 201; Giessen, 154; Rostock, 98.

The Iowa Anti-cigarette Law is being circumvented by some manufacturers who make a cigarette covered with a light tobacco wrapper instead of paper, which makes it not a cigarette in the meaning of the Iowa statute.

Dr. Charles F. Leach, a medical missionary, formerly a practising physician in this city, was murdered with his wife and infant son on May 5th. He was working as a missionary at Fsax, near Tunis, and was meeting with most gratifying success. It is thought that religious fanaticism inspired the Mohammedans to assassinate him.

Dr. George Peters, of Toronto, has succeeded the late Dr. Laughlin McFarlane on the staff of the Toronto General Hospital and as professor of clinical surgery at Toronto University.

Fees for Insurance Examinations.—At the annual meeting of the Florida Medical Association, held in Sanford, April 7, 1896, the following resolution was adopted and the secretary authorized to send a copy to every medical man in the State, and to the insurance companies:

"*Resolved*, That it is the sense of this association, in convention assembled, that we most emphatically protest against the reduction of examination fees for life insurance as proposed by the several insurance companies, and that we insist that so long as said insurance companies require the high and necessary standards of examination as have been in force, we refuse (and so advise all physicians in Florida) to make such examinations for less than the usual fees that have heretofore been paid."

Hamline University, of Minneapolis, on April 8th graduated its first class since incorporating the Minneapolis College of Physicians and Surgeons as its medical department. The class numbered twelve.

In Illinois there are over one thousand towns without a resident physician. At least such is the statement going the rounds of our exchanges. The towns must be very minute.

Reviews and Notices.

TWENTIETH CENTURY PRACTICE. An International Encyclopædia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Volume V. "Diseases of the Skin." New York: William Wood and Company. 1896.

THE appearance at the present time of Vol. V. would naturally lead to the inference that one-quarter of the proposed series has been completed. Such is, however, not the fact, since Vol. VI. has already been distributed out of its regular order.

The test of a book's utility and fulness is often to be found in referring to the index. Instead of adding, as is usually done at the end of a review, "the volume is finished with a full index," the reviewer, in the present instance, has made use of the index to test the fulness of the book. With very few exceptions every cutaneous disorder looked for, however rare, was found entered under at least one of its designations, and, turning to the pages referred to, an account of the affection was to be found, though sometimes, to be sure, given in a brief manner. Throughout the entire book one cannot avoid the impression that what he is reading is thoroughly modern. One well versed not only in the books of the day but also in current journal literature will be surprised to note how certain subjects are treated, in advance even of the times. Still this is what one might naturally expect from a work having the scope and title of the series to which this volume belongs.

There are many dermatological puzzles still unsolved and one man's guess ought to be as good as another's, or, as the Irishman would say, even better. Many of the views here advanced concerning moot points in etiology or pathology would seem to have been inspired by modern progress in bacteriological and other branches of scientific research. The guessing is not so uniformly like that in the last skin book one has read. Certain things have to be said in much the same way as previous authors have said them, but new works need not of necessity be constructed from the torn-out pages of those previously written by other men. The volume before us shows little evidence of unnecessary cribbing. Indeed, the standing of the eleven contributors is such that if it were thought best to incorporate previous writings in this

volume almost any one of the authors could have drawn upon his own former work.

Dr. Brocq, of Paris, has furnished the chapter on the papular affections including the lichen group and pityriasis rubra pilaris. This will be a portion of the book in which most American dermatologists will be interested, since these particular diseases must be acknowledged to present many points which are still open to final decision, and here as well as in France their discussion has often been warmly engaged in. Especial stress is laid upon what the author calls lichenification, a condition associated with many pruriginous states and to be diagnosed from lichen rubra planus, etc.

Dr. Whitehouse, of New York, has been given two subjects, both of considerable extent: the erythematous affections and the bullous affections. Both have been treated with evidences of careful research.

Parasitic diseases have been exhaustively and most interestingly discussed by Dr. Bulkley, also of New York. Numerous surprises are here in store for him who has not booked up on this branch for the past ten years. The chapter includes the most recent investigations.

Dr. Crocker, of London, has written in his characteristic and pleasing style upon the squamous affections and also a chapter on the phlegmonous and ulcerative diseases.

Dr. Montgomery, of San Francisco, has had charge of the portion which treats of the hair and nail diseases, of which he has made a very readable chapter, and for those who wish to pursue the subjects further there are fifty-three bibliographical references.

Dr. Van Hariingen, of Philadelphia, is responsible for all that is said upon diseases of the sebaceous and sweat glands. The various acne forms have been considered in a very systematic manner, and many formulæ and prescriptions are scattered through the text.

Dr. Bowen, of Boston, has well acquitted himself of the task of telling in a concise manner all there is to be told about benign neoplasms.

Dr. Leloir, of Lille, France, has presented a most interesting and rather long chapter upon the dermato-neuroses. Probably no one is better qualified than this distinguished specialist to treat upon the various, and at times complicated questions which arise in connection with this important branch of dermatology. Many excellent therapeutic suggestions are here made.

Dr. Kaposi, of Vienna, has become sufficiently identified with that rare and striking disease, Xeroderma pigmentosum, to have it sometimes called Kaposi's disease. It is therefore most appropriate that the editor has secured the services of this distinguished teacher in the preparation of a short chapter relating to it. A number of histological illustrations add to its interest.

Dr. Hyde, of Chicago, has had the difficult task of confining within less than a hundred pages all that one should know about eczema and dermatitis. It is probably always better to know less than to know "so dashed much that isn't so," as Josh Billings put it. Dr. Hyde has acted on this theory in leaving out much that has been taught in previous years about eczema.

Beginning as we did with the index, it is only right that we bring to a close what we have to say with a word about the introductory chapter.

Dr. Allen, of New York, has succeeded in so condensing the knowledge now possessed as to the skin's histological structure that it is all told upon twenty pages, inclusive of six good-sized woodcuts. The writer states that "no attempt has been made to make this chapter exhaustive." In compensation there is a rather full bibliographical list.

It would be an injustice to stop here and not say a word of commendation for the editor. His work has been done with evident care and intelligence. To secure accurate and at the same time elegant translation of the writings of foreign contributors and to make sure of the orthography of the many new dermatological terms is a task which deserves a word of praise when it is so well done as in the present instance, to say nothing of laying out the plan of campaign and choosing wisely the executive staff. There are a few slight typographical errors. Upon page 469 occurs the sentence, "since she weaned her last hilde." The typo must have changed the position of the "c" after the proofsheets were in.

As a whole the volume compares very favorably with those that have gone before, and dermatologists will have no cause to regret the manner in which their branch is presented in the "Twentieth Century Practice of Medicine."

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

SECTION ON DISEASES OF CHILDREN.

First Day—Tuesday, May 5th.

THE CHAIRMAN, DR. A. C. COTTON, of Chicago, delivered the opening address, taking as his subject

Has the Milk Laboratory Come to Stay?—The marked advances which have of late years been made in the preparation of infant food had guided him, he said, in the selection of a topic. He first passed rapidly in review the prevailing opinions in regard to feeding by artificial means which have from time to time governed physicians in the selection of infant food.

Whatever has been the accepted method for the given time, the echo has always come from the past. "I told you so." If it is thought best to treat the milk chemically, the echo says, "I added lime water years ago." If the fermented products, kumyss or matzoon, find favor, the echo from the past says, "I advised buttermilk" or some fermented preparation years ago. When sterilization is in vogue, the echo cries, "Did I not boil it years ago?"

A new impetus has been given to discussion of the subject by the establishment of milk laboratories, mainly through the efforts in this country of Dr. Rotch in Boston, and so clearly do they fill the indications for accurate scientific feeding that they must be considered as standing in the same relation to the physician in matters of diet as the well-equipped and well-managed pharmacy does in matter of therapeutics. The milk laboratory, then, the speaker concludes, fills a pressing need and has undoubtedly come to stay.

The next paper was read by DR. C. G. SLAGLE, of Minneapolis, upon

Diagnosis in Diseases of Children.—Pædiatrics can never become a strict specialty, since he who attempts to adopt it as such must be a diagnostician in all departments. He must be a practitioner in every branch, and something more. It is the "something more" upon which he would invite discussion. Diagnosis is the most difficult problem. It is the culmination of all we can learn, and is the real practical test of every man's knowledge and skill. Some few, and only a few, possess a natural tact for diagnosis. System in examination is often lacking. Some unskilled in the art claim that exact diagnosis is no longer necessary, but this is a fallacy. In infants and children it is especially important that not only accurate but early diagnosis be made. Especially important is this in contagious diseases. The speaker thought that a man who could diagnosticate correctly four-fifths of his cases was a fairly good diagnostician. Physical signs in the chest do not afford the same aid in the child that they do in the adult. Forty years ago pædiatrics had little standing as a specialty. There was but one American text-book. Much of the credit for the rapid advance made in recent years the speaker thought due to the efforts of Jacobi, who had done so much to elevate the specialty. Many American authors were highly complimented on the work they had done in this field.

DR. LARRABEE said that too much attention could not be paid to diagnosis in the education of young men. The value of this study is greatly enhanced by close attention to diathesis. We have, each one of us, a weak point somewhere by inheritance. These weak points must be watched for and brought to bear upon the diagnosis of disease. Stress was laid upon the necessity for examination of the nude outstretched body. Inspection often reveals a minute symptom

which will point the way. Physiognomy, he thought, should be studied and the facies closely read.

DR. MOODY, of Louisville, said the absence of the aids found in the adult offer obstructions which can be overcome only by tact and patience. We can tell much by inspection of the child's expression. Examination of the chest sounds, especially during sleep, he found more satisfactory than auscultation in the adult. The thinness of the chest tissues secures an advantage over examinations of adults.

The next paper was by DR. LARRABEE, of Louisville, upon

Pædiatric Therapeutics as Proven by Experience.

—It is well at times to examine our weapons, powder, and ammunition. We must not degenerate into selectors of therapeutic proprietary remedies. Prescribe single and simple remedies with a correct knowledge of their elimination from the body and of the organs exercised in such elimination. Small and frequently repeated doses were advocated in infantile therapeutics. Numerous instances of such successful medication were quoted from the speaker's practice. Polypharmacy results in compound incompatibilities. One ought not to carry an emergency case filled with compounds which depend upon the knowledge and skill of the pharmacist for their preparation. Antiseptics for intestinal use were then taken up, and pure guaiacol was highly spoken of for certain conditions. Nascent phenic acid, as now obtainable in this country, made after the Debat formula, has long been used by the speaker and is highly thought of. We can never go back to astringents for infantile diarrhœas. In typhoid fever hydrotherapy was advocated. Milk, as such, should never be given alone, but in gill doses mixed with lime water. Buttermilk, when obtained fresh, is to be preferred. Antitoxin serum treatment has in his hands been the means of saving life, but he has also seen deaths result from its use. In speaking of emetics, while turpeth mineral was advocated, it was thought that antimony and syrup of ipecac should be banished from infantile therapeutics. Water is too often overlooked as an external means of treatment in the exanthematous and other states. Water is the only expectorant in bronchitis and pneumonia which the speaker ever gives.

DR. SLAGLE agreed that antimony and syrups should be abandoned, but he found turpeth mineral too irritating, except possibly in membranous croup, as a last resort. He prefers sulphate of aluminium and powdered ipecac.

DR. TULEY thought local treatment should not be abandoned when we use antitoxin. Stomach washing should supplement emetics.

DR. LOVE, of St. Louis, said that too little stress was laid upon the importance of the subject of infantile therapeutics. If he could choose but two remedies, he would name water and calomel. The hydropath, who was looked upon with disfavor in the past, has taught us much of the value of water. Lavage should not be ignored. The adult can overdrink and expel the water of his own volition, but the child's stomach must be washed.

Turpeth mineral is an excellent emetic in laryngitic stenosis. Opium should be withdrawn from the list of useful drugs. Syrups should be ruled out entirely. Conservatism is most of all necessary at the bedside of the baby. Antitoxin must be applied early. Most cases reported are in reality those of follicular tonsillitis.

DR. KLEES, late of Munich, spoke briefly, but reserved most of his remarks for the general discussion upon the antitoxin question.

DR. LARRABEE said that when a non-absorbable emetic was necessary, turpeth mineral was the best one to use, partly because of the small dose required.

Alcohol should be omitted from infantile therapeutics, because depression must of necessity follow. Feeding or food stimulation is much better.

DR. COTTON said the subjects of the papers read touched every practitioner closely and opened up a wide field for discussion.

DR. ELMER LEE, of Chicago, read a paper entitled **The Fallacy of the Claims Made for Antitoxin as a Treatment for Diphtheria.**—The history of the origin and the clinical use of antitoxin was briefly entered into, and reference was made to the discovery in 1884 by Pasteur of the hydrophobia treatment, from which it was shown that the improvement in the percentage of death due to the treatment consisted not in a better understanding of the process, but in the greater dilution of the Pasteur lymph. It was shown that an analogous condition has been the experience of clinicians with reference to the use of antitoxin. The stronger the antitoxin, the greater the danger. The explanation given concerning the reason for the early use of antitoxin is entirely dependent upon the relative strength of the patient to withstand the assault upon the system made by the introduction of extraneous poisonous matter. Diphtheria is classified by the author into true clinical diphtheria and diphtheria of the bacteriologic laboratory, a distinction which did not exist previous to the present stage of bacteriology. The first class is diagnosed by the clinician at the bedside, while the second depends chiefly upon the findings of the culture tubes within the laboratory. The bacteriologist affirms that the throat manifestations are paramount in importance, contrary to the experience of clinical observations. Systemic poisoning, owing to lowered vitality, are essential factors in the causation of diphtheria. The special pathologic change in the fauces is considered by the author to be of secondary importance. The use of antitoxin as a curative agent is empirical rather than scientific, owing to the utter impossibility of measuring the exact chemic action which takes place within the blood. It is seriously questioned whether it is possible to successfully neutralize a toxemia by the introduction of a foreign substance which has no natural place in the human economy. The proposition agrees with the supposed effect based upon the theory of *contraria contrariis curantur*, but is utterly inconsistent with natural physiologic reasoning. The difficulty of determining the exact value of a therapeutic agent makes it next to impossible to put absolute reliance in statistical tables furnished by the sponsors of antitoxin treatment. If the cases were all of similar character, and the treatment could be classified by control experiments, the conclusions would approach reliability. As it is, it must ever remain largely a question of personal experience and faith as to the value of the curative influence of special drugs and preparations. Very much is done to increase the belief in the efficacy of antitoxin by the modern secular press, the family of the patient frequently requesting and almost demanding that antitoxin should be used, the position of the physician being dependent upon the impressions made by the inaccurate statements of newspapers. The value of the treatment is thus prejudiced in its favor, which sometimes throws a shadow across a conservative judgment as to the true effects. Undoubtedly fatal results have occurred, but in each instance some special plea has saved the treatment from condemnation. The use of antitoxin, therefore, goes on, owing to the seductive claims which were published at the outset and which the profession has not had the experience necessary nor the courage to correct.

The careful records of the Willard Parker Hospital furnish sufficient evidence upon which to base a fair judgment as to the value of antitoxin. It is shown from this hospital that the claims of the foreign path-

ologic investigators have failed of being substantiated. When all the facts, based upon a cooler judgment, are taken into consideration, the clinical experience of the whole profession renders it necessary to proceed further in the use of antitoxin with caution. It is true that diphtheria when treated by antitoxin has appeared to be favorably influenced, but the claim that it is a reliable and safe treatment is far from being established. A little time is still required in which to enable the profession to sift the facts and determine the place of antitoxin in therapeutics. Already the chief promoters who favor antitoxin for the cure of diphtheria are rapidly receding from the position that antitoxin is also a preventive of the disease. It is almost certain that the ensuing year will witness a return to former methods of treating diphtheria, judging from the straws which show the way the wind blows.

The next paper was by DR. JOSEPH W. STICKLER, of Orange, N. J., entitled

An Experience with Antitoxin with Instructive Results.—The writer first related a clinical case in which the serum was used in increasing laryngeal stenosis, membrane being demonstrable by the laryngoscope and the depression making rapid progress. Recovery began at once and was complete at the end of a week. In Case II. the Klebs-Loeffler bacillus was demonstrated. The depression was great, the system was profoundly poisoned, and the patient died twenty-four hours later. This case showed the futility of using the serum when the economy is profoundly affected. It is only indicated in a case similar to the first.

A paper was read by DR. LOUIS FISCHER on

Some Practical Points on the Effects of Antitoxin and Intubation, with Especial Reference to Infant Feeding in Malignant Diphtheria.—In making the injection, those parts of the body should be selected where there is no danger of injecting air into a large vein. Intubation should be made use of to avoid asphyxiation in severe stenosis. It is imperative to overcome dangerous symptoms, such as high temperature, as quickly as possible, but antipyretics should not be given. Enemata and water should be used and remedies given hypodermatically as much as possible. In malignant cases the respiration may reach as many as a hundred per minute. Its fall indicates an important improvement, just as does the disappearance of albumin from the urine.

In the discussion of these two papers PROF. EDWARD KLEBS, of Zurich, spoke first. He said Dr. Lee took the view that the bacilli were not surely proven to be the cause of diphtheria. He thought we must at the present day admit, even from clinical experience alone, that the disease is an infectious one. It is true that the bacilli are often found in the throats of healthy persons, but it is probable that in such persons they are exercising only their non-poisonous effects, as is observed in very many other organisms. Children often are taken sick just after catching cold. In such cases the organism has been previously present, but exerts no deleterious effect until the process of catching cold causes some change in the tissues of the body which permits the previously innocent bacilli to develop. He had lost a child of his own in such a way. Dr. Stickler's cases, giving one favorable and one negative effect, are in keeping with the history of all remedial measures. Our results are not uniformly successful by any measures. The speaker advocated fair play in the antitoxin controversy. We must first consider the experimental foundation for the whole question. There is an anti-poisonous effect from these substances—this we must admit. The experimental observations must be admitted and accepted as they relate to man. The preventive influ-

ence must not be confused. We have better ground for saying that preventive injections cannot have a good influence than for saying that they have, since these substances are found to be good culture media. Antitoxin has no immunizing power, so far as the speaker is aware. Statistics always have elements of error connected with them. In the past year there has been a very great diminution in the death rate. This must be taken into consideration. The danger alluded to by Dr. Lee requires carefully prepared statistics. Evidently children have been killed by injections. This imposes so great a responsibility upon the physician who uses the method that the question requires much discussion. It is a bad plan to inject in the region of the chest—in the subclavicular region, for example, where the veins are large and form a plexus. Then, too, it is not well to inject so near the centres of respiration. The gluteal is a much better region. The vessels are smaller and the injection can be made directly into the muscle. The shock of the injection alone might be responsible for the sudden deaths in some cases in which no air is found to have been injected into the veins. The cause of death must reside in the poisonous substances which exist in the fluid, but how do they come to reside there? He believes that the poison gets accidentally into a single bottle in the process of filling. An occasional bottle may be spoiled; this often happens in bacteriological work, as every one knows.

We conclude then that we can never be sure. Personally, he would always inject a guinea-pig before using a new bottle on a child. He strongly advised giving up preventive injections. He admired the bacteriological management here in this country, with the board of health examinations made gratis. In Europe the authorities refuse to do this, on the ground that it is too expensive. He thought without flattery that the Americans were in this respect more liberal. Some antiseptic should be added to antitoxin which does not itself coagulate albumin, but which will prevent any other organism from growing in it. He spoke of a new antiseptic, chinisol, much stronger than carbolic acid and existing as a very soluble powder, which he thought might be employed. He had found it very efficacious as an external antiseptic in eczema, etc. He intended proposing it to those interested in antitoxin preparation.

DR. E. CASSELBERRY, of Chicago, said intubation had been in his hands very unsatisfactory in stenosis. Patients coming to the stage of operation during the past year have been saved by the use of antitoxin. Indeed the latter has resulted in a saving of patients extending to so high a figure as seventy-five per cent. The swelling associated with the presence of membrane subsides within twenty-four hours. The bronchopneumonia does not so frequently supervene. In laryngeal diphtheria antitoxin has been a decided aid. He does not advise it as a preventive measure. The clinical is equal to the bacteriological test. Records show that deleterious results come mostly from its use in health. We should wait until a reasonable diagnosis of the presence of diphtheria can be made before using antitoxin.

DR. LARRABEE said there was no longer a germ theory, but a germ fact. It is only during germ activity that we have disease. It is surprising that we have thought of immunizing against a disease which does not immunize against itself. Antitoxins, if properly prepared, should arrest the disease in its progress. He has seen four children die who would not have died had they not used antitoxin. On the other hand, he had seen twelve patients recover from stenosis under its use who would have died without it. The fatality in reported cases of sudden death by injection of air cannot be explained. He has observed a sudden

and inexplicable anuria in such cases. That heterogeneous toxins or ptomaines are present, he thought was shown by the rashes often produced. Ocular inspection should cause us to exclude turbid-appearing serum. Septic matter should be removed from the throat, as it is when the antitoxin is not used. The blood can be fortified against destruction as in former days by the muriate-of-iron tincture given internally, and it should be applied to the throat externally.

DR. W. B. PARKS, of Atlanta, said that most of the diphtheria in Atlanta is follicular tonsillitis and patients get well without antitoxin.

DR. ROSENTHAL, of Philadelphia, said the latest report by Dr. Billings, of New York, shows that after antitoxin is used the blood is not altered. Individually, he has never seen abscess or other bad effect. His injections are made with the utmost antiseptic care in the interscapular spaces, sealing the puncture with iodoform collodion. He believed that antitoxin possesses great powers, but against the Klebs-Loeffler bacillus alone. If there is compound or mixed infection, then we must use other remedies, and the tincture of the chloride of iron is the best drug he knows of. Since using antitoxin he can remove the intubation tube much sooner than formerly. Bacteriologic investigations have their necessity, but bacteriology is not everything.

DR. ROSS, of Kohamo, Ind., said he never had seen, out of about fifty injections, any local signs of irritation and only once an erythema. Not a patient of his was lost, nor was a patient lost in his city in about two hundred cases, while those on whom it was not used furnished a number of deaths.

DR. GRAY, of Connecticut, said that in Bridgeport he has seen about seventy patients treated; twenty-eight of his own, out of which number only one died. Better results were obtained from initial doses of one or two thousand units than from the small doses of a few cubic centimetres. Recovery was rapid in all the cases, excepting the one resulting fatally.

DR. TOMLINSON, of Michigan, said it was very gratifying to him that, having defended the treatment at last year's meeting, so much could now be said in its favor. Even if antitoxin has killed a few, it has cured thousands, and he would give it up on this account no sooner than he would discard cocaine because death has resulted from its use.

DR. BELL, of Atlanta, spoke of the use of antitoxin in the New York Infant Asylum as showing conclusively during his time of service that an antitoxic effect was produced. These children stand comparative large doses of iron. He believed in using antitoxin for its immunizing effects when the bacilli were found in the throat.

DR. GARRISON, of Illinois, said two-thirds of the population in her town had had antitoxin injections made for supposed diphtheria, but the bacillus was never to be found and there were no deaths.

DR. BAKER spoke of his experience at the Willard Parker, where he observed one hundred and fifty cases, but he saw no results which could not have been obtained without antitoxin. He thought two years more would be required before we can speak finally as to the value of antitoxin.

DR. WILSON, of Ohio, spoke of a severe epidemic in which he lost his cases until he began using antitoxin. Then a series of sixty cases recovered. Those who refused to use antitoxin in his town were the ones who lost most of the patients that succumbed.

DR. KUTLE, of Pennsylvania, said he believes that a true attack of diphtheria does immunize; hence the argument which has been used is fallacious.

DR. KLEBS said we have different forms of immunity. Recurrences in diphtheria do take place, but not so often as in pneumonia. We cannot compare

different infectious diseases with each other. Many of the children in a family in which diphtheria exists may show bacilli in the nose or throat, and without any injection may never become diphtheritic. These bacilli may be highly infectious to others, but do no harm to the child showing their presence.

DR. ELMER LEE in closing said that the position taken in his paper is a correct one. The treatment by serum is not based upon scientific principles. His own weak point was that in criticising antitoxin he could offer no substitute.

A letter was read from DR. JOSEPH WINTERS, of New York, in which the increased number of reported cases of diphtheria was commented upon as due to the present methods of diagnosis. Dr. Winters stated in this letter that he could find no value in the antitoxin treatment.

A vote of thanks was extended to Dr. Klebs for his valuable contribution to the meeting's interest.

Infantile Scorbutus was the title of a paper read by DR. ALBERT H. BURR, of Chicago. This disease is assuming greater importance by reason of its increasing frequency. This is partly due to the ingenuity of man in devising sterilizers and proprietary foods. A case was reported in a thirteen-months-old child, brought for treatment for a supposed spinal trouble. After six weeks' treatment the child was in a worse condition than before. Emaciation was progressive, and the prognosis of fatal issue from marasmus was made. Purpuric spots had appeared upon the shoulders and other parts, some of which suppurated. There was pain upon manipulation. Mellin's food had been the exclusive diet from birth. The child weighed thirteen and a half pounds, and could not move its head from the pillow. Food was changed to raw cow's milk, orange juice, and scraped beef, etc., and among other medicines protonuclein in one-grain doses was administered. After a week the gums were no longer spongy, and there was an increase of one pound in weight. A soft-boiled egg was then added to the dietary. Cure was manifest at the end of six weeks. The chief points were swellings of the femur and scapula and suppuration of the purpuric spots. Every child should have natural food. The nearest approach to mother's is modified cow's milk. No continuous administration of any prepared milk or commercial food should be allowed to the exclusion of fresh or raw elements. We must be ever on the lookout for scorbutic malnutrition in artificially fed infants. Prompt relief will save many such cases.

DR. W. A. DIXON, of Ripley, O., read the following:

Observations in Cases of Epilepsy Following Injuries to the Head in Infancy, Childhood, and Early Youth.—A large percentage of cases, he said, may be traceable to injuries in early life. The speaker is personally familiar with the history of numerous cases from the date of injury to the appearance of epilepsy. There was in these cases no other known cause. Cases were cited from practice. Case I. was trephined over the seat of injury and a cystic tumor as large as a medium-sized orange was disclosed and removed. After this the epileptic seizures ceased. In a number of other cases the epilepsy came on ten or more years after injury. These patients either continue to have attacks or have died from the effects. Some cases are probably caused by injury at childbirth from the forceps pressure. Parents should be instructed to avoid head accidents to their children so far as possible.

DR. W. J. BELL, of Atlanta, showed

Casts of the Trunks of Twins, aged fifteen months, the offspring of a negro hunchbacked woman, in whom there was marked rachitic chest deformity. Both children died from some lung trouble within

forty-eight hours of each other. They both presented identical deformity with anterior bulging of the chest walls. In discussion the question was asked if it was now admitted that such a condition as congenital rachitis existed. The question was answered in the affirmative.

The next paper was one

On the Use of the Stomach and Rectal Tubes in Children, read by Dr. W. J. Bell, of Atlanta. The writer advocated the use of the stomach tube in infantile fermentative changes in the alimentary canal and described his manner of washing out the stomach and bowel. Food is only given an hour later. The rectal tube is much more generally useful. Marked fall in temperature often follows irrigation of the colon. Placing the child on its left side, thus lowering the head and trunk offers an excellent method of treating persistent dysentery and gastro-enteritis.

Treatment of Infantile Spinal Paralysis was a paper next read by DR. MAYER, of Chicago. It consisted largely of histories and was not presented *in extenso*. He divides the cases into those of moderate and those of great severity, the latter including those in which the patient is unable to walk. Treatment is preferably by the faradic current, if contraction of the paralyzed muscles can be secured by it; otherwise the galvanic is given in as strong a current as possible. Stress was laid on the necessity for long-continued treatment.

In the discussion of these papers together, DR. MANLEY, of New York, took up the subject of meddling some midwifery, and thought the expert should make a proper diagnosis early and avoid injurious effects of forceps, etc., which might and often did do damage to the head, and which might in after-life occasion epilepsy. Operation should be performed if depression of bone can be made out distinctly. The paper was also discussed by DRs. WORK, DIXON, and MOWRY.

The Evolution of Girls was the subject of a paper by DR. HARRIET E. GARRISON, of Dixon, Ill. The question of evolution scarcely enters into the present discussion, she said, so far as it relates to descent from angels or ascent from the lower forms of animal life. Nerve force must be stored up by the mother before she brings her child into the world. The animal functions have their nerve supply in the posterior portion of the brain. The brain must have room to grow, and not be compressed by faulty position of the infant during its period of development. The position usually forced upon children is faulty. They should be encouraged to assume ever-changing attitudes and positions in lying, and should be allowed to creep and toss about to bring the muscles into play. Too much propping up with pillows and encouraging girl babies to sit up and to walk early are wrong. Later in life the bad effects of too much erect sitting in school, etc., should be counteracted by rest in the horizontal position with the hips raised. All forms of out-of-door exercise in which boys engage should be afforded to girls, including military tactics.

DR. SLAGLE deprecated the tendency to too great refinement in the girl's education and development at the expense of the nerves. He advocated the bicycle in moderation.

DR. SMALL, of Pittsburg, said that in bicycle-riding for girls the handle bar should be always two inches higher than the seat. This prevents stooping and helps expand the chest.

DR. HIBERGER, of Washington, prescribed the wheel and found the menses less difficult in those who rode.

DR. COTTON was sceptical about the possibility of development of the anterior lobes of the brain by encouraging creeping and the prone position.

DR. SMALL, of Pittsburg, read a paper upon **Retention in the Newly Born**, reporting the histories of three cases. The first case related to the plugging of the female urethra with inspissated mucus. During the first seventy-five hours of life there was no act of urination. The passage of a probe resulted in a gush of urine and no further treatment was required. A child's catheter corresponding to No. 9 of the French scale was shown. It was six and a quarter inches in length, with a slight curve near the beak. Instrument-makers' catalogues in this country make no mention of such a child's catheter. The literature of retention in infants is very scanty. It is said that retention from inspissated mucus is not very uncommon. How long we should wait before using a catheter in such cases, is the question which the writer wished discussed.

DR. SLAGLE said he never catheterized a female child and rarely a male. Unless there is obstruction it is usually unnecessary, as mild means will answer.

DR. WORK has seen retention in only three instances, out of a large obstetric experience. If the bowels have moved, especially if several times, we may well wait till the next day. An occlusion by the secretions is usually the only thing to overcome and this can be done by a curved blunt probe.

DR. BYERS thought the condition described must be very rare. It is usually relieved by itself.

DR. GRAHAM said he had rarely seen retention. Prolonged labor may produce temporary paresis. He saw no necessity for the curve in the catheter presented. It should not be an angle. A simple silver probe ought to be sufficient.

DR. CUNNINGHAM reported a case in which no urine had been passed. An imperforate meatus was found. The child was therefore circumcised. In the night there were convulsions. Iliot poulitices were used, as it was thought best not to pass a probe and there was no evidence of bladder distention. Convulsions occurred every half-hour. A catheter was now passed and the urine withdrawn, and no convulsive seizures followed.

DR. ALLEN, of New York, thought the mere contact of the metallic probe might, by reflex action, cause bladder contraction and produce the desired result without passing the instrument into the bladder. In this connection he related an instance of congenital occlusion of the greater portion of the penile urethra. The day after birth he had operated by perineal section, relieving the bladder of its accumulated urine, and had then bored through from this perineal wound and secured an opening to the meatus, which was kept open by means of a piece of soft catheter of small calibre till the wall was healed. The perineal wound healed promptly and well and urine was passed through the new urethra. About a month later alarming symptoms set in, attended with pronounced jaundice, and the child died. On autopsy, bladder and kidney changes were found. The question was asked whether such a case had come within the experience of any one present. There was no response.

DR. MANLEY, of New York, said that such instances as those in the paper would be found described by Boyer, and also in Monod and Terillon's work. The causes of retention are usually stenosis of the meatus of the prepuce and stenosis of the meatus urinarius proper. It occurs quite frequently, contrary to the general opinion as expressed by those who had spoken. The urethral tissue in infants is very delicate and contains no muscular fibre, while the bladder contains three times as much as the adult bladder. Since in the infant there is no space of Retzius, aspiration through the abdominal wall is very dangerous for the peritoneum. The straining due to stenosis in boy infants accounts for the relatively great frequency of inguinal hernia in the male.

DR. COTTON spoke of the catheter as a means of differential diagnosis between retention and suppression.

DR. SMALL in closing spoke of the ease with which the catheter he presented entered the urethra.

DR. MANLEY, of New York, read a paper upon the **Fractures in the Shafts of Bone in Children**.—We must remember that the shafts of the bone in infants are composed of comparatively soft tissue. No constitutional disease in the infant predisposes to fracture during the stage of growth and development. It is not sufficiently emphasized in text-books that in infant fracture, when there is shortening, it is only at times due to overriding. Children grow more rapidly when on the back. This growth continues in the well limb, but stops in the injured limb. In compound fracture more progress has been made than in the simple. Muscular relaxation was formerly considered a *sine qua non* to success. A tight splint should not be put on at once, on account of the delicacy of the tissues. The limbs should be put in a comfortable position and topics applied until circulation has been re-established. The vascular is the first question to interest us. After twenty-four hours, muscular spasm has passed off and great force is not required. Better results will be obtained from treatment without splints. Some of the simplest fractures are compound. An artery may be injured in simple fracture so that the extremity dies. No matter how bad the compound fracture, the idea of amputation should never be entertained. The object should be to save the limb first and set it afterward. He spoke of a case of periosteal reproduction after severe injury producing compound fracture and loss of the whole shaft of the tibia in a boy. We have in the child two forces as against one in the adult, the natural growth from both ends of the shaft coming to our aid.

DR. ELLA BURNS, of Alabama, inquired as to the possibility of subsequent growth taking place in the shortened limb, making it in time as long as the other.

DR. MANLEY could not state if this ever took place. He thinks plaster of Paris has been the cause of numerous deformities.

DR. WORK thought the paper replete with conservatism, which he believed all should practise, more especially in children. He used binders'-board splints almost exclusively. Put on wet, they help to keep down the inflammation.

DR. SLAGLE thought the theory of growth being suspended would explain some mysterious cases of shortening.

DR. COTTON said no absolute rule can be devised to fit surgical procedures. If we want the primary union mentioned, we must have coaptation as well as the comfortable position on a pillow the speaker had advised.

A Conservative View on Antitoxin, a paper by Dr. Love, was read by title.

SECTION ON DERMATOLOGY AND SYPHILOGRAPHY.

DR. L. DUNCAN BULKLEY, OF NEW YORK, CHAIRMAN.

Chronic Ringworm of the Scalp was the subject of a discussion opened by DR. L. D. BULKLEY, of New York. He said this disease belongs especially to childhood. In his private practice there is only two and a half per cent. of affected patients over thirteen years of age, and the same ratio holds good for public practice. Many of those affected go for years unrecognized and untreated, endangering all children with whom they associate. Children certified to have been cured are found on careful examination to show

abundant evidence of the disease. Its recognition is not always an easy matter. The typical case exhibits one or more bald patches of a more or less leaden color, with stubbed hairs over the surface, but in cases which have lasted any length of time a simple tonsure may be found. The disease is often masked by the growth of hair over the patch, hiding a few broken stumps. Few cases can be thoroughly cured in a short time, and from three to six months is an average time of treatment. The subject of treatment is a large one and could but barely be touched upon, he said, in this opening of the discussion. It will often tax the ingenuity of the physician to the utmost. Time is a very essential element. Reports of rapid cure are to be accepted with caution and the element of faulty diagnosis not overlooked. It is now generally accepted that cases exhibiting the microsporon variety of fungus are more likely to be rebellious than those showing only the megalosporon.

The next paper was presented by DR. HENRY A. PULSFORD, of South Orange, N. J., entitled

Experience in the Treatment of Ringworm of the Scalp in the New York Skin and Cancer Hospital.

—The paper was based upon seventy-five cases treated and constantly under observation. Only twenty were discharged cured. Unna has reported cures in two or three weeks' time, but few if any others have seen similar brilliant results. Wickham has cured only from forty to sixty per cent. in the course of fifteen months. We must be sceptical of results reported when the methods of determining the cure are not definitely given. Wickham's suggestion is to cut the hair and leave undisturbed for a week, cutting again and leaving undisturbed for two weeks, and finally examining after a second two weeks and only then putting the case down as a cure. The best cure for ringworm is puberty. It is self-limited. The writer doubts the efficacy of epilating the healthy hairs on the margin of the patch. It may aid in distributing the disease to neighboring parts. Indiscriminate epilation is of no avail. In the series reported the average duration was five and a half months. In those cured the treatment lasted seven and a half months. In six patients a vigorous treatment was carried out for periods varying from thirteen to seventeen months without wholly eradicating the disease. In addition to repeated hair-cutting and epilation, parasitocides were employed, such as bichloride, carbolic acid, and iodine, various plasters, collodion and gelatin paint to exclude the air, croton oil and other irritants to set up inflammation in the follicles. The bichloride in particular was thoroughly tested in strong solution as introduced by Bazin forty years ago. Strengths of from one-half to two per cent. have been used, but never continued long enough to work a cure. Naphthalin in twenty-per-cent. ointment has given encouraging results, two cases being cured after five and a half weeks. Two cures resulted from veratrine, from eight to thirty grains to the ounce. In some cases treated by chrysophanic acid there was no improvement whatever. One case was cured in nine weeks. It does not seem to reach far enough into the follicles, and is powerless against the deeply situated fungus. Preparations of mercury have proven the most efficacious of those used. Under any drug we must corroborate Wickham's dictum that the treatment cannot practically be reduced to less than eight months.

Treatment of Scalp Ringworm in Institutions was the title of a paper next read by DR. CHARLES W. ALLEN, of New York, in which the great difficulties of securing proper co-operation of managing-boards was pointed out, especially in isolating the cases and in taking the measures necessary to a speedy stamping out of epidemics. The use of "clippers" in asylums and other children's institutions was deprecated, because it was found that while these instruments are

capable of being cleansed, the disinfection is not so easily accomplished as is the case with shears, and in point of fact diseased and healthy heads are indiscriminately operated upon in many institutions without the necessary precautions, thus rapidly spreading the disease. Epilation, to be of any use and to make sure of its doing no harm, should be employed only in the variety showing distinct circumscribed patches of limited number, and should be carried out only by trained assistants possessed of tact and intelligence. Cutting the hair close at weekly intervals over the entire scalp of boys and girls alike he had found the most practical. It was advisable that graded wards be established in all institutions in which epidemics occur, so that the cases apparently cured may at once be placed by themselves away from the cases still surely infectious, and transferred from these after an interval to still another intermediary ward before being finally sent back among the well children. Several epidemics in different children's institutions were drawn upon for the cases observed, and the deductions reached from their observation and treatment noted. In the last series of ninety cases in an infant asylum, after trying the usual forms of mercurial and other parasiticide remedies, a large number were treated with chrysarobin in collodion, which gave excellent results and applied in this combination lessened the dangers and disadvantages of the staining and inflaming qualities of the drug. It was thought, too, that the collodion acted favorably by shutting out the air, since the fungus has been demonstrated to grow in a much more flourishing manner when an abundant supply of atmospheric air is supplied. Though not so necessary as when the ointment is employed, the writer advocated the use of a caoutchouc cap fitting snugly the forehead, if not the entire scalp. Unna's suggestion to raise only the back of the cap when new ointment is applied, while a good point, is not so necessary when the collodion is used. The matter of paramount importance is to make sure a patient is well in fact, and not only so in surface appearance, before being discharged. Another and more important thing for institution authorities is to practise painstaking scrutiny of the scalp as a prerequisite to admission of new cases having to mingle with the mass of inmates. It is much wiser and better financially, if in no other way, for an institution to prevent epidemics than to cure them, or, as some do, by their shortsighted methods, to cause them. The reported quick cures of chronic scalp ringworm are for the most part fallacious.

Several months of patient and painstaking attention are usually necessary. The speaker had, however, seen during epidemics instances of rings presenting pink borders develop upon the scalp of blond babies, occasionally implicating the skin of the forehead and the scalp region equally, which were cured within a very brief period by applications of iodine or chrysarobin.

Discussion.—DR. WOLFF, of Atlanta, said he had had extensive experience in institutions, and agreed with Dr. Allen's conclusions concerning the necessity for isolation. The plan of treatment found most satisfactory is to avoid epilation and to rub in twice a day the following:

R Chrysarobin	5
Salicylic acid	2
Ichthyol	5
Vaseline	85

This must be persisted in for several weeks and followed by

R Powdered zinc oxide	6
Precipitated sulphur	4
Silicated earth	2
Benzoated lard	25

until the irritation has subsided. With this he has obtained fairly good results, but has never obtained such results as Unna has claimed, his own cases extending to eleven months, and a few persisting for two years. He agreed that there is great difficulty in inducing the management of institutions to see the necessity of proper isolation.

DR. HUTCHINS, of Atlanta, said he has used pyrogalllic acid, three per cent. in collodion, in crural trichophytosis, or eczema marginatum, reducing this to two per cent. if necessary. This he has found curative in a very short time. Kerosene with from one to four grains of bichloride to the ounce, changing to ichthyol and salicylic acid, from ten to fifteen grains to one drachm of zinc ointment or benzoated lard, cured a single case within three months.

DR. SCHWARTZ said that he has found mercurial ointment too astringent. Pyrogalllic acid is open to the same objection. Formaldehyde he has found peculiarly penetrating, and thinks it may have a parasiticide action, since it is used as a germicide. He thinks epilation of the margin of the patch may increase the chances of spread.

DR. RAVOGLI said that he has seen much ringworm in institutions and cases in the hospital sent from children's institutions. He has given up the newer remedies for the plan of treatment advocated by Hebra, using the modified Wilkinson ointment twice daily. This is followed by a two-per-cent. alcoholic solution of carbolic acid frequently applied. Microscopic examination is made two weeks after seeming cure, and he has never had recurrence in the cases described.

DR. BRAYTON, of Indianapolis, said that he has used Boetger's paste, made with milk of lime from freshly slacked lime, through which a stream of sulphuretted hydrogen gas is passed for one or two hours, or till saturation is reached, when it becomes green. This is now sulphhydrate of calcium, CaH_2S_2 , and is a perfect depilatory. In one case this paste was applied to the scalp, causing deep depilation, eating off the hairs considerably below the surface. No notice is found of this paste except in Vol. I. of Watt's "Chemistry Dictionary."

DR. GILCHRIST spoke of experiments made upon the growths which demonstrated how various simple substances, such as soap, destroyed the spores so they would not grow. He had himself demonstrated that the fungus grows in cultivation both upon the surface and deeper in the media, but deeper in the appearance changed. Clinically the appearance in colored children is that of *seborrhea sicca* rather than of trichophytosis, showing the value of the microscope. In colored children the curly hair does not break off so much or show so much when broken off. Chronic ringworm is very common in colored children and in the family it is very difficult to properly treat. The deep penetration into the lower layers of the epidermis explains the difficulty of cure as much as the penetration into the follicles.

DR. BULKLEY said clippers should be boiled every time after use in soda solution and dried in the oven. Then they are no more dangerous than the shears. He has thought he has seen shaving spread the disease. In shampooing with green soap he adds bichloride in the proportion of from two to four grains to one ounce.

DR. HUTCHINS thought the bichloride may become changed by the alkalinity of the soap, producing a chemical decomposition. Concerning Boetger's paste, he said that in using it we are applying a strong and penetrating parasiticide and hence it should be better than shaving. He agrees with Dr. Allen's statements regarding the soil. He habitually puts his patients under rigid dietetic and general treatment. Until puberty we have much difficulty in curing the disease

permanently, unless the greatest care is taken to change the soil.

DR. GILCHRIST said it is interesting to note that in tinea sycosis there are two distinct forms—one going along the surface and not attacking the follicles. He has seen within a year at least fifteen such cases.

DR. BULKLEY said it was well that all children entering institutions should be examined for scaly patches, since broken hair shafts may be absent.

DR. WILLIAM L. ALLEN, of Davenport, Ia., said he had seen much ringworm recently in an institution. He has used a one and a half per cent. solution of bichloride combined with biniodide of mercury. After a year's treatment out of eighty cases only six remained uncured. New cases coming in all the time kept up a continual census of about eighty. In the third year there were found out of this number eight cases which had been of the original number. The rest were new cases. The scalps were now washed with green soap and a bichloride solution, thirty grains to the ounce, was applied with caution. In some instances this proved terribly escharotic, but in others there was no irritation by it. One death was attributed to mercurial poisoning, however. The institution has five hundred inmates, ranging from two to sixteen years of age. At present there are about forty-six cases of ringworm, all doing well. Only newly admitted cases now receive the strong mercurial solution. New children coming into the institution often get the disease in an average time of six weeks from admission. Half these children are girls, and none of them has previously had the disease.

DR. C. W. ALLEN asked if clippers were used, and if the girls had the hair cut. The speaker said the girls do not have the hair cut except when coming in with the disease.

DR. WOLFF said his cases are all boys, although all the children, boys and girls, have the hair cut—he thought with clippers, but he was not sure of this.

DR. SCHWARZ said the exchange of caps was accountable for much of the spread. Gifts of second-hand articles of headwear are sometimes made to children's charity institutions. These should not be made use of before they have been thoroughly sterilized.

Special Dermatitis from Crab Bites was the title of a paper read by DR. GILCHRIST, of Baltimore, based upon one hundred and fifty-six observations made at the Johns Hopkins University. The condition occurs in those whose occupations force them to handle live crabs. A slight abrasion of the skin is first noticed, usually upon the finger, from which the patch starts and travels up and down the fingers and spreads out over the palm and back of the hand. The margin becomes raised, red, and is particularly well defined. There is no pain on pressure, and it never goes on to suppuration. There is acute inflammation of the corium and thickening of the epidermis. Scratches from the crab shell as well as the bite will occasion the affection. A ferment is supposed to be the cause, since all culture experiments are negative and microscopic examinations show an absence of micro-organisms. Treatment is carried out by means of bichloride soakings and carbolic injection, or the application of the German salicylic cutaneous plaster of about twenty-five per cent. strength. The latter is found to offer the best method of treatment, one application of the plaster usually sufficing. Plain adhesive plaster was tried in some instances and found efficacious.

In discussing this paper DR. ALLEN, of New York, suggested that the same condition probably exists in these cases which has been described by Rosenbach under the name of erysipeloid. The speaker has seen this same creeping erythema involving the fingers and hand, in fishermen among others. His most recent case was

in a woman who had been engaged in preparing lobster and fish shortly before the attack. He has obtained excellent results from ichthyol solutions and ichthyol in collodion.

DR. BULKLEY, of New York, agreed with the last speaker that the cases probably all belong together. He has seen the same condition result from handling meat. It is in no sense erysipelas.

DR. GILCHRIST said he has been unable to find any reference to the condition he described in any of the text-books on dermatology. The cases have become so frequent at the out-door department of the hospital that all now made the diagnosis of crab dermatitis at a glance. He thought it worthy of a distinctive designation, but had no doubt Dr. Allen is correct in classifying it with the condition already described in Germany.

A Case of Acute Circumscribed Œdema of Gouty Origin was reported by DR. BERNARD WOLFF, of Atlanta, Ga. Œdema of the acute circumscribed variety must not be confounded with that of menstrual, malarial, and arthritic origin, as Quincke has pointed out. As to causation, it cannot be differentiated from these three types. Osler says the disease may be hereditary. Alimentary irritants have been given as the cause in some instances. There is a close affinity to urticaria. There would seem to be a greatly increased permeability of the vessel walls. Spasm of the muscular coats of the veins, a theory advanced by Unna, is not accepted by Quincke in explanation of urticaria, the giant form of which this disease closely resembles. If gout be regarded as a toxæmia, why cannot such a condition so lower the vitality of the vessel walls in a reflex manner as to diminish their power of resistance to the passage through them of the elements of the circulating fluid? Or, again, may not the toxic principle, having itself passed into the tissues, attract to it a special exudate? A case is reported of a lady of fifty-six, of good family history, but for fifteen years the subject of gout, the last joints of the fingers being distorted by gouty deposits. Six years ago, while sitting at an open window, the patient suddenly experienced a stiffness and rigidity of the left half of the upper lip, accompanied by tingling and numbness. There was no extension of the swelling. Coincidentally the joints became red and painful. After a few hours the attack disappeared, but recurred at intervals of four or five months for two years. The œdema was of board-like hardness. The attacks are now less frequent. The similarity of cause in both affections and the attacks being synchronous made the writer believe that there was a relationship.

Further Observation on Urticaria was the title of a paper read by DR. T. C. GILCHRIST, of Baltimore, Md. The author referred to his statement at the last meeting of the association that he had excised portions of wheals produced artificially at exact periods of time, viz., two, five, eight, ten, fifteen, twenty-five, forty, and sixty minutes, and the results showed the complete pathology of the urticaria wheal. After fifteen minutes a complete picture of acute inflammation of the skin was presented by the sections. There were extensive emigration of polynuclear leucocytes, marked exudation of serum, small quantities of fibrin, particularly in the neighborhood of the blood-vessels, pronounced dilatation of the lymphatics, and an increase in the number of lymphoid cells. The epidermis was practically normal. The present paper contained observations on three additional cases of urticaria factitia and the examination of spontaneous wheals, together with the application of improved technique. "Mastzellen" were stained after a slight modification of Unna's method and they were found to be apparently increased in numbers. In these further cases the results were the same, viz., acute in-

flammation of the skin. Other points noticed were nuclear fragmentation of the polynuclear leucocytes and in one case even of the fixed connective-tissue cells, a point to which the speaker's attention was called by Dr. Welch, of the Johns Hopkins University. On account of the evidence of this nuclear fragmentation presented by Dr. Welch the author thought, and this idea was again suggested to him, that some powerful irritant, probably a toxin, was set free from the blood-vessels upon producing the wheal, demonstrating a toxæmic condition of the blood. The presence of indican in the urine in large quantities in some of the cases examined might possibly point to the chemical nature of this toxin. After due consideration the author thinks this theory explains all the phenomena of all varieties of urticaria. Dermatologists who have examined urticaria pathologically have generally agreed with the belief in the inflammatory nature of the wheal. The author brought forward the fact that in these wheals we are able to study the early stages of inflammation in man, which heretofore has never been done. It was found that the polynuclear leucocytes were observed first in the vessels in two minutes; in five minutes the emigration of these cells was first noted; in eight minutes there was beginning disintegration of these cells; in fifteen minutes there was an increase in number of lymphoid cells and apparently of "mastzellen."

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 7, 1896.

DR. EGBERT H. GRANDIN, VICE-PRESIDENT, IN THE CHAIR.

The Polyarthritis of Scarlet Fever.—DR. HENRY W. BERG read a paper on this subject. He stated that the acute infectious diseases are quite universally supposed to leave as a specific sequel of their occurrence a predisposition to the subsequent development of chronic osteitis, both of tuberculous and non-tuberculous character. How much truth there is in this assumption is doubtful, for two reasons: First, the more or less direct connection in point of time between the occurrence of the earliest joint manifestation and the infectious disease does not prove a specific etiological connection between the two maladies. Second, the universality of the occurrence of acute infectious disease is such that very few persons affected by chronic joint disease can fail to recall being the subjects of measles, scarlet fever, or mumps at some time previous to the development of the joint manifestations. The speaker said he had accordingly been extremely sceptical as to the etiological connection between chronic joint disease and the acute infectious diseases, and this feeling of doubt had led him to observe and study with especial interest a series of joint complications occurring in the course of scarlet fever. Joint affections are more frequent in this disease than in any other of the acute infectious diseases.

Dr. Berg then briefly reported six cases of polyarthritis complicating scarlet fever seen during his service of two months at the Willard Parker Hospital in the summer of 1895. In all of these cases more than one joint was affected, and in most of them the arthritis affected the joints of both sides of the body. In several of the cases the smaller joints, those toward the periphery of the extremities, such as the joints of the hand and foot, wrist, elbow, and knee, were affected. Five of the cases ended in almost perfect recovery, while one was discharged with two suppurating joints. The speaker expressed the opinion that the occurrence of polyarthritis as a complication of scarlet fever does not render the prognosis of the lat-

ter any worse *per se*, so far as regards danger to life. This is in contradiction to the view held by many writers that polyarthritis occurs only in scarlet fever patients who are extremely apt to die. In all the cases that have come under his observation during the past two years the patients made a fairly good recovery. Disability of a more or less chronic character occurred in some of the joints affected, but even this yielded to appropriate treatment.

Dr. Berg mentioned four varieties of polyarthritis occurring as a complication of scarlet fever or other acute infectious disease: 1. Cases in which there is a simple inflammation of the joint structures without effusion of serum and with little swelling. 2. Cases in which the clinical symptoms are chiefly those of synovitis. The other structures of the joint are in an acute inflammatory condition, but this gradually subsides as the swelling and effusion disappear. 3. There is a group of cases in which the arthritis consists of a simple or (later) a purulent synovitis, accompanied by or terminating in osteitis, with or without necrosis of the affected joint ends of the bones. 4. Cases in which there is from the very beginning a suppurative polyarthritis, with purulent inflammation of even the shafts of the bones and rapid destruction of all the joint structures.

As to the bacteriological cause of this complication, the opinions of the different authorities do not agree. It appears highly probable, however, that the polyarthritis is not produced by the specific germ of the scarlet fever, but is the result of mixed infection. It is easy to understand where the absorption of the streptococci and other germs helping to produce this infection occurs. It is evidently in the throat, and chiefly in the nose and pharynx.

The time of the occurrence of arthritis as a complication of scarlet fever, that is to say, the stage of the disease in which it occurs, is almost uniformly during the period of desquamation or later. All the patients observed suffered from a greater or less degree of nephritis. In most of the cases the latter preceded the joint lesions. Many writers have considered these joint complications of scarlet fever as identical with rheumatism; indeed the complication is frequently termed scarlatinal rheumatism. Clinically, the affection certainly resembles rheumatism in some respects. In both conditions many joints are apt to be affected; in both the amount of inflammation varies from a vague feeling of soreness to an intense inflammation of the joints. But, on the other hand, there are many points of difference. Rheumatism may affect the larger joints, such as the hip, as frequently as the smaller, while in this complication the largest joints are immune; in acute articular rheumatism the inflammation seldom goes further than rheumatic synovitis, while in scarlatinous polyarthritis the inflammation may affect all the joint structures and much more frequently terminates in purulent arthritis and necrosis of the joint ends of the bones. While rheumatism is a primary disease, these joint complications are evidently secondary septic manifestations. The frequency with which rheumatism is complicated by endocarditis and pericarditis is well known; in the cases of polyarthritis coming under the speaker's observation, not a single one gave any clinical symptoms of a lesion of the heart. Furthermore, in none of the cases was there any sign of inflammation of any of the serous membranes, excepting those of the joints. Lastly, not a single one of the cases was benefited to any appreciable extent by the use of salicylic acid and its compounds. On the contrary, the arthritis of scarlet fever is not in any way modified by this class of drugs. These considerations lead him to express his adherence to the view that the polyarthritis of scarlet fever is not a rheumatic manifestation and that

there is nothing in common in the complications, prognosis, and therapeutics of the two conditions.

Prognosis.—By far the largest proportion of cases of polyarthritis complicating scarlet fever are of the first or second variety, which terminate in recovery. The fourth variety, in which the arthritic process is from its inception a purulent one, accompanied by a general condition of septicæmia, is almost uniformly fatal. The prognosis of the third class is more interesting; in these cases there is general arthritis, involving all of the structures of the joint, with or without the formation of pus, and these cases may terminate in recovery or in chronic joint disease.

Treatment.—Remembering the causation of this complication, much can be done from a prophylactic standpoint. It is logical to suppose that any form of treatment which will diminish the number of germs in the throats of scarlet-fever patients will diminish the danger of mixed infection and thus prevent complications. Scarlet-fever throats should be irrigated, whether true diphtheria be present or not. For this purpose, corrosive sublimate solution (1 to 4,000) can be used with the fountain syringe three times daily, or oftener if required. As to the active therapeutics of a medicinal nature, the indications are to allay pain and specifically to influence the disease. To relieve the pain we can use phenacetin, opium, and other narcotics and anodynes. Ice bags applied to the inflamed joints are of much benefit in relieving pain and reducing the severity of the inflammation. The most rational remedy which can be expected in this disease will be the use of the antistreptococcus serum, or streptococcus antitoxin. In many instances, however, the treatment of these complications demand more of surgery than of medicine. While mild cases will pass off readily with rest, counter-irritation to the joint, and symptomatic treatment, cases of the second and third varieties will require careful surgical management. In cases of the second class, so sensitive are these joints that the slightest movement produces agony, and it is often necessary to devise an appropriate splint which will give the joint absolute rest. This splint should be applied in the position most comfortable to the patient, and should be modified to suit the modified position of the limb. If fibrous ankylosis occurs, passive motion is indicated. Breaking up of the adhesions under an anæsthetic is not advisable. A serous effusion in these cases should not be disturbed by aspiration or incision, however long it persists. It is almost invariably reabsorbed and the joint recovers absolutely. Where we suspect pus the suspicion should be verified by the aspirator, and when found the joint should be incised, washed out, and drained. The early detection of pus in such a joint and immediate incision will generally prevent the occurrence of a chronic osteitis or perhaps total destruction of the joint.

DR. NEWTON M. SHAFFER said that this subject has interested him for many years, and his experience has taught him that while the acute infectious diseases of childhood may be complicated by acute joint lesions, he has never seen a case in which chronic tuberculous joint disease resulted. He was inclined to agree with the statement made by Dr. Berg, that there is no etiological relationship between these acute joint lesions and rheumatism. Dr. Shaffer said he wished to call attention to another phase of this subject, namely, the effect of an attack of scarlet fever or other acute infectious disease upon a tuberculous joint lesion in some instances. The improvement following such an attack is sometimes almost magical. He has seen a number of cases of tuberculous joint disease of long standing in which rapid improvement followed the onset of an acute infectious disease, and cases have been reported in which complete recovery took place.

DR. JOHN W. BRANNAN said that in several particulars his observations in connection with this subject did not agree with those of Dr. Berg. About eight years ago he saw a young man with a well-marked mitral insufficiency, who, while he had never had rheumatism, gave a history of scarlet fever. Since then he had seen a number of cases in which cardiac lesions developed during the course of an attack of scarlet fever or shortly afterward. In one case pains in the joints were also present, and these, as well as the violent action of the heart, were readily controlled by the administration of the salicylates. At the present time there are seventeen cases of scarlet fever in the Willard Parker Hospital, and among these there are three cases of arthritis. Two of the latter have developed a distinct cardiac murmur since the onset of the arthritis. In all three of these cases the administration of salicylate of soda has produced a marked improvement in the symptoms. The fever has diminished, the pain is lessened, and the heart murmur is fainter. For this reason Dr. Brannan said he was inclined to regard this complication of scarlet fever as rheumatic in character.

DR. LAMBERT, in reviewing the subject of the bacteriology of scarlet fever, said that its true etiology is still an open question. Pfeiffer and his adherents claim that the disease is due to a protozoon, while other observers say that it is the result of some form of streptococcus. A special streptococcus has been isolated by one investigator. Recently a Russian found a diplococcus present in the blood in thirteen cases of scarlet fever examined by him. He does not claim that this is the cause of scarlet fever, but mentions that he has never been able to find it in other diseases. These few facts, Dr. Lambert said, do not of course indicate the vast amount of work that has been done in this direction; they simply show that the problem is still unsolved.

DR. SAMUEL KETCH expressed the opinion that in tuberculous subjects there is a connection between the acute infectious diseases, notably scarlet fever and measles, and the development of tuberculous joint lesions. He has seen a number of cases which would tend to confirm this view. The speaker said that while he does not believe that scarlet fever is as common a cause of chronic joint disease as the textbooks would indicate, yet he cannot entirely discard the idea that in a tuberculous subject it acts as a trauma in the production of tuberculous joint trouble.

DR. W. R. TOWNSEND said that three years ago he saw a case in which the knee-joints became affected early in the course of an attack of scarlet fever. Both knees were swollen and extremely painful. The patient was put on salicylates and made a good recovery.

DR. S. H. DESSAU said he has always looked upon these joint affections of scarlet fever as being rheumatic in character. Two or three such cases have come under his observation, and in every instance recovery followed the use of antirheumatic remedies.

DRS. JUDSON and CHAPPELL continued the discussion.

DR. BERG, in closing, said he did not wish to be understood as saying that cardiac affections, namely, an endocarditis or a pericarditis, may not complicate scarlet fever; if such a complication occurs, it is probably due to the action of the streptococcus or mixed infection, just as the polyarthritis itself is, and not to rheumatic poisoning. He called Dr. Brannan's attention to the fact that not infrequently cardiac lesions develop in scarlet-fever patients who never give any symptoms of joint trouble at all. According to his experience, mild cases of polyarthritis occurring in the course of scarlet fever get well under any form of treatment, while the severe cases are unaffected by

the salicylates, piperazin, and other antirheumatic remedies.

SECTION ON SURGERY.

Stated Meeting, May 11, 1896.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Fracture of the Patella Treated by Suture.—DR. JOSEPH A. BLAKE presented a young man who had sustained transverse fracture of the patella by muscular effort to save himself from a fall, four weeks ago; treatment followed a week later by suturing the two segments together by wire through transverse incision. A point of interest was the presence of the lateral patellar ligament torn from its attachment to the tibia, still attached to the upper fragment of the patella, lying completely across the broken edge of the latter, and which evidently would have prevented bony union without the cutting operation and removal. Thus far the result had been perfect. A plaster cast was still worn, laced up on the front of the leg.

Diabetic Gangrene; Amputation of Thigh.—DR. ARTHUR L. FISKE presented a man, sixty-six years of age, who had been cured of varicose ulcers of the leg in 1893. Others developed in 1894. Sugar was found in the urine, gangrene commenced in the sole of the foot and extended. The temperature was septic and on consultation Dr. Fiske amputated the limb at the point of selection, in the thigh, antero-posterior flap. The femoral artery was found atheromatous. Before the operation the urine contained 7.5 per cent. of sugar, five days afterward only 2.5 per cent., and within a few weeks the sugar had disappeared entirely and the man's health had become better than it had been in years. In Dr. Powell's paper read before a meeting of the New York State Medical Society it appeared that in eleven cases of amputation for diabetic gangrene five patients died. The more dangerous cases were those in which the urine contained albumin in addition to sugar.

Dr. Fiske also presented a woman, aged sixty-one, whose breast he had amputated for ulcerating carcinoma a year ago. Her urine had contained more than two per cent. of sugar and sugar was still present, but the breast had healed favorably and there had been no recurrence of carcinoma. The pectoral muscles and axillary and clavicular glands were removed with the breast.

Intestinal Fistula; Suture.—DR. E. M. FOOTE presented a boy, sixteen years of age, who had had a fistula in the right groin for two years. At first it had discharged pus, then feces. The history was somewhat indefinite. Dr. Foote closed the opening in the intestine eighteen days ago by incision in the loin. Union had been complete.

Separation of Epiphysis of Head of Humerus.—DR. JOHN B. WALKER presented a boy, three years old, who had been brought to him while the shoulder was enormously swollen, and with a history of having fallen. Motion was obtained just below the tuberosity; no crepitus. He made a diagnosis of separation of the epiphysis. The child now had almost perfect use of the arm.

Plastic Operation for Restoration of the Ear.—DR. B. F. CURTIS presented a man advanced in years, illustrating the result of an attempt to restore the ear by plastic operation after its removal for epithelioma. Only the lobe of the ear had been left. An extensive flap of integument had been raised from the neck and gauze placed beneath it; then the lower attachment was divided and the flap, attached by a pedicle above, was turned over, modelled somewhat in imitation of the normal ear, and attached by sutures. The result had been fairly good, but in spite of the size of the

flap it had shrunken so much as to permit of but little further shaping. He hoped to overcome its tendency to droop by a further minor operation. Skin grafts had left the wound in the neck nearly of the appearance of the surrounding integument.

Discussion on the cases being in order, THE CHAIRMAN said Dr. Fiske's case reminded him of one of cellulitis of the hand in which the complaint had started from a small wound and had run a very obstinate course. Finally sugar was discovered in the urine, which cleared up the case; they amputated the arm just below the elbow with good result, and the patient was still living in fairly good health, although the urine was not free from sugar.

DR. LILIENTHAL said he had amputated the breast in a young woman whose urine contained five per cent. of sugar, and, although the wound healed primarily, yet there was no reduction in the amount of sugar. It had been his observation that in amputation of the thigh for gangrene the sugar disappeared from the urine, but why it should disappear in such cases and not after amputation of the breast, he was unable to explain.

DR. JOHN ERDMANN, commenting on Dr. Walker's case of separation of the epiphysis of the head of the humerus, said he once read a paper on some cases in all of which he was able to make out some motion and to feel the bicipital groove.

Multiple Calculi of the Prostate.—DR. L. BOLTON BANGS read the paper. By calculi of the prostate was meant those which formed within the body of this gland from material furnished by the gland exclusively—material which did not come from the urinary tract and primarily had no admixture of urinary salts. They formed insidiously, grew slowly, and occupied a sac which they painlessly made for themselves within the tissue of the prostate. They were usually multiple; under certain conditions two or more might amalgamate and form a stone of considerable size. They were found during midlife, but were said to exist even during childhood. Under the head of prostatic calculi the text-books had recorded many interesting cases, but some of these were not such, strictly speaking, and should have been described as urethral calculi.

As many as three hundred had been found. As a rule they did not cause symptoms except after erosion into the bladder or urethra, when the mass had attained considerable size. They were not infrequently met with at autopsy in considerable numbers and size in persons who had had no symptoms during life. In these days of castration for enlarged prostate, the possibility of a mistake in diagnosis should be borne in mind.

The theory of the formation of prostatic calculi was that they started in the minute concretions which were found microscopically in a large proportion of prostates examined after death. Some observers regarded them as a normal product of the gland, but Dr. Bangs thought they were abnormal and the result of some disturbance of function.

A typical case was related, that of a man of sixty-five, who on two occasions passed a stone per urethram with symptoms pointing to renal calculi, and Dr. Bangs believed that such was their origin. Later he had difficulty with urination, and the family physician felt a calculus in the prostatic urethra which he failed to dislodge. It caused little trouble for a year. Dr. Bangs then saw the man and felt the stone projecting from the body of the prostate into the urethra. After extracting it, he found a prostatic pouch containing twenty-nine other stones closely packed and faceted. After their removal the gland was about one-third its previous size. The patient made an uninterrupted recovery. As already stated, Dr. Bangs was of opinion

that the first two calculi were of renal origin, the others primarily prostatic.

THE CHAIRMAN remarked that the symptoms varied in intensity very much in different cases of prostatic calculi. He had removed one stone in a boy which had penetrated the bladder, was three inches in length, having received accessions from the urine. The symptoms of irritation had been intense.

DR. F. TILDEN BROWN recalled one case of prostatic calculi in which crepitus was quite distinct, although there was no appreciable increase in the size or prominence of the gland.

DR. BANGS replied to a question that the stones seldom produced marked symptoms so long as they were in the sac and had not projected into the urethra or bladder. Crepitation was not always present, as shown by the case of an aged man in whom he had diagnosed prostatic calculi. He emphasized the view that it was a mistake to teach the medical student that concretion in the prostate was normal. He regarded it as the beginning of what might prove to be a very serious pathological process.

Arthritis (?) of Hip in an Infant.—DR. W. R. TOWNSEND presented an infant, four weeks old, with moderately firm swelling of thigh and hip, which had been noticed as early as the third day after birth. The labor had been easy. The temperature had not gone above 101° F., fluctuation was absent, and aspiration had failed to secure pus. The tumor he thought might be a malignant growth.

DR. LILIENTHAL was of opinion that it was a new growth. He mentioned a case of congenital angioma of the buttock which extended to the knee, and finally required amputation, performed by Dr. Gerster. Some fifty ligatures were employed.

Diagnosis in Some Common Shoulder Injuries.—DR. A. C. VIETOR read a paper which contained the histories, with details of repeated examinations, of some fourteen cases of injuries to the shoulder without fracture or dislocation. The object of the paper was to show the necessity for such systematic examinations in all cases in order to arrive at a correct diagnosis and prognosis, if this were possible. It was especially necessary to determine whether there was altered electrical reaction pointing to a neuritis or atrophy of muscle. In a few of the cases there had been no history of traumatism, and in most of them it was only by careful study that such lesions were discovered as limited atrophy, slight paresis, limitation of motion in certain directions, altered reaction to faradism or galvanism in a special nerve branch coming from the brachial plexus. The cases had been seen at the Good Samaritan Dispensary, clinic of Dr. W. W. Van Arsdale.

DR. VAN ARSDALE expressed his appreciation of the importance of studying these cases minutely, as described in the paper, and then referred to experiments of M. Deroche, who had repeated seven times, and always with the same results, those done for the first time by Raymond and Ovanoff. He dissected the posterior roots of the last three lumbar nerves of the left side in dogs and rabbits. After cicatrization had taken place, he assured himself that numbness was complete from the thigh to the knee of the left limb, so that irritation of this region was not felt. The right limb was left intact. An arthritis was then set up in both knees by introducing a thermo-cautery into them. No pain was felt in the left limb, but much in the right. Three months afterward the animals were killed, and in both knees the lesions of arthritis were found; but the muscles of the thigh of the left limb were of normal size, while those of the right were atrophied. M. Deroche thought he found that the atrophy was due to diminution of interfibrillary substance, and that there was an ascending degenera-

tion of the posterior columns of the spinal cord of the same side. However that might be, the inference was certainly justifiable that massage acted to prevent muscular atrophy by maintaining an influence, a movement, or something in the muscles which the spinal cord was for a time unable to impart to them, and in order to do this it should be applied very soon after injury.

New Instruments.

A SELF-RETAINING VAGINAL SPECULUM FOR OPERATIONS IN THE DORSAL POSTURE.

By H. J. GARRIGUES, A.M., M.D.,

NEW YORK,

GYNECOLOGIST TO ST. MARK'S HOSPITAL, ETC.

The principle of making a vaginal speculum hold by its own weight when introduced into the vagina of a patient lying on her back with the knees or the feet drawn up is an old one. So long as the instrument was to be used only in trachelorrhaphy or in other operations in which it need not be removed and replaced during the operation, a blade ending in a tube to which a pail with water was attached answered fairly well. But the new operations for vaginal hysterectomy in which the speculum often is removed and reintroduced

many times, call for an instrument composed of one piece that is easy to handle.

I formerly employed Auvard's speculum, an imitation of the one Dr. Jacobs, of Brussels, used on his visits to this country last summer, but I soon found that the two sharp perpendicular ridges that form the upper part of the canal of that instrument were much in the way and in difficult operations cut the fingers and hands of the operator. Another objection was that the canal designed to carry off blood and other fluids was angular and so narrow that it was difficult to clean. After some experiments I have succeeded

Garrigues' Self-Holding Vaginal Weight-Speculum.

in making an instrument that has proved serviceable to myself and others in all vaginal operations in the dorsal decubitus, especially curetting, packing, trachelorrhaphy, colpotomy, salpingo-oöphorectomy, and hysterectomy. By the shape of its curve and the size of its angle it adapts itself easily to the posterior vaginal wall and holds even if the perineum and the entrance to the vagina are torn. The lateral wings lie flat against the nates and hold them out of the way; and the canal is cylindrical, smooth, and so wide that two or three fingers find room in it. At the lower end is a slightly prominent flange to which a rubber tube may be attached, but as a rule the fluid flows simply down into a slop-pail or strikes the flap of the inflated rubber cushion on which the patient lies. An inch higher up is a mass of lead which forms one piece with the efferent canal and gives the whole instrument a weight of two pounds. The distance between the weight and the blade is long enough to keep the former clear of the nates.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

COLLEGE OF PHYSICIANS—COLLEGE OF SURGEONS—ROYAL SOCIETY—CLINICAL SOCIETY—SPONTANEOUS DISLOCATION OF HIP—ABLATION OF BREAST—THE LATE WILLIAM LOCKHART—DR. SHARP—INSPECTOR-GENERALS ANDERSON AND FLANAGAN.

LONDON, May 8, 1896.

THE College of Physicians has accepted an oil portrait of Dr. J. Copland, the author of the great medical dictionary which bears his name and is a monument to his erudition. The collection of portraits and autographs of medical and scientific men formed by the late Dr. Greenhill has also been presented to and accepted by the college. Ten members have been elected fellows. There is no objection to any of them, but it would have been better to make up the usual dozen with the names of older men, who have been inadvertently passed by or who scorn to seek an honor which should have been offered them.

The College of Surgeons is still in trouble about the representation of members on the council. Mr. Rivington, always as sincere a reformer as he is an able surgeon, has given notice that at the next meeting of the council he will propose that the resolution adopted against this representation be rescinded. So the council will get another opportunity of considering whether it is just to shut out the body corporate from all rights and privileges in their own college.

The conversation of the Royal Society was held on Wednesday. The "new photography" was the great attraction in the exhibition, although the old photography ran it close. There were photographs of splashes of water taken by the electric spark with an exposure of only three-millionths of a second. Also the stereo-photo-chromoscope for recording and reproducing colors as well as the phonograph does sounds. A rapid photo-printing machine was also shown, which must greatly advance the illustration of periodicals.

At the last meeting of the Royal Medical and Chirurgical Society three papers were read, viz.: 1. "Spontaneous Dislocation of the Hip, with Some Remarks on a Class of Cases often Mistaken for Rheumatism." 2. "A Method of Obtaining a Complete Skin Covering after Ablation of the Breast." 3. "The Transplantation of Skin Flaps for the Filling up of Considerable Defects after Amputation of the Breast."

Dr. Barwell read the first paper. The patient was a naval officer, who on account of an obscure affection of the hip had been sent from St. Leonards by Dr. Fenning. He had served for the last three years in Chinese waters, and during the homeward voyage was greatly troubled with boils. These culminated in erysipelas of the face while he was passing through the Red Sea. He was landed at Malta and went into hospital, where several sores and some abscesses formed about the face, accompanied with high temperature. One night he was attacked with severe pain in the right hip and thigh, and when he left his bed he was very lame. This pain was ascribed to sciatica and was treated accordingly. He came under Dr. Fenning's care on October 8th, still suffering from pain and lameness, his temperature ranging to about 100° F. A striking feature in the case was that the pain was felt in the anterior crural nerves as much as in the sciatic nerve. Mr. Barwell, on first seeing him, noticed the peculiar and uneven step indicative of hip mischief. As the patient stood on the left foot he placed the right one a good deal in front, keeping the

knee bent and the body bowed; when standing on the right foot the other heel did not reach the ground by a considerable distance, and the prominence of the trochanter was absent from its normal place. Dislocation of the head of the femur being diagnosed, it was reduced by Bigelow's method. Three days later the patient walked perfectly straight and without any limp; all his pain had disappeared. He has passed again to active service.

Dr. Norman Moore asked for information regarding dislocation of the hip-joint in cases of enteric fever. He had read all the post-mortem accounts of St. Bartholomew's Hospital since the year 1867. No case had been met with there, neither had he seen the condition.

Mr. Barwell said he had seen three cases of dislocation of the hip in undoubted enteric fever, and in a fourth case there was strong reason to believe that the disease was typhoid fever. In one case, in a girl aged nine years, he attempted reduction two years after the dislocation, but failed. In the case of a girl aged sixteen, in which the diagnosis was confirmed by Murchison, he attempted reduction about four months after dislocation, but failed. In this class of cases there was no sign of inflammation in the joint, but the bone slipped on to the dorsum ilii from a healthy socket.

Mr. Mayo Robinson read the second paper named above, which was illustrated by diagrams and photographs of cases. So far as he could ascertain, the practice among surgeons had been, he said, to draw the parts together as far as possible and then to leave the remainder to granulate, or to cover the remaining surface by Thiersch's skin grafts, the former being a tedious and the latter an uncertain and not always successful method. He showed that by means of one or two single incisions with sliding of the flaps the whole of a very extensive wound might be closed, and that primary union might thus be secured. Although some tension was necessarily present, the observance of antiseptic precautions had prevented sloughing, and in a number of cases in which he had operated he had not experienced any trouble. He concluded his remarks by saying that he believed it would be found that the adoption of the method portrayed, or some modification of it which would carry out the principle of completely re-covering the large wound surface, would not only render these extensive operations less formidable by shortening the convalescence, but would tend to greater thoroughness, as it would also enable surgeons to operate in cases otherwise hopeless.

The third paper was by Mr. Butlin and Mr. Beadon Adams. In cases of cancer in which it was necessary to remove large areas of the integument, too rapid healing and subsequent contraction might often be prevented by transplantation of flaps of skin in the immediate neighborhood of the wound. The flaps should not be more than three and one-half or four inches in length. They should have large bases. Flaps were more easily procured on the lower margin of the wound. Asepsis was not the only condition necessary to ensure the vitality of the flaps. It was found that tension on the flaps was of comparatively small importance in determining sloughing. Mr. W. G. Spencer said that for nearly all cases in which there was not enough covering the lower flap should be undermined to a much greater extent than was commonly done. The undermining could be carried down to the lower ribs and behind to the angle of the scapula. This gave an extraordinary amount of room, and ulceration of a flap from the twisting of its pedicle was avoided. The undermined flap might if necessary be buttonholed at its lower portion to prevent accumulation of blood. Mr. Watson Cheyne confirmed this. He always removed a large amount of skin, all that

which lay over the prominence of the breast. Formerly he performed skin grafting, but afterward he found that undermining was a better procedure. He carried this out in all directions quite up to the neck and down to the abdominal muscles, and he drew the edges together with stout silver wire passed at a distance of about an inch from the edges of the flaps. It was only necessary that the wound should be oval. The stitches sometimes cut through, but this made no material difference. In about ten per cent. of the cases, in which stitching together by these means could not be done, he had employed flaps and skin grafting. An objection to the operation by flaps was that the patient was already often collapsed after the extensive dissection, and the plastic proceedings added to the length of the operation. In such cases he stitched the wound together as much as possible, and then in three or four days skin-grafted the remainder of the wound. Cases treated in this manner did very well, indeed, and he had very few failures after skin grafting. Mr. Wallis had seen flaps in plastic operations about the face become very congested and threaten to slough, but this had been prevented by multiple pricking of the flap. The objection to this method for the breast was that it involved the exposure of the wound. Mr. Barwell said he used large lead-button sutures where the tension was greatest, and he frequently relieved the stitching by making incisions parallel to the wound edge and then sewing these latter up in a direction at right angles to the wound edge. As he believed that the resistance was chiefly in the subcutaneous tissue, he was careful to divide any prominent fibrous bands. Mr. Bowlby said that the patients appeared to suffer more pain when the flaps were dragged together, and that the patient was more hidebound with the dragging than with the flap method. Cases in which the tumor extended toward the clavicle or toward the sternum were more suitable for flaps, while the wounds extending toward the axilla came together better by dragging.

Mr. Mayo Robson, in reply, said that it was only in the exceptional cases that he used the flap method, as undermining and dragging were better when possible, taking care that when dragging was resorted to the stitches should be placed well away from the edge of the wound. In his flaps he took the whole thickness of the tissue, and he had done it in stout people as well as in thin ones without producing sloughing. He used no drainage whatever.

Mr. Butlin, in reply, said his flaps appeared to be much like Mr. Mayo Robson's, except that in very fat people he thought it better to take skin only. The flap method avoided the necessity of skin grafting, which was to the patient a second operation. The after-contraction by the flap method was small, and the upper extremity could be moved with ease.

William Lockhart, F.R.C.S., died on April 25th, at Blackheath, where he had resided for many years. He was eighty-four years of age, and had been for twenty-five years a medical missionary in China. His first diploma dated 1833, and he became F.R.C.S. in 1857. He was also a fellow of the geographical societies of London and Paris. He embodied his views of medical missions in an interesting volume entitled the "Medical Missionary in China." He was the writer of reports on the hospitals of Peking and Shanghai, and contributed to the *Dublin Medical Journal* translations of Chinese works on midwifery, inoculation, and other medical subjects. He passed through some thrilling experiences during his missionary career, especially during the Tai-Ping rebellion, particularly when endeavoring to prevent the burning of Shanghai, which, however, he was doomed to witness. He founded the first hospital there; its successor is the most important Chinese hospital at the present

time. He married a sister of Sir H. Parkes in 1841, who survives him. Some years ago their golden wedding was kept with their children and children's children.

William Sharp, F.R.S., M.D., who died on April 10th, was a link with the medicine of the past. He attained the ripe age of ninety-one. He took his college and hall diplomas in 1826-27, and began practice a year later at Bradford, where he became senior surgeon to the infirmary. He was an active advocate of local museums and his work in promoting them largely contributed to his being elected F.R.S. in 1840. He removed to Hull in 1843, and in 1847 to Rugby, where he remained the rest of his life. The archbishop of Canterbury gave him the degree of M.D. in 1856. The authority of this ecclesiastic to confer degrees was claimed among other privileges as successor to the Pope of Rome, and was exercised at intervals by holders of the see of Canterbury from the time of the Reformation. I believe the archbishop still gives degrees in divinity, and he affected to confer an M.D. as late as 1862, but this would be useless, as the medical act of 1858 authorized the registration of such degrees in medicine only if presented prior to the act. So any since 1858 could only be looked upon as marks of presumption on the part of the archbishop and cheap tokens of his personal favor. It is right to add that the later favors were shown only to men qualified to practise by the corporations or universities. Dr. Sharp continued library work up to 1892. He published several pamphlets on therapeutic problems, in some of which he seemed to lean to homœopathy, but he criticised Hahnemann and his work unsparingly. In 1886 he issued an essay on "Therapeutics Founded on Organopathy and Antipraxy." By "organopathy" he meant influencing diseases by drugs which acted on particular organs. I don't think the essay had any influence on medical thought, but this and some other articles were regarded with good nature as the eccentricities of an old man of considerable powers who was willing to become a system builder, an occupation which on many others seems to exercise a fascination.

Inspector-General Arthur Anderson, C.B., M.D., died on April 26th, in the eighty-second year of his age. He entered the army in 1838, and served in the Crimea, China, and India. He obtained a number of distinctions, had been principal medical officer of Bengal, and eventually served in the same office at Netley Hospital, after which he retired.

Deputy Inspector-General of Hospitals and Fleets J. Flanagan died on April 30th, aged sixty-one. This officer had been some time retired.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE LANGERHANS AFFAIR—CONGRESS FOR INTERNAL MEDICINE—TETANY AND RICKETS—LUMBAR PUNCTURE—DIABETES ACUTISSIMUS—A NEW ARTERIAL PHENOMENON—A CASE OF LEPROSY—A MEDICAL COURT OF HONOR.

BERLIN, May 16, 1896.

THE quiet which had settled upon the scientific world here during the holidays was suddenly disturbed by the case of Langerhans. The misfortune which fell upon Professor Langerhans, to lose his son immediately after having himself administered by way of prophylaxis an injection of diphtheria antitoxin, has been so widely published in the daily press all over the world that there remains little to add to the sad tale. The general impression here is that the sorely afflicted father acted rashly in publishing the statement that his son's death was due to the antitoxin before

there had been an autopsy to determine the cause of death. But neither the autopsy nor the examination of the serum nor that of the horse from which it had been taken gave any evidence that death was due to the antitoxin, and while the cause will remain a mystery the antitoxin treatment of diphtheria has received no setback.

In the Congress for Internal Medicine, which closed about two weeks ago in Wiesbaden, a number of new questions were brought to the front. Herr Cassel read a paper on the relation between tetany and rachitis. Among six thousand cases at the polyclinic he had sixty of tetany, all in nursing infants, and in thirty-two of these there were also symptoms of rickets. In most of these the evidences of the disease were only slightly marked, but in two of them there was laryngismus stridulus. The speaker could see no evidence from these cases that there was any causal relation between tetany and rachitis, and he had never seen any improvement whatever as regards tetany in the result from antirachitic treatment. He regarded tetany as an independent affection caused by unhygienic conditions. In severe cases he found benefit to result from prolonged baths (twenty minutes) in water at a temperature of 28°-30° R. (96°-99° F.), from small doses of chloral hydrate, and especially from an improvement in the hygienic surroundings of the little patients—a direction in which, in Berlin, there is room for much to be done. Cassel's theory received confirmation from the fact that he had never seen tetany among the children of those in the upper classes.

Those who took part in the discussion did not agree with the author as to the origin of tetany, for they thought that the relation between that and rickets could not be denied. It was suggested that the disease might possibly arise from an auto-intoxication by toxins formed in the gastro-intestinal canal of the patient. Heubner thought laryngismus stridulus and tetany were in no sense identical affections, the latter not being a specific affection, but one that might be excited by any irritation of the cerebral cortex, just as are spasms of the extremities. The speaker had often seen general convulsions and even true epilepsy follow laryngismus stridulus.

In the same meeting the operation of spinal or lumbar puncture was warmly and justly praised. Albert Fraenkel, of the Urban Hospital, reported a case in which the diagnosis of tuberculous meningitis was made by means of spinal puncture, and Stadelmann and Fürbringer reported a number of other cases in which a correct diagnosis was arrived at as a result of this operation. Fraenkel advised that the fluid so obtained be treated in the centrifuge and the sediment be examined for tubercle bacilli. There are cases of quite advanced tuberculous meningitis in which there are absolutely no severe symptoms, neither headache, nor vomiting, nor retardation of the pulse, and the speaker referred to one in which a purulent exudate was found on the surface of the brain, and yet the patient, twenty-four hours before his death, was apparently in perfect health and was walking in his garden. Stadelmann said that in his case he was enabled to determine the pneumonic nature of the meningitis by finding Fraenkel's diplococcus in the exudate. Therapeutically also, lumbar puncture was of value, as it had resulted in the disappearance of the headache. From this interesting discussion the conclusion was arrived at that lumbar puncture was the only means for determining with certainty the diagnosis in a case of doubtful exudative or purulent meningitis.

Benda and Stadelmann also reported an interesting case. It was that of a woman, twenty-three years old, who was perfectly well one week before her death. She was taken with severe abdominal pains, glycosuria (five per cent.) and acetonuria, and finally fell into

diabetic coma and died from heart failure. The autopsy showed extensive infarcts in the pancreas and multiple points of fat necrosis in the omentum. These were of fatty crystals, so that the omentum presented the appearance of a cloth sewn with bright stars. Stadelmann regarded this as a case of diabetes acutissimus, for it had without question begun only a week before, and he thought the disease of the pancreas should be referred to an infection. After complete destruction of the pancreas the diabetes set in and caused the death of the patient.

Litten, to whom we owe the so-called diaphragm phenomenon, recently presented a communication to the Verein für innere Medizin regarding a physical sign in the larger arteries of pathological and diagnostic significance. Starting from the well-known fact that an arterial murmur may be caused by pressure upon the trunk of an artery, he asked himself what phenomena corresponded to this murmur, if the pulse corresponded to the tone, or what perceptible movements of the arterial wall can be called forth by compression. He could perceive a murmur in all the larger arteries from the diameter of the aorta to that of the radial as an expression of the unknown symptom. The sign can be appreciated, however, only after a certain measure of experience, but makes an extraordinary impression upon the observer. The phenomenon is best observed in the subclavians and the abdominal aorta when the latter, as in enteroptosis, is easy of access. The method of examination is the following: With one finger light pressure is made on the artery while the palpation is made with a finger of the other hand. In pathological conditions, in cases of diseases of the arterial system, this murmur takes on a blowing character. These affections are those in which there is an increased blood pressure and dilatation of the arterial system, such as aortic insufficiency—true or false, Graves' disease, arteriosclerosis, poisoning by amyl nitrite. In these affections the symptom is very strongly marked, and may even be felt in the smaller arteries of the foot. Of especial practical value is it in the diagnosis of sclerosis of the ascending and abdominal aorta. Litten reported two cases of disease of the abdominal aorta, in which the diagnosis was materially aided by this symptom. The first case was one of nervous and very painful palpitation, and here only the usual murmur caused by compression of an artery could be felt. In the second case the phenomenon was very marked, and this, added to the almost uncontrollable pains in the abdomen, permitted of a diagnosis of sclerosis of the abdominal aorta to be made. The correctness of the diagnosis in each case was shown later at the autopsy. The author also presented some patients in whom the symptom was very beautifully shown.

At the last meeting of the Berlin Medical Society Blasko reported a case of leprosy and read a paper upon the prevalence of this disease in Germany. The case was one of anæsthetic leprosy in a fifteen-year-old girl from the eastern part of Prussia.

There is at present in German medical circles an agitation on foot for the establishment of a recognized and authoritative medical court of honor. This court would have jurisdiction over physicians only in what concerned their professional conduct, and not in the ordinary affairs of life.

IS APPENDICITIS A MEDICAL OR A SURGICAL LESION?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The article by Dr. MacArtney, "Appendicitis from the Medical Standpoint," in your issue of May 2d, and the letters from Drs. Morris and Wyeth in your issue of May 9th in reply thereto, are intensely

interesting to the active practitioner, and present very clearly the medical and also the surgical side of opinion on the treatment of this frequent and dangerous disease.

I believe all three of these gentlemen are truthful in their statements of facts as they have observed them, and sincere in the opinions which they have expressed, but it is evident that they cannot all of them be correct in the positions assumed, and that some further explanations are needed to make the truth appear.

Dr. MacArtney has described in an admirable manner a line of treatment which seems to me to be sensible, which in his hands has certainly been successful, and which, it appears to me, is consistent with our present knowledge of the pathology of appendicitis. It is almost identically the treatment which I have followed for the last twenty-two years, with the same measure of success as is reported by Dr. MacArtney. I have kept notes of but a few of my cases and cannot tell just how many I have treated, but it has been more than the twenty-four reported by Dr. MacArtney. Some of these cases have been very severe, attended by great pain and high temperature, and several times a distinct tumor has been felt in the region of the appendix. None of my patients died, all made good recoveries, and only two were operated upon—one recently for recurring appendicitis (six attacks since last October), and one in a neighboring city, whom I saw but three times, developed an abscess which pointed and was opened near McBurney's point.

It is evident that our surgical friends, Drs. Morris and Wyeth, have never tried the medical treatment recommended by Dr. MacArtney. If they will carefully try it in the next twenty cases, from the very commencement of the primary attacks, they will find very few instances in which an operation will be needed. In order to accomplish the best results, this treatment should be intelligently applied from the commencement of the disease.

It is implied in Dr. Wyeth's letter that he did not believe the physician who stated, at a meeting of the American Medical Association, that he had treated seventy-five cases of appendicitis by medical means only and that all the patients had recovered. I should be entirely willing to believe the statement of a careful physician to the effect that he had treated seventy-five consecutive cases of appendicitis in private practice, and that all his patients had recovered under medical treatment. Such a statement would be in line with my own experience and that of Dr. MacArtney.

Dr. Wyeth, I am inclined to believe, does not see in his practice the average case of appendicitis. Those cases which reach the surgeon are the severe and neglected ones, and many of them, without doubt, can be treated successfully only by surgical means.

I am not blindly opposed to all surgical procedures in this disease, but what I do contend for is that, if these cases receive proper medical treatment from the start, very few of them will require surgical treatment.

I cannot believe that the statistics referred to by Dr. Wyeth and compiled by Dr. Samuel Lloyd fairly represent the results of medical treatment in private practice in this country. They are so far from my own experience that I am confident some error has been made. The closing statement of Dr. Wyeth's letter is as follows: "It is probable that the proportion of cases which recovers under so-called conservative management would number about fifteen in every hundred, which might be increased if it were permitted to include cases which recover from a single attack, but which are subject to repeated seizures (recurring appendicitis)." This statement seems to me absolutely absurd; as well might Dr. Wyeth tell me that not over fifteen per cent of typhoid fever patients recover under medical management. I am sure this statement

is not founded upon the careful observation of a large number of cases well treated in private practice.

Hospital cases should not be considered in making up statistics of this disease. Many of them are recurrent cases, the earlier attacks of which have not been properly treated, and the subjects generally are in such poor condition that no treatment can be expected to give the best results.

I should not consider a case well treated unless opium in some form (I prefer morphine by the mouth) was given from start to finish in sufficient quantity to completely "mask" the most prominent symptom, which is pain.

H. L. WALDO, M.D.

TROY, N. Y., May 15, 1896.

Relations of Medical Examining Boards to the State, to the Schools, and to Each Other.—Dr. William Warren Potter, of Buffalo, president of the National Confederation of State Medical Examining and Licensing Boards, chose this title as the subject of his annual address at the sixth conference of this body, held at Atlanta, May 4, 1896. He said there were three conditions in medical educational reform on which all progressive physicians could agree—namely, first, there must be a better standard of preliminaries for entrance to the study of medicine; second, that four years is little time enough for medical collegiate training; and third, that separate examination by a State board of examiners, none of whom is a teacher in a medical college, is a prerequisite for license to practise medicine. It is understood that such examination can be accorded only to a candidate presenting a diploma from a legally registered school. He further stated that a high-school course ought to represent a minimum of academic acquirements, and that an entrance examination should be provided by the State for those not presenting a high-school diploma or its equivalent. He did not favor a national examining board, as has been proposed, but, instead, thought all the States should be encouraged to establish a common minimum level of requirements, below which a physician should not be permitted to practise. Then a State license would possess equal value in all the States. In regard to reciprocity of licensure, Dr. Potter thought it pertinent for those States having equal standards in all respects to agree to this exchange of inter-State courtesy by official endorsement of licenses, but that other questions were of greater moment just now than reciprocity. Until all standards were equalized and the lowest carried up to the level of the highest, reciprocity would be manifestly unfair. He urged that the States employ in their medical public offices none but licensed physicians. This, he affirmed, would tend to stimulate a pride in the State license and strengthen the hands of the boards. He denied that there was antagonism be-

tween the schools and the boards, as had been asserted. He said that both were working on parallel lines to accomplish the same purpose, that there could not possibly be any conflict between them, and that they were not enemies but friends. The medical journals of standing from one end of the country to the other, he affirmed, were rendering great aid to the cause of reform in medical education, and the times were propitious. He concluded by urging united effort by the friends of medical education, saying that "the reproach cast upon us through a refusal to recognize our diplomas in Europe cannot be overcome until we rise in our might and wage a relentless war against ignorance, that shall not cease until an American State license is recognized as a passport to good professional standing in every civilized country in the world."

Jenks Memorial Prize.—The subject announced for this triennial prize by the College of Physicians of Philadelphia is "The Etiology and Pathology of Diseases of the Endometrium, Including the Septic Inflammations of the Puerperium." The conditions are that the "prize must always be for some subject connected with obstetrics or the diseases of women or the diseases of children," and that "the trustees can in their discretion publish the successful essay, provided the income in their hands may in their judgment be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said trustees. In case they do not publish the said essay or paper, it shall be the property of the College of Physicians of Philadelphia." The prize is open for competition to the whole world, but the essay must be the production of a single person. The essay, which must be written in the English language, or if in a foreign language accompanied by an English translation, must be sent to the College of Physicians of Philadelphia, Pa., U. S. A., before January 1, 1898, addressed to Barton Cooke Hirst, M.D., chairman of the William F. Jenks prize committee. Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers or their agents within one year. The committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

Railway Transportation of Contagious Diseases.—From advance sheets of the *Medico-Legal Journal* we give the following extracts from the report of the standing committee to the section on railway surgery of the Medico-Legal Society of New York: "It is the duty of railway managers to consider how best to protect all who travel from the dangers of infection. Tuberculosis is transmitted by means of the sputum. Apartments which have been occupied by a consumptive or person sick with any contagious disease should not be occupied by others until disinfected. The sleeping-car is the point of greatest danger. Fellow-passengers and employees can and should be protected. Car sanitation is important to the public of the entire world, but it is a delicate question, affecting personal liberty. Car sanitation, soon to be advertised by railways, will bring them profit in proportion to the perfection to which they carry it. As preventive measures the committee advise: 1, Education of the public through the daily press; 2, legislation, State and national; 3, isolation of passengers; 4, disinfection of berths and compartments; 5, a conference between railway men and railway surgeons."

SOME POINTS IN THE THERAPEUTICS OF DISEASES OF THE HEART.¹

By W. H. THOMSON, M.D., LL.D.,

PROFESSOR OF THE PRACTICE OF MEDICINE, NEW YORK UNIVERSITY MEDICAL COLLEGE.

IN no other connection is the subject of etiology so important as in the treatment of affections of the heart. On that account we would prefer to speak of the therapeutics of cardiac diseases as determined chiefly by the consideration whether the affection be primary or secondary in its causation. According to our decision of this question, our indications and measures for treatment may not only be different, but in many cases may seem to be opposite in their nature.

A young man, for example, with a perfectly healthy heart and a healthy state of the whole circulatory apparatus in arteries, veins, and capillaries, has a rapidly developing acute rheumatic fever, till he ends the week with the development of a mitral lesion. A year afterward we find him dyspnoëic, with congested lungs, sallow skin, enlarged liver, and with much œdema of the lower extremities. Another man, fifty years of age, who always had considered himself healthy, has noticed a gradually increasing shortness of breath on going up-stairs. We find him with a pulse of high tension, a hard radial artery, and with a ringing second sound at the semilunar valves. A year afterward he also is very dyspnoëic, with congested lungs, enlarged liver, and with œdema of the legs. But, however numerous the symptoms which these two patients have in common, they certainly are very different from each other when we can properly say to the first that he should stay in bed, and to the other that he should stay out-doors as much as possible. The valvular lesions, and the results of those valvular lesions, may be the same in both cases, but for all that they are not cases of the same heart disease, for in the first the trouble began with the heart, while in the second it ended with the heart. In how many respects, therefore, the treatment of the cardiac affection may be accordingly contrasted on account of these elements in the history of these patients, is a subject which affords a convenient text for our remarks on some points in the therapeutics of heart disease.

Primary heart affections are so commonly of rheumatic origin that this fact alone furnishes us with certain indications which should not be lost sight of. The first of these is the progressive nature of rheumatic heart disease, simply because it is rheumatic. Thus, I have been struck by the number of cases in my experience in which a primary condition, not of rheumatic origin, occurring in young subjects, though it caused permanent valvular change at the time, yet remained thereafter stationary. In the beginning of my practice I was called to a girl, aged twelve, with endocarditis developing in an attack of measles. She

has had a loud mitral murmur for twenty-five years since, but without any seeming injury whatever to her health. On the other hand, nothing is so deceptive as the favorable prognosis, as regards life, of the first attack of a rheumatic carditis. The patient may leave his bed with apparently nothing but a slight cardiac murmur, and soon he feels quite well. He returns, however, twelve months afterward, complaining of attacks of palpitation and of cardiac pains, and auscultation reveals a much increased and permanent condition of cardiac mischief. This has been shown to be particularly the case in children after recovering from chorea, and the rule is, the younger the patient—with, therefore, the most tendency to active muscular exercise and rapid heart action—the more surely inclined is a slight initial cardiac lesion to develop into a serious structural alteration. What is true, therefore, in general of rheumatism, that any one once attacked by it is more liable than others to repeated returns of the affection in his joints, is still more the case with his heart. Inflammation is more likely to recur there with him than anywhere else because of special reasons.

The first of these reasons arises from the continued mechanical operation of the initial valve lesions. These begin with the deposit of beaded rows of fibrin just within the border lines of the valves. Soon these become organized upon the smooth lining membrane like so many trachomatous masses in granular conjunctivitis, with the same grating and irritating effects upon the incessantly moving valves, thus leading in time to deeper inflammatory thickening, with tendency to deforming contraction of the subjacent textures. The heart, therefore, becomes more irritable and liable to inflame with much less provocation than at the first attack. Meantime, its own functional activities explain how, from the first, the rheumatic inflammation caused more structural change there than rheumatic inflammations ordinarily do elsewhere, for here we have the seat of the most unceasing and rapid movements in the whole body. It is therefore the last place in the body where the great indication in inflammation, of rest to the inflamed part, can be secured. The only other texture which is apt, though far less often than the heart, to have permanent structural changes set up in it by acute rheumatism is the pleura, and that also is an unresting tissue.

From these considerations, one of our first indications in the treatment of primary heart affections is the prophylaxis of rheumatism. For this purpose I would recommend particular attention to the state of the tonsils in those who give, along with a tendency to rheumatism, a history of frequent attacks of sore throat. The prompt use of salicylates internally, with the first signs of tonsillitis, and the local application of tincture of iodine are, in my opinion, good preventives in these patients of subsequent rheumatic infection. The habitual employment of hot water douches night and morning to the throat, with the addition of oil of peppermint to the water, is also an excellent measure in the hygiene of the mouth, for the relation of oral infection to chronic pharyngitis, otitis, rhinitis, and tonsillitis is, I believe, a fact of much practical importance for physicians to recognize.

¹ Read before New York County Medical Society, May 25, 1896.

Of equal, if not of greater, importance is the protection of the skin, owing to the easy sweating of rheumatically inclined persons. Whatever be the relation of acute articular rheumatism to microbic infection, the clinical fact is undoubted that rheumatism prevails most in the localities where persons are most apt to be chilled while the surface of the body is wet. It is, therefore, endemic not only in damp and wet climates, but also among the inhabitants of hot and dry desert regions where the rapid radiation of heat in the night causes the early morning temperature to be often quite cold, and thus act upon the skin of those who were freely perspiring from the heat of the previous evening. Rheumatic patients, therefore, should always protect the skin with flannel, and this is quite as needful by night as by day.

Coming to the affections of the heart itself, the pulse of rheumatic patients should be frequently tested, as it often furnishes valuable advance information of the imminence of increased cardiac mischief. I have repeatedly advised such patients to go to bed on account of habitual rapid action of the heart when they did not otherwise complain of rheumatic symptoms, and with the best results. Indeed, to rest in bed we would assign the very first place in the therapeutics of primary heart affections. We have here virtually a case of isolated disease. Practically it is the heart alone which is to be considered, and the first indication is to quiet it. This cannot be done unless the patient lies down. I need not say how often we find hospital patients admitted with every symptom of cardiac distress, and then note a marked improvement in them in a few days, solely due to their being kept in bed, without any medication meantime having been administered. It is easy to see that an embarrassed valve may work fairly well if only seventy-five movements a minute are demanded, but quite otherwise if there be one hundred and twenty instead, and that the most urgent symptoms may subside spontaneously after any measure which eliminates the element of overaction.

In many acute conditions of the kind, however, rest in bed does not suffice to bring down the pulse, and for such we have a medicine whose service in primary heart disease I regard as invaluable, and that is aconite. Many times I have found the patient's symptoms not only not relieved, but rather aggravated by digitalis, strychnine, and other supposed heart tonics, the pulse growing feebler and more irregular, until by a change to aconite the dyspnoea has been lessened, the anginous attacks have been relieved, and the pulse has become both fuller and steadier under the influence of this drug. Aconite is not only a heart sedative in inflammatory cardiac states, but it has a decided effect upon inflammatory pains. In a great many cases also the cardiac rest which it induces will tend to increase the strength of the heart more than will follow upon the administration of heart stimulants. It should also be noted that in common with other vegetable nervines, it produces no permanent effects upon heart muscle, any more than tobacco does upon the habitual smoker. I have never seen a case of heart disease in which aconite has seemed to weaken the heart in inflammatory states, though it be taken three times a day for months continuously.

I, of course, in the limits of this paper, cannot more than touch upon certain aspects of the subject of the treatment of heart affections, and I will therefore only allude to the relief of some special conditions. One of these presents us at times with the most distressing example of how heart disease can produce dyspnoea, and that is when a pericarditis has resulted in the formation of adhesions to the pleura, sternum, and ribs. Every movement of inspiration may then tend to draw upon the walls of the heart and thus in-

terfere with the cardiac systole. To give such a patient digitalis may simply increase his sufferings, but I have found firm strapping of the left side of the chest sometimes of the most undoubted service.

In mitral stenosis, as Foxwell has shown, the resultant hypertrophy of the right side of the heart causes the area of cardiac dulness in adolescents to increase in a different direction from what it does in right dilatation in older patients, as after emphysema, the dulness extending upward and to the left, in many instances quite up to the second left rib articulation instead of transversely to the right. For the dyspnoea of mitral stenosis, especially when it occurs in severe paroxysms, I have found belladonna, often combined with compound spirits of sulphuric ether, much the best remedy. In no other valvular lesion do we find such a tendency to irregular rhythm as in mitral stenosis, and that may be one reason for the superiority of belladonna here, as also for its incontestable superiority in the relief of cardiac pains when they occur in the hypertrophied hearts of rheumatic patients. I would ascribe these pains to the disturbance of the rhythm of the cardiac contractions when the balance between the two sides of the heart is disturbed by the greater hypertrophy of one side, and belladonna, with its allies among the solanaceae, is characterized above all other agents with the property of restoring the deranged action of rhythmical muscular fibre, and thus relieves spasm whether in the bronchial tubes, in the alimentary canal, or in the urinary bladder. In mitral stenotic cases I have often found digitalis inferior to strophanthus, sparteine, and caffeine.

In all primary heart diseases we should always remember the evil effects of anaemia. Anaemia of itself may cause structural heart disease, as in chlorosis. The most extreme fatty degeneration which we may ever find in a heart is often met with in patients who have died from pernicious anaemia. Now, considering the special tendency of acute articular rheumatism to produce anaemia, it would seem as if we should early administer iron to combat this sequel. But, however invaluable iron is in other forms of heart disease, I regard it as almost certainly mischievous in rheumatism. Repeatedly have I found its administration in these patients to prolong the convalescence, keep up a subfebrile temperature, increase the pain, and apparently increase, instead of diminish, the anaemia. In fact, there are a good many loose ideas about iron as a specific for all forms of anaemia, but which we have no time to discuss now other than to say that in all febrile anaemias, as in phthisis, rheumatism, and pernicious anaemia, iron is as likely to do harm as it is to do good.

The best remedy for rheumatic anaemia, in my opinion, is cod-liver oil along with small doses of arsenic. I have fancied that I have found the sulphide of calcium in as large doses as the stomach will bear without nausea, doses of one-half to one grain four times a day, to be of service in acute rheumatism and to hasten the convalescence. I am at present taking observations on this point, but they are too few yet to warrant a conclusion.

The great aim in adolescent primary heart affections is to carry the patient along until the changes of middle life can develop, when the liability to acute articular rheumatism has ceased. It is significant how many cases of cardiac murmur we find nowadays in patients in middle life which have lasted for years without any inconvenience. Many a patient having mitral stenosis, which produced most serious symptoms at twenty, seems spontaneously to recover at about forty, apparently from the increase in the left ventricular cavity natural to that time of life, operating to dilate the previously narrowed auriculo-ventricular orifice.

The first consideration to which I would advert in

secondary disease of the heart is that unlike other viscera, such as the lungs, liver, kidneys, etc., which contain within themselves the chief conditions for their specific functions, the heart is but a part of the apparatus of the circulation. Not only, therefore, will disorders of the heart affect the circulation, but the converse is equally important, that disorders of the circulation will affect the heart. In the latter case our attention, instead of resting at the cardiac valves, should also include a consideration of the whole circuit of the circulation. Thus, in primary disease of the heart its hypertrophy and dilatation are mainly due to disorder of its valves; in secondary diseases the disorder of the valves is mainly due to antecedent hypertrophy and dilatation.

Secondary affections of the heart, therefore, begin chiefly at the periphery of the circulation, so progressively embarrassing the flow of blood there that the central organ first increases in size and in strength to balance the increased work which it has to do. But as all hypertrophied muscles are more apt than normal ones to undergo degeneration, so the main danger is the supervention of dilatation and, following upon that, increased weakening in its power of emptying itself. The chief indication, therefore, is now to keep up the strength of the walls of the heart and to let all concomitant valvular affections take care of themselves.

For this purpose I would divide our remedial measures into the constitutional and the symptomatic classes of agents. The first of the constitutional, and the most important and continuous in its operation, is the effect of fresh air. The oxygen of our respiration is nature's great source of muscular power, as is exemplified throughout the whole animal kingdom that muscular strength is directly proportioned to the activity of the respiration. On the same principle, iron is the most effective among drugs, because iron is our respiratory food and has no other function in the body but as the carrier of oxygen to enable us to breathe. The recognition of this fact in modern therapeutics has led to the recommendation of mountain climbing as a cure for failing heart power, and when resorted to in the right cases and in proper measure it undoubtedly is a great advance over the old views which confounded secondary with primary disorders and hence advised that every patient with heart disease should be very careful about muscular exercise.

Next to as continuous breathing of the open air as possible, I would rank properly applied massage, especially that form in which the patient exerts a carefully regulated resistance to the flexion and extension of his muscles by the operator. I have seen many cases of most striking improvement, especially in senile hearts, by the addition of this procedure to other measures of treatment, for it must be remembered that the movements of the aged in walking are not only slow but very limited in their range, and not at all calculated to react as favorably upon the heart as the above-mentioned exercise, given when they are recumbent, seems to do. The improvement in breathing after some weeks of this massage is too unmistakable to be doubted.

Of course, the seat and nature of the peripheral obstruction which reacts upon the heart will modify the symptomatic medication. Dilatation of the right side of the heart with resultant dropsy, due to chronic bronchitis, is one of the most curable of heart affections, if only you can cure the bronchitis first. The trouble is that a vicious circle of interacting influences is set up in these cases whenever the heart becomes involved, the bronchitis becoming worse when cardiac congestion of the lungs supervenes; and this in turn increases the heart weakness. In such cases, again, hours spent in a dry equable air help the

weakened bronchial muscles and the weakened right ventricle as well. Among medicines the tincture of the chloride of iron with strychnine does more good to the cough than any cough mixture. It is in these cardiac cases also that arsenic and the potassium iodide so often do good, but these drugs are also useful in the treatment of chronic bronchitis itself.

The most common as well as most serious of secondary heart diseases, however, are, of course, those dependent upon general arterial disease. It has been rather graphically said that a man is as old as his arteries, and increasing experience with the causes of decline and death in our patients after middle life will lead, we think, most physicians to agree with this statement. The first sign of the coming danger from this source we would put as shortness of breath upon exertion. If the significance of this were more appreciated in time by many who ascribe it only to their growing fat, or to their sedentary habits, many valuable lives would be prolonged and years of usefulness saved. It is instructive to note also the entire difference in the meaning of a rapid pulse in secondary cardiac dilatation from the rapid pulse of primary heart disease. In secondary dilatation it is not from irritation of the heart itself, but because the organ is not capable of emptying itself fully enough with each stroke to meet the needs of the circulation, and therefore has to increase the frequency of its systole. Digitalis, and not aconite, will lessen this symptom.

This leads me, in conclusion, to mention briefly the particular uses of some of our symptomatic remedies. In secondary cardiac dilatation digitalis certainly takes the lead of all other drugs, but there is not one in the list whose administration should be less a matter of routine. In the first place, we have now in all cases of peripheral obstruction a coadjutor to the action of digitalis which has removed one of the chief former obstacles to the remedial effect of this drug, and that is nitroglycerin, which, by dilating the arterioles, whereas digitalis contracts them, enables us to ease the heart of the peripheral obstruction against which it had to contend before on account of the increased arterial pressure caused by the digitalis. But another serious effect of digitalis when given too continuously and in too large doses is that it causes a gastric disturbance which is very difficult to allay. In cases, therefore, of much dilatation, with cardiac arrhythmia, general dropsy, and pulmonary oedema, it has been my practice to begin with free doses of an ounce of the infusion of digitalis four times a day for two or three days, and then to change its administration altogether to a permanent dose of half a grain of the powder three times a day, which dose may then be kept up for a long time with great benefit.

Prior, however, to these smaller doses, and during the administration of larger doses, we have an adjuvant to the action of digitalis which I think cannot be appreciated too highly, and that is calomel, given in doses of one-half to two-thirds of a grain three times daily, until the first slight signs of mercurialization are manifest, when its administration should be stopped. The increased beneficial effect upon the heart and circulation of this short course of calomel in these cases is often as striking as any effect in therapeutics.

As a modification of the digitalis treatment I often use a combination of the three tinctures of strophanthus, nux vomica, and digitalis in equal parts, dose twenty to thirty drops of the mixture three times a day, particularly in aortic regurgitant and mitral stenotic cases.

Of course, the commonest cause of general endarteritis is renal disease, but the relations of this subject to cardiac disease are too wide for us to enter upon now. I can only say that in chronic interstitial nephritis the high tension of the pulse and the low

specific gravity of the urine seem both to be favorably affected by the action of small doses of corrosive sublimate. In the cerebral derangements of such patients which are short of apoplexy, both the cardiac symptoms and the cerebral have often seemed to me to be improved by a pill containing two-thirds of a grain of sparteine sulphate, one-half grain of pulverized digitalis, and one-twenty-fourth of a grain of corrosive sublimate.

In all cardio-renal cases with extensive dropsy I would avoid a milk diet. Repeatedly have I seen the dropsy at once decline upon a marked restriction being ordered in the amount of fluids taken and the administration of solid food.

We forget often that opium is a powerful heart stimulant, as its anodyne and soporific properties are so much more familiar to us, but for severe attacks of cardiac dyspnoea we can hardly do without it as an occasional resort. I would, however, mention that in very many cases of nocturnal attacks of dyspnoea in cardio-renal patients, chloral acts to a better advantage than any other remedy for this particular complication.

STATISTICS OF DIPHTHERIA.

By C. G. COAKLEY, M.D.,

CLINICAL PROFESSOR OF LARYNGOLOGY, MEDICAL DEPARTMENT, NEW YORK UNIVERSITY.

THE study of the statistics of the infectious diseases is exceedingly valuable to the medical profession. We find, however, that in some of the infectious diseases the study presents difficulties that are not to be found in others and that diphtheria probably offers us a greater degree of uncertainty than any of the others.

One of the greatest difficulties lies in the uncertainty of the diagnosis. Physicians readily learn to accurately diagnose the exanthems, but with some of the infectious diseases, notably tuberculosis and diphtheria, we have been able only since the discovery of their pathogenic organisms to accurately differentiate these diseases from others presenting very similar subjective and objective symptoms.

In order that the statistics of diphtheria may be properly appreciated, I shall divide the disease into two periods, an early period and a late period. The dividing line between these two periods can be quite accurately drawn, and it may be taken as that period when the use of diphtheria antitoxin became quite a factor in the treatment of this disease; for, whatever may be the fate of the antitoxin treatment of diphtheria, it certainly has stimulated not only its advocates but its opponents to more accurate observation of the disease, and has been the most effective means of furnishing to the bacteriologist the requisite cultures, from the study of which so many valuable conclusions have been drawn. The beginning of the year 1894 may be taken to separate these two periods. True, the Klebs-Loeffler bacillus had been known and studied, and many valuable experiments made and conclusions drawn from these in the ten years previous to 1894, but the busy general practitioner merely read of these results. Few physicians up to that time (1894) availed themselves of the aid that bacteriology offered in the diagnosis of diphtheria, even after the establishment in 1893, by the Board of Health of this City, of a laboratory for such bacteriological diagnosis.

Let us examine first this early period of the disease. What constituted diphtheria during this period? A group of constitutional symptoms which varied considerably in individual cases from the slightest to the most severe, together with the appearance in the throat of a pseudo-membrane, also varying in character, position, and extent. We cannot wonder, then, that there

were frequent differences of opinion among physicians seeing the same case as to whether the patient had or had not diphtheria. Some physicians would call almost all anginas presenting any appearance of a pseudo-membrane, diphtheria. In the Scientific Bulletin No. 1, Health Department, New York City, Dr. H. M. Biggs states (page 2) that "during the year 1891 4,874 cases of diphtheria were reported to this board, and, so far as can be judged from the data at hand, at least one-third and perhaps more of these cases were not diphtheria." On the same page he makes the statement that "in those cases in which bacteriological examinations have shown the absence of Klebs-Loeffler bacillus, the mortality has varied from one to five per cent." We are inclined, therefore, to the belief that many physicians whose death rate in diphtheria in this period has been very low, would have found it necessary to exclude many of their cases had they submitted cultures from their patients' throats to bacteriological diagnosis. On the other hand, some physicians have had a very high death rate. In view of our present knowledge of diphtheria derived from bacteriology, we feel sure that they have passed over many of the milder forms, which if included would have reduced their mortality rate. We may mention here that bacteriology has taught us that there are severe and fatal pseudo-membranous affections of the throat in which the Klebs-Loeffler bacillus is not found, but which present all the local and constitutional symptoms even to the sequela paralysis, which clinicians have regarded as justifying the diagnosis diphtheria. Without bacteriological examination it is impossible to differentiate these two conditions, and in this early period the statistics of diphtheria have been made incorrect by their inclusion.

What constitutes diphtheria in the late period of the disease? The discovery of the Klebs-Loeffler bacillus in the cultures taken from the throats of patients presenting any form of inflammation of the fauces. Park and Beebe¹ say: "The examination by a competent bacteriologist of the bacterial growth in a blood-serum tube which has been properly inoculated and kept for fourteen hours at the body temperature, can be thoroughly relied on in cases where there is visible membrane in the throat, if the culture is made during the period in which the membrane is forming and no antiseptic, especially no mercurial solution, has lately been applied." Koplik, among others, has shown that the secretion in the lacunæ of the tonsils has been found in some cases to contain the Klebs-Loeffler bacillus. Again, Park and Beebe state: "We have found that children, and to a less extent adults who are brought in direct contact with true cases of diphtheria, very often receive the diphtheria bacilli into their throats, and that these bacilli may exist and develop in these throats for days and weeks." The same observers, examining cultures from the throats of three hundred and thirty healthy individuals, "where there had been no history obtained of direct contact with diphtheria," found virulent characteristic bacilli eight times, non-virulent characteristic bacilli twenty-four times, non-virulent pseudo-diphtheria bacilli twenty-seven times.

The finding of the Klebs-Loeffler bacilli in its different degrees of virulence in individuals who constitutionally and locally are apparently free from disease has led many to become sceptical as to the value of bacteriological examinations in the diagnosis of diphtheria. A broader and better view to take, however, is that neither clinically nor bacteriologically are we as yet in possession of a full knowledge of diphtheria, and that the more opportunities the practitioner affords to the bacteriologist for studying cultures from the

naturally be led to judge that any new method of treatment pretty generally employed during 1895 ought to be credited as being superior to former methods of treatment. When we examine the columns showing the number dying per 10,000 inhabitants, we find 11.73. This is a saving of nearly 5 per 10,000 over the preceding year. Can this saving be attributed to new methods of treatment? If we examine the figures in the fourth column, there will be noticed a periodic rise and fall in the number dying; thus from 1881 to 1882 there is a fall of 4 plus; from 1883 to 1884 a fall of 2.75. Remaining nearly stationary for nearly four years, it rises again in 1888 by nearly 4, with a further rise the following year (1889) of nearly 2. Next year (1890) it falls nearly 4, with a still further fall of 3.9 the next year; then rises by jumps of 3.8, 1.1, and 6.7 to 1894; and, lastly, falls nearly 5 in 1895. How much of this fall in 1895 may be due to change in the character and type of the disease and how much to treatment, is something, I am free to confess, I am unable to answer. We notice that in 1895 the death rate, 14.48 per cent., was a phenomenal one. It is but little more than half of that of 1894, and less than half of what it was in the majority of the years here tabulated. There is nothing phenomenal, however, in the number 11.73 dying per 10,000, for in more than half the years it was less than this. When next we come to examine in detail the figures for New York, we find pretty much the same conditions, viz., increase of cases from 1893 on, increase in the number of people dying in 1894, the death rate coming down in 1894 but the number per 10,000 rising. The number of cases in 1895 increased, the deaths were fewer, there was a great reduction in mortality rate to 16.46, and also considerable reduction in the number dying per 10,000. A greater reduction, however, took place between 1881 and 1882 and 1882 and 1883, and a closely approximating reduction between 1889 and 1890. Brooklyn, for the years 1894 and 1895, showed nearly the same conditions; but we are surprised to find that the mortality rate there was still so high, 26.63. From the study of all the foregoing statistics, we believe that 1894 was an epidemic year. In 1895 the death rate diminished. Did that epidemic die a natural death or was it helped out of existence by antitoxin?

Examination of the statistics of diphtheria from the Boston City Hospital and the Willard Parker Hospital shows the following:

	B. C. H.			W. P. H.		
	Cases.	Deaths.	Per Cent.	Cases.	Deaths.	Per Cent.
1888				258	60	23.25
1889				383	79	20.62
1890	415	151	36.38	292	67	22.94
1891	237	105	44.30	289	85	29.41
1892	387	185	47.80	295	79	26.77
1893	419	203	48.44	343	108	31.48
1894	598	266	44.48	699	205	29.32
1895	1,566	207	13.21	778	190	24.42
		To May	1, 1896	251	58	23.10

In the Boston City Hospital the most striking fact is the great increase in the number of cases for the year 1895—1,566 for that year, and only 598 for 1894. The deaths for 1895 are 207; those for 1894 are 266. The death rate for 1895 is 13.21 as against 44.48 for 1894. It is a curious coincidence that the number of cases for 1895 is nearly three times that for 1894, while the percentage of deaths is less than one-third of what it was for 1894.

In the Willard Parker Hospital we find no such discrepancy in the percentage of deaths. The cases have increased greatly in 1894 and 1895, but the death rate has not been so markedly lowered. In fact, there are three years, viz., 1888, 1889, and 1890, in which

the death rate was lower than that of 1895. The death rate thus far this year to May 1st has been 23.10. It was lower than this in 1889 and 1890.

I believe the great interest in diphtheria brought about by the antitoxin treatment may have been a factor in increasing the number of cases at the Willard Parker Hospital. How many of these cases have been of a milder type and thus have affected the death rate, only those who see the cases there know.

As a result of our study of the statistics of diphtheria, not only in the cities above named but also in many others here and abroad, we find the conditions so different in the early and late period, as we have divided the disease, that any comparison of the death rate of the latter period with the death rate of the former period will be apt to lead one to erroneous conclusions.

REMARKS ON THE RATIONAL TREATMENT OF UTERINE FIBROIDS.¹

By WALTER B. CHASE, M.D.,

GYNECOLOGIST TO THE BUSHWICK HOSPITAL, BROOKLYN, N. Y.

THE time at my disposal this evening will not permit of any exhaustive study of fibroma uteri. I shall not therefore enter upon any discussion of the subject, either histologically or etiologically, nor will questions of differentiation from other growths occupy our attention. It is the most frequent of all the benign neoplasms of the uterus coincident with functional activity of the reproductive organs, and while the percentage of cases in which it becomes a menace to life is small and the mortality attending it still smaller, it is, nevertheless, so frequently a source of annoyance, distress, or disability, as to force itself upon the attention of the general practitioner or specialist. For purposes of clinical study uterine fibroma may be divided into two classes: the hard and the soft, or otherwise known as fibroma and myoma. The disease may be diffused or circumscribed, or confined to the corpus or involving the cervix. As to variety I shall divide it as follows, to wit: diffused, submucous, subperitoneal, and intramural. Uterine fibroids vary from those of the size of a pea or hickory nut to those of large dimensions, weighing from one hundred to one hundred and fifty pounds. The frequency of symptoms for which the patient seeks relief are in about the following order: first, hemorrhage; second, pressure causing discomfort or pain, either from size or position; third, general impairment of health; and fourth, acute septicemia from rapid absorption of structure undergoing retrograde metamorphosis.

It is not to be assumed that all cases of fibroma require treatment, either surgical or medical. If not large in size and not a source of discomfort, they may produce no symptoms and their presence may not be recognized. It may be laid down as a principle of action that interference should be had the same as in ovarian cystoma, before the growth attains great size.

The causes which lead to menorrhagia are so numerous and so diversified that questions of differentiation cannot be entered upon. The diagnosis of fibroma having been constituted, and the variety and extent of the disease settled, the question of treatment will engage our attention.

Medical treatment must be tried in a certain proportion of cases, for there is a class of patients who will not submit to heroic measures, unless the condition is of great urgency; besides, they are entitled to the benefit which may be derived from systemic medi-

¹ Read before the Brooklyn Medical Society, May 15, 1896.

cation. Few drugs exert any curative influence on fibroma. Those worthy of trial in suitable cases are ergot and *hydrastis canadensis*: both have the power of diminishing the calibre of the uterine blood-vessels, and ergot stimulates contraction of muscular fibres of the uterus. Influence of drugs on the subperitoneal variety is likely to be unavailing, while in the interstitial cases ergot sometimes produces marked results, examples of which I reported in the *Brooklyn Medical Journal* several years since. The well-known physiological effect of pressure, persistently applied, produces absorption, and to this influence in part must be ascribed the power of ergot in producing absorption of fibroid growth and in moderating and controlling hemorrhage. It is alleged by Emmet that the effect of ergot on intramural fibroids is liable to produce excessive pain and to so diminish the blood supply as to endanger the vitality of the growth, thereby inducing sloughing and sepsis. While I have never seen such results follow its use, the possibility of such effects should always be borne in mind. The uterine contractions incident upon its administration in submucous fibroids and intra-uterine fibrous polypus may eventuate in their detachment, partial or entire, or the same force may expel them from the uterine cavity, thereby converting sessile growths into pedunculated ones. In fact, this extrusion of fibroids into the uterine cavity not infrequently takes place independently of medication and should be regarded as conservative evidence of nature's attempt at cure.

When this occurs medical treatment should be supplemented by surgical aid for their entire removal, either by snare, écraseur, spoon, or scissors, done under the most rigid aseptic precautions. It should be remembered that fibroid growths sometimes diminish or disappear coincidently with gestation, and that those of moderate size disappear spontaneously. There is a susceptibility in fibroma to rapid growth and equally rapid diminution in size. Physiological causes dependent on some change in their nutrition, either the result of diminished blood supply or increased activity of the lymphatics, or both, when once set in operation, result in cure or disintegration. Small fibroids developing in the cervix or cervical canal are frequently sources of annoyance and disability entirely out of proportion to their size. Enucleation is the proper treatment, and in my experience the results have been highly satisfactory.

Hemorrhage as a symptom of fibroma is the result of interrupted circulation, ulcerative disease, and degenerative changes of the endometrium covering areas of the growth. In such a condition curettage often acts in the most salutary way by its alterative influence on inflammatory and degenerative structures. Hemorrhage not controlled by such measures requires more active interference. This symptom of hemorrhage is often not due so much to the size as to the location of the growth. Submucous myomas are the most frequent causes in the production of hemorrhage. In cases in which the growths are not too large and persistent and hemorrhage and pain are the prominent symptoms, two methods of procedure are open to choice apart from hysterectomy—one, removal of the ovaries; the other, ligation of the uterine arteries.

It is proper to mention at this stage of the discussion that the state and surroundings of the patient may have much to do with the method of treatment adopted. The woman of ease and opulence, who can without stint command all which medical skill has to offer, may by a prolonged period of rest, mental and physical, be carried safely past the menopause by the use of legitimate palliative treatment, while her less favored sister under circumstances of want and deprivation would fall a victim to such plan of treatment. This makes evident the necessity for discrimination

as to treatment, and the suggestions hereinafter made should be applied accordingly.

If there is reason to expect in a given case that the blood supply can be diminished by ligating the uterine arteries so as to arrest the hemorrhage and prevent the larger growth of the tumor without causing sloughing, it is a proper and conservative method of procedure. It is an operation usually easy of accomplishment, and involves little or no risk to the patient, so far as the procedure *per se* is concerned. It is done as follows: having previously sterilized the vagina, the patient is anesthetized and placed on her back with the knees flexed as in the operation for vaginal hysterectomy. An incision an inch long is made on each side of the cervix through the tissues at the vaginal junction into the broad ligament. Gently separating these structures by the knife handle or blunt scissors and keeping close to the uterus, so as to avoid the ureters, until the uterine artery can be felt, a ligature of some absorbable material is carried around it with an aneurism needle or a Cleveland's ligature carrier and tied in at least three knots cut short, and the incision closed with running catgut sutures. This method does not deprive the woman of her reproductive functions and lacks the objection to mutilation, so deeply seated in a woman's heart. In cases of a severe type in which this method is not successful resource may be had to the removal of both ovaries.

If, however, the growth is large, or moderately so, and there is reason to presume that there is much increase in the calibre of anastomosing vessels, which would in normal conditions be insignificant, removal of the ovaries for artificial production of the menopause may prove delusive and unavailing. It is, however, gratifying to note that a recent *résumé* by Marcy, of Boston, on the results of Battey's operation for this and analogous conditions, shows results more satisfactory than the experience of many had warranted. Dorsett, of St. Louis, and Martin, of Chicago, both produce gratifying evidence of the utility of the ligation of the uterine artery or arteries for such growths. This method of treatment is not applicable to large fibromas, as the impairment of nutrition might induce sloughing. Caution should, however, be exercised in not predicating too much for the patient in either method of procedure, as it may not prove successful. If resource is had to the latter method of operating, great care should be exercised that thorough work be done and no portion of ovarian tissue escape excision; otherwise the function of menstruation will not be arrested. It is held by some, and apparently upon tenable grounds, that it is better to include in this procedure the removal of the Fallopian tubes, thereby diminishing the liability to the development of subsequent disease and insuring greater certainty of cessation of menstrual functions.

In cases sufficiently grave to warrant castration the operator should carefully weigh the reasons, if any exist, why the uterus should not be included with the appendages. The choice between Battey's operation and complete removal of the uterus and its appendages covers debatable ground, and each will continue to have its advocates until larger experience decides which has the paramount claim to our confidence. In this as in many other conditions the results of individual experience will and should govern very largely the mode of individual practice. It must be acknowledged that the arguments against hysterectomy in bleeding fibromas of this class are more sentimental than real. The seat of disease is in the uterine structure, for which operation is proposed, and depriving the woman of her ovaries may at the best only influence this abnormal state by the arrest of periodical functional activity of this organ, and this may or may

not be sufficient to arrest the pathological condition. True, there may be some added risk in removing the uterus, but it would not of necessity outweigh the greater good which hysterectomy makes probable. The liability of these growths to undergo malignant degeneration or suppuration will have due weight in deciding the question. These are the questions which the operator can determine in each individual case. There is, however, a class of cases of large growths in which no such perplexing question perturbs the surgeon, and in which none but radical measures are admissible.

The revolution in methods which has attended the surgery of uterine fibroids (and I might say of abdominal surgery as a whole) within the last decade gives the subject of their management new and far-reaching interest. It is not my purpose to follow the successive steps of the intra- and extra-abdominal methods of German teachers and others, which have been improved upon and superseded by the American methods of Eastman, Baer, Goffe, Kelly, and others; suffice it to say, the evolution has been so complete and radical as to approximate perfection and rob the procedure of much that was formidable and dangerous. It is one of the marvels of modern surgery to note with what ease and safety large fibroids can be removed. The simplicity of this method, whether by supravaginal amputation or by complete extirpation, must recommend its adoption; it is the same except in the final steps, and does not vary in principle and but little in detail, whether the tumor is large or small.

To those familiar with the Trendelenburg posture no argument is needed to demonstrate its superiority over the horizontal position. It gives a clear field for observation, except in adhesions or in great intestinal distentions, and great facility for rapid manipulation. The steps of the operation are briefly as follows: After opening the peritoneal cavity in the median line by the shortest incision by which the growth can be delivered and easy manipulation accomplished, adhesions between the tumor and abdominal walls and intestines should be gently separated, the intestines pushed upward into the abdominal cavity and held in position by a large thick laparotomy gauze sponge. The growth is lifted out of the peritoneal cavity by volsella. A double ligature is then passed through the broad ligament so as to include the ovarian artery and the intervening tissues are divided. A second double ligature again transfixes the broad ligament so as to include the uterine artery, which can usually be felt pulsating under the finger, care being taken to keep sufficiently near the uterine body so as not to include the ureter, and the intervening structures are divided by scissors. The broad ligament and arteries on the other side are to be similarly tied off. These four ligatures usually cut off the arterial supply from the uterus and tumor. Sometimes in large growths other arteries may require ligation, or the proximal side may be held by pressure forceps to prevent reflux from the uterus. This method of applying pressure forceps may be used in ligating the ovarian and uterine arteries, in which case two single ligatures would be used on either side. The peritoneum covering the uterus at a point three-quarters of an inch or an inch above the junction of the cervix with the body is incised anteriorly and posteriorly. Anteriorly it is dissected or pushed downward with the handle of the scalpel, thereby separating the bladder from its attachments to the uterus. The posterior flap is carried down a similar distance, the cervix is amputated, and all that is required to complete the operation is to stitch these peritoneal flaps together over the stump of the cervix and attend to the toilet of the peritoneum. Before putting in a running catgut suture to

approximate these peritoneal flaps, it is oftentimes easy to turn in the stumps of the broad ligaments in such a manner as to leave them extra- and post-peritoneal. If deemed wise to remove the cervix with the corpus entire, it can be easily accomplished by keeping up traction and by the use of curved scissors, snipping the attachments little by little around the entire cervix, having previously sterilized the vagina.

Considerable variation in the method of applying the ligatures will obtain in different cases, from changes in the breadth and depth of the broad ligament owing to the increase in size of the uterine body or thickening due to inflammatory exudates. In some cases it is better to secure the uterine artery after incising the broad ligament than by transfixion. In others Kelly's method is simplest and best. The complications attending fibroma are so many and so diverse that the technique suitable to a simple case must be subject to variation. It is desirable to leave the stumps of the broad ligament with some free border, so that if they cannot be turned under when stitching together the antero-posterior peritoneal flaps, their peritoneal edges can be united by running suture, thereby covering in all raw surface. After complete hysterectomy both the vaginal surfaces and peritoneal flaps can be approximated by catgut sutures.

Should drainage for any reason be deemed necessary, iodoform gauze can be carried through a portion of this opening from above downward into the vagina, and as much left in the peritoneal cavity as seems necessary to cover any raw surfaces not otherwise provided for. In all cases of *cœliotomy* in the female, the vagina should be sterilized so as to be in proper condition for drainage should emergency so require. I have adopted this method of downward drainage after *cœliotomy* for various conditions, those primarily septic and those in which the peritoneal cavity became accidentally infected by the rupture of pus tubes or abscess cavities, with the most gratifying results. Unless infected, the peritoneum is closed without drainage.

It is well in allowing the patient to resume the horizontal position after having occupied the Trendelenburg posture, to do so slowly and to watch carefully that the changed blood pressure does not cause hemorrhage. By so doing the risk of secondary hemorrhage can be greatly lessened and probably eliminated.

No reference has been made to vaginal section for fibroids for the reason that unless the growths are small they cannot be delivered through the vagina without morcellation. When small, it may be the better method, as it is usually attended with much less shock than the abdominal method. The steps are the same as those in ordinary hysterectomy and need not occupy our time.

At the present time the adoption of *cœlio-vaginal* hysterectomy for large fibroids with broad attachments is finding favor, and promises in properly selected cases more rapid accomplishment with the minimum of shock and hemorrhage. It is accomplished by first tying the uterine arteries and severing the base of the broad ligaments. There are forms of subperitoneal fibroids which may be removed by myomectomy if pedunculated or sessile; the peritoneum covering them may be incised, the arteries tied, and the peritoneum carefully approximated.

No reference has been made to treating uterine fibroids by Apostoli's method, for the reason that there is little or no evidence that it has any power to promote absorption of fibrous structures, though its efficacy in reducing the size of *œdematous* fibroids is not disputed. The danger of its use in the presence of diseases associated with fibroids more than outweighs any of the advantages therefrom.

Fibro-cystic growths of the uterus are infrequently

met with, and like solid fibromas may be large or small. They sometimes attain very large dimensions. Palliative methods of treatment promise little or nothing, and galvanism is positively contraindicated. They may spring from almost any portion of the uterine body, but very infrequently from the cervix. In a recent hysterectomy for general fibroma I found, attached to the uterine body, a fibro-cystic growth which was sessile and intraligamentous. Nothing short of radical surgical measures holds out promise of successful treatment.

291 HANCOCK STREET.

CONGENITAL OCCLUSION OF THE URETHRA—REPORT OF OPERATION FOR ITS RELIEF.¹

By CHARLES W. ALLEN, M.D.,

NEW YORK.

GENTLEMEN: I wish to report briefly an instance of a rather rare condition. On April 19, 1895, there was born in the Maternity Hospital on Blackwell's Island a male child. Upon the following day, April 20th, it was reported to the visiting surgeon, Dr. Marx, that no urine had passed. Examination showed that there was no meatus urinarius externus. An incision was made in the expectation that this would open into a channel, as is the case ordinarily. No opening was found, however, and the cut was extended somewhat deeper, and numerous attempts were made to force a passage through with a fine probe. Dr. Walsh then saw the patient, and, likewise after careful examination, made ineffectual efforts to enter the canal. These gentlemen then kindly referred the case to me, I being at the moment the only member of the City Hospital staff on duty. After a vain attempt to bore through from the external opening, and not knowing how far back the absence of the urethra might extend, I proposed to do an external perineal section, to which Drs. Marx and Walsh assented. The operation was somewhat tedious, as the urethra was not easily distinguished from the other tissues, and never having before operated upon a subject of this age, I preferred to go slow rather than to go wrong, and besides I wished to keep the perineal wound as small as might be. Having entered the bladder and allowed the accumulated urine to escape, and after irrigation, I passed a probe from the perineal wound into the proximal end of the urethra. The instrument became arrested in the middle portion of the pendulous urethra and from this point on the tissues were simply bored through by forcing the instrument toward the artificial meatus already established. A section of a small-sized bougie was fastened in the anterior urethra, brought up to about the calibre of a No. 9 French instrument. Antiseptic irrigations were made and the perineal wound was packed with iodoform gauze. The case was transferred, according to the hospital rule, to the surgical service, where I saw the patient about a week later. He was then in excellent condition. Urine was being passed by the urethra, as I was informed it had begun to pass upon the day following operation; the perineal wound was almost closed; and, as I understood, instruments were being regularly passed to maintain the calibre of the anterior urethra.

Going off duty on the 1st of May I did not again see the case, and it is only now, wishing, because of the rarity of the condition, to put it upon record that I find the child died on May 16th, nearly one month after the operation. The only history I can find shows that on May 6th the child began to show a temperature of 103°-104° F., respirations running from 40 to

50 per minute, and he was thought to have pneumonia. On May 10th jaundice appeared, and Dr. Herter saw the child with Dr. Brewer. The urine was passed toward the close in very small quantity and was of a very dark brown color. Before death the temperature became subnormal.

The autopsy record showed: Perineal wound entirely healed. Heart enlarged. Weight of left kidney, three ounces. Weight of right kidney, two ounces. The left kidney measured two and a half inches in length and was lobulated. The hilum was distended with urine, as was also the ureter. The right kidney was two inches in length, slightly lobulated, capsule adherent in sulci. The cortex of the kidney was pale yellow and the normal markings were absent from the pyramids. The ureter was distended with urine. The bladder walls were over one-eighth of an inch in thickness. The urethra was pervious from the bladder to about one-fourth of an inch behind the glans penis.

This, gentlemen, is all I know about the case. Whether the passage of instruments was continued after the time of change of service, whether Dr. Brewer or his house surgeon knew anything of the previous history of the little patient, what was the cause of the high temperature, what treatment was given, etc., are all lacking. The history books of the institution do not show. The history I have given has been kindly furnished me by Dr. Gilliam, who was present at the operation.

I have just returned from a meeting of the American Medical Association in Atlanta, where a paper was read by Dr. Small, of Pittsburg, upon "Retention of Urine in the Newly Born," during the discussion of which I inquired whether any present were familiar with this variety of occlusion without hypospadias or an opening somewhere for the escape of urine.

While speakers said they had observed a gluing together of the urethral walls, forming a temporary occlusion easily overcome, and the more common occlusion just at the meatus requiring simply a slight incision, none reported having seen such a condition as I have described.

I am somewhat familiar with text-book articles bearing upon the question of deformities of the male genitals, and without looking up the subject at the present time, I think I am safe in saying that the condition of absence of urethra in a considerable portion of its normal extent, or such a firm adhesion between the two halves of the canal as to entirely obliterate it, is rare.

Slight obstructions, due perhaps to inspissated secretions, or to easily overcome stenoses, are not so rare, and a probe or small-sized catheter readily overcomes them. Here, however, there was complete obliteration for a considerable distance, and I believe I pursued the proper course in performing perineal section. To have bored a way through from the meatus, not being able to determine at what point the patulous urethra would be encountered, and perhaps not knowing when it was encountered, if indeed the instrument entered it at all, instead passing up alongside, seemed to me unsurgical and unwise.

Such a course has been pursued with successful results, to be sure. Dr. Campbell related such an instance in 1891,¹ in which there seemed to be no urethra. After prolonged effort with various blunt instruments a passage was forced into the bladder, and at the age of three years the child seems to have suffered no harm from the operation. Dr. Adams has reported two instances of occlusion.² In one case no instrument could be passed and the child died forty-eight hours after birth. In the second case a probe passed into the urethra met an obstruction not far in, which

¹ Read before the genito-urinary section of the New York Academy of Medicine, May 12, 1896.

² British Medical Journal.

² British Medical Journal, February 28, 1891.

was overcome when considerable pressure was exerted with a soft French catheter. The first of these cases may have been similar to mine, though there was apparently a meatus present. The second case belongs in the same category with those just reported by Dr. Small in Atlanta. Dr. Guibé in November, 1895, related before the Société Anatomique a fatal instance of congenital stricture at the junction of the anterior with the posterior urethra. The prostatic portion was dilated to the same size as the bladder.

An opinion seems to prevail that instrumental exploration of the urethra in the newly born is rarely if ever called for. Whenever the report is made that the urine has not been passed, and there is evidence of accumulation of urine in the bladder, even if not pronounced, I should advise careful exploration of the canal.

126 EAST SIXTIETH STREET.

ABDOMINAL SECTION PERFORMED SUCCESSFULLY ON AN INFANT.

By ALFRED C. CARPENTER, M.D.,

NEW YORK.

On February 28th I was asked by Dr. Joseph Moorhead, of this city, to see a patient of his in consultation with him. The patient was an infant, male, two months old. Its abdomen was greatly distended; the temperature was 102.4° F., pulse 120, respiration 80.

The mother said she first noticed that the abdomen had begun to swell when the child was three weeks old, and that it had slowly increased until two days before my visit, when it rapidly became enormous. The bowels had been moving very scantily and only with great effort, and finally had ceased to move at all. I diagnosed the case as one of chronic intussusception and advised an immediate operation, giving the mother very little hope of recovery.

The child was brought to my sanatorium. Chloroform was administered by Dr. Moorhead. The intestines were so greatly distended with gas that it was necessary to puncture them to allow it to escape and relieve the pressure upon the obstruction before we could manipulate them. The bowel was reduced without difficulty. The abdominal cavity was flushed out, the intestines were replaced, a small wick of iodoform gauze was introduced for drainage, and the wound was closed. Recovery was uninterrupted, and the child was taken to its home ten days after the operation, the wound having entirely healed and the bowels moving naturally. According to the statistics given by Mr. Frederick Treves, of London, out of a total of seventy-three cases, there were thirteen recoveries, all of them in patients over three months of age.

There have been only two successful cases reported in which the patients were three months old—one by Dr. Wiggin in the *MEDICAL RECORD*, the other by Dr. Kelsey in the *New York Medical Journal*.

From all available statistics this is the youngest successful case of abdominal section on record.

219 EAST NINETEENTH STREET.

Suture of Wounds of Large Venous Trunks.—Dr. M. Ricard (*La Presse Médicale*) reports two cases in which the continuity of the vessels has been preserved by suture. In one case, brachio-cephalic, he employed the Lembert suture and supported the vein by carefully suturing tissues above it. In a second he sewed up an incision in a dilatation of the femoral just as if it had been an ordinary wound, and then stitched the skin above it. The union in both cases was perfect. There was no hemorrhage nor disturbance of the circulation. The lumen of the vessels seems to have been left free.

Progress of Medical Science.

Longevity of Physicians.—The average longevity of the members of the medical profession is an interesting subject. A French statistician has made an inquiry on the subject which is very encouraging for the doctors. He finds that in the sixteenth century the average duration of a doctor's life was only thirty-six and one-half years. In the seventeenth it reached forty-five and two-thirds years, in the eighteenth forty-nine and two-thirds years, and at the present time he finds that it is fifty-six years. This interesting man of science proposes to find out whether the average longevity of the patients increased in the same proportion.—*Evening Sun*.

The Different Methods of Electrolysis in Stricture of the Urethra.—At a recent meeting of the Société Médico-chirurgicale (February 10, 1896) Dr. Desnos reviewed the various procedures which have been advanced for the relief of stricture by the electrolytic current. There are two essentially different methods which claim our attention; one which we may call the rapid method, the other the slow. The first, which was experimented with by Mally and Tripier, is due to Jardin, who has constructed an ingenious instrument modelled after the *Maisonneuve*. Currents of variable intensity are employed, but of sufficient strength to permit the electrolytic blade to traverse the stricture in a single séance. The negative pole is the one always used in the urethra. In slow electrolysis, or the method of Newman, currents of very feeble intensity are employed, applied in the neighborhood of the stricture, not by means of a blade as in the former case, but by an olivary bulb somewhat larger than one which will pass of itself. This is left in contact with the stricture, while a current of from two to four milliamperes at most is passed. At times the obstruction is rapidly overcome and the engaged bulb is felt suddenly to be liberated; at others the stricture resists, but between the sittings a work of regression has gone on, so that at the expiration of several days an increase in the calibre of the canal, often quite marked, is noticeable. In employing linear electrolysis of moderate intensity the following phenomena are noticeable in the first twenty-four hours: Intense redness at the point of application of the current, as well as extending to the whole periphery of the urethra, which is ecchymosed. In depth these lesions go beyond the limits of the mucous membrane, and if the intensity of the current has been somewhat elevated and prolonged interstitial hemorrhages are to be seen, which seem to Dr. Desnos to play a certain rôle in the genesis of consecutive accidents. Experiments upon dogs, from which the foregoing observations were made, agree with the author's experience in man. The moment it becomes necessary to employ somewhat elevated current strength in order to overcome the stricture in a single sitting, a rapid recurrence of the stricture is noted; but what is especially important is the fact that this new stricture is firm, tense, and non-dilatable, presenting, in a word, the features of traumatic stricture, whence the very great resistance to dilatation in urethra which have been electrolyzed. It is by no means the same after the slow method with feeble currents as in the method of Newman. Here accidents are scarcely known; as to results, they usually are good. The writer admits that he has not been so successful as Newman (who claims not to have had a single accident in several hundred cases), having had several non-dilatable strictures following the application of this method. Unfortunately it is an extremely slow

method. Ten or twelve days must be allowed between the sittings and from twenty to twenty-five applications are often necessary, causing the patient if not the physician to give it up for another method. In discussing the question Dr. Labbé considered the rapid method not electrolysis at all, which is a molecular decomposition of the tissues, but a chemicaustic or a true cauterization, while Newman's method seems to act by true electrolysis. [These opinions, coming from observers of known ability and care in utterance, must be at least gratifying to the originator of a method of electrolysis on this side of the water whose claims have received little encouragement from leaders in genito-urinary thought among his fellow-countrymen. They should also cause enthusiasts to pause and consider the ultimate results, before giving themselves up wholly to the methods advocated by a brilliant and rapid operator who recently spent some time in introducing here his instrument, which we understand is protected by patent and can be purchased at a correspondingly high price.—ED.]

Traumatic Intracranial Hemorrhage.—Deaths by intracranial hemorrhage, the result of violence (as a blow on the head) are of common occurrence, says a writer in the *Boston Medical and Surgical Journal*, March 12, 1896, as is shown by the records of our criminal courts and mortuary statistics. A fall on the head, a blow from a cane or the fist over the temporal, parietal, or occipital region, may be soon followed by dangerous if not fatal symptoms of compression due to hemorrhage, and in many cases there will be absence of fracture and other external marks of violence. The bleeding in a large proportion of subjects comes from lacerated branches of the middle meningeal artery and is between the dura and cranium, resulting in a firm clot adherent to the dura; the hemorrhage is due to separation of the dura from the bone in consequence of the blow and laceration of the vessels as they enter the arborescent bony grooves. As diagnostic signs of this lesion we have the primary stunning, then a period of consciousness of variable duration, then the secondary coma attended by certain localizing symptoms dependent on the region of the cortex implicated. First the motor symptoms—that is, motor aphasia, from pressure at the bottom—then involvement of the face, then of the arm, and rarely of the leg centres.¹ The dilatation of the pupil on the same side as the lesion is another localizing sign. The indications will not be materially different whether the clot be inside or outside the dura; nor has the modern surgeon any hesitation about the propriety of penetrating the dura when there is extravasation of blood beneath it. Intracranial hemorrhage due to external violence is still the bugbear of the ordinary practitioner, who realizes that such cases are generally fatal, and who is still dominated by such views relative to the utility of trephining as were formerly prevalent and found expression in the declaration of Druitt that "trephining is a last resource, and, it must be confessed, a very desperate one, which modern surgeons become daily more unwilling to resort to."² Even Gross taught that the only case in which trephining is really warrantable is "where the extravasation is associated with or dependent on the fracture of the skull, complicated with depression or serious injury of the soft parts, or where the fracture is situated directly over the course of the middle meningeal artery."³

Naturally, an impetus to bolder surgery followed Listerism and modern aseptic methods, and trephining

is now generally regarded by the surgeon as imperatively indicated in most cases where there is reason to believe that there is hemorrhage within the skull—whether there be fracture or not—provided that there are external marks, as contusion, ecchymosis, and swelling, or other definite localizing indications. Wiesmann has considered the matter from the point of view of statistics. He states the mortality of non-operated cases as 89.1 per cent. and that of operated cases as 32.7 per cent., a difference most remarkably in favor of trephining. It has not been shown that this ratio of lessened mortality is an overestimate. The subject has been frequently discussed before medical societies. In the discussion before the Philadelphia Neurological Society in 1894, Drs. Taylor, Keen, Laplace, Dercum, and Sinkler participated; three unsuccessful and several successful cases were reported. It was also discussed before the Suffolk District Medical Society several years ago, Drs. Elliot, Putnam, Warren, and Bradford taking part (*Bos. Med. and Surg. Jour.*, February 9, 1893). At this meeting, Dr. John W. Elliot reported two cases of intracranial hemorrhage in which the operation was successful; in both the hemorrhage accompanied depressed fracture. Dr. Putnam alleged that "the most satisfactory of the operations done at the hospital have been in this class of cases." Dr. Warren pointed out that the point of election for trephining in cases of hemorrhage is the pterion or the part where the parietal bone joins the frontal and temporal bones. "If no clot is found there, trephine farther back on a line parallel with the roof of the orbit." He thinks it a point of great importance "that we should not only relieve the pressure caused by the hemorrhage, but that we should also undertake, by making an opening into a cranial cavity, to remove all the fluid which remains there." The point of election for drainage "should be a lower point in the cavity of the skull than the one selected for searching for a clot or the vessel itself, that is, through the squamous portion of the temporal bone, just above and a little behind the external auditory meatus." Dr. Griffin, of Lincoln, Neb., in the case of a man who was injured over the arm and leg centre in a brawl, used a bradawl and chisel for trephining, and found the operation surprisingly easy! The middle meningeal artery was bleeding profusely and was tied. The man got well.¹ It has been remarked that in cases of intracranial hemorrhage without a compound fracture of the skull, it is not always easy to find the bleeding vessel or even the blood clot by trephining. During a period of three years, Kroenlein trephined four closed skulls for the purpose of arresting hemorrhage from the middle meningeal artery. Two of his patients recovered, while the remaining two died because the extravasation was located posteriorly to the trephine openings and could not be found and removed at the time of the operation. Kroenlein therefore recommends that in cases where the surgeon is reasonably certain that the symptoms of compression are due to hemorrhage, exploratory trephining be continued until the hæmatoma is found. Thiersch had to remove three discs of bone before the blood clot was found.² Scudder and Lund³ in an analysis of forty-five cases of trephining for intracranial hemorrhage since 1886 found thirty-three recoveries and twelve deaths, a mortality of twenty-seven per cent., which is a considerable improvement on older statistics. This improvement has doubtless resulted from the more accurate diagnosis which a careful comparative study of the symptoms in numerous cases has made possible, and in part from improvement in the operative technique.

New York, June 6, 1896.

THE RANK AND FILE.

IN these commencement times, when the colleges parade their graduating classes amid tingling music, fragrant roses, and impassioned oratory, the looker-on is apt to put the question to himself, How many of all the flushed anticipations of brilliant futures will be paled before the stern discipline of inevitable disappointment? When we match ordinary professional success against real fame, the proportion which gains the latter is exceedingly small. The higher the degree the less the chance. To attain a pinnacle means the success of one in ten thousand. The law of proportions is founded on a mathematical certainty. The lower grades show more liberal chances, the sweepstakes in the race are not so heavy, and are purposely open to ordinary competitors. Still the training to race develops becoming assurance, creates proper endurance, and in the end makes the essence of actual capabilities. If not a spirited and sweeping record breaker, we get the good and serviceable burden bearer. There are many of these in every field of struggling effort. They are in the majority which is always respectable, always efficient, and which does the really necessary and valuable work for any community. We speak for such of the aspirants for high places who, in spite of every laudable effort, must be contented eventually to find their actual places with this majority. It may not be on account of any lack of merit on their part, but rather in the elucidation of the general and greater law, which necessarily has the fewer and more definite exceptions.

While all should be keenly alive to offered opportunities, the best immediate results and the most lasting benefits are the satisfaction of the work itself and the healthful contentment which always belongs to judicious effort and reasonable anticipation. While every graduate cannot hope to be a great man, in the more popular sense, he can at least be a good one, safely enjoying the ever-present satisfaction of constantly doing his best.

It is such who must make up what is oftentimes affectedly and patronizingly called the rank and file of any profession. But each individual is such an important part of the whole that he very necessarily shares in a credit which is large enough for the freest distribution and varied enough for every particular need. It is every man in his place, with a place

for all. No position is so small or so unimportant that it cannot be profitably occupied by an honest worker. In the most obscure village there is always room and place for the one who loves his vocation. The sick are everywhere. Their claims on good service are equal the world over. The size of a town does not govern the character of this skill. It is the glory of the rank and file that it occupies its position so well and so creditably. Each representative of the army medical is a host in himself, a natural leader among his fellow-men, a centre of influence for the most practical good, an efficient helper in times of direst need, a trusted and honored citizen in matters which concern the public welfare, and a beloved and cherished neighbor in that family life of a community which reflects the glow of the hearth fire and brings sunshine in the home. Is not such position enough for any ordinary ambition? What more can any prophet ask than honor in his own country, and a daily welcome among his friends? Even if fame be not gained, the greater and better part of what remains is not lost. We salute the colors of the rank and file.

CONSERVATIVE GYNECOLOGY.

IT was a judicious conservatism that prompted one of the speakers at the recent banquet of the American Gynecological Society to declare against the prevailing craze among the younger members for newer and more brilliant operations. The criticism was respectfully received, as was to be expected on such occasions, although with some of the hearers there was manifest more of courtesy to opposite opinions than of real contrition for past and future sins. It cannot be denied that gynecology of late years has more than held its own in devising, executing, and perfecting startling operative procedures. The enthusiasm that naturally follows such successes is always contagious and always dangerous. The cultivated skill of the majority of operating gynecologists engenders an ominous presumption as to still greater ventures. It may appear a little harsh to assert that many of these operations are unnecessary, but we venture to suggest in view of past history that such will be proven before very long.

Gynecological operations, like everything else belonging to the gentler sex, must have their fashions and their fads. The smaller the field, the higher the cultivation necessary. Operations of different names and different kinds have so densely occupied this well-worked field that there is hardly room for partition fences. Every conceivable surgical procedure has been practised within the pelvic limits, while the number of special instruments that have been devised to give the uterus a bare fighting chance is enough to sink a ship. Sims' spoon handle has twisted itself into so many different shapes and wrinkled itself into so many possibilities of universal adaptation, that it is as often used at one end of the economy as its distinguished and useful progenitor at the other. So with hooks, plain and clenching; scrapers, sharp and dull; scissors, flat and curved, long and short, thick

and thin; pincers, rough and smooth, heavy and light; needles, long and short, flat or speared; squirts, hot and cold, insipid or salty, aseptic and antiseptic—all find their place on the operating-tray ready to pay tribute to the willingness and daring of the skilful hand that must use each device in turn, and christen each with an impartial benediction for necessary service rendered.

Of the ovary, in times past at least, it might be truthfully said, "The Lord gave, but man taketh away," and of the gynecologist, "Blessed is he who has his pathological jar full of them." Next came new quilting patterns for the perineum and the radical plumbing of pus tubes, and now the uterus, so long celebrated in toast and song, has built a new reputation for herself and statistically smiles from a monument of hysterectomies. The race for novelties has been long and hot. The warning for a slower pace is timely and just. Let us hope that the time will soon come when we can realize the long-expected millennium of a broader and higher conservatism, when the uterus shall cease its troubling and the ovary be at rest.

We speak of unnecessary operations only, and would by no means detract from reputations worthily won and modestly enjoyed. But the line between the fashionably ambitious innovator and the judiciously conservative operator is not yet clearly drawn. However, the revenge of the ovary may be nearer than we suspect. Already, with retaliatory smirk, she appears willing to share her pressing burdens of distinguished consideration with her now anxious analogue, whose right to be is so seriously questioned in connection with the newly discovered reflexes focussed on a tumefied prostate.

THE PSYCHOLOGY OF CROWD PANICS.

THE recent crowd panic on the Hodynsky Plain in Russia, with its frightful loss of life, emphasizes the danger in all large gatherings of sudden explosions of fear and demonstrates the impossibility of controlling a thoroughly frightened multitude. It is the history of every crowd under like circumstances, although the damage done in the present instance outweighs that of any similar occurrence in history. The latest estimate of the number of the dead is three thousand six hundred, that of the wounded being over twelve hundred. It is also stated that over five hundred thousand peasants were gathered on the plain in question, with a very inadequate police force and with all the elements which might tend to make the mass of humanity irritable and excitable. The lesson of results is one which the world at large will not easily forget. The horror of the situation passes the power of description, even by the alert and graphic newspaper correspondents. It was a tidal wave of unreasoning brutality forced against the comparatively weak barrier of human resistance. To such as look upon a crowd as an aggregation of human force, a multiplication of personal energy, and an ever-present consciousness of individual weakness, it is surprising that such calamities are not of more frequent occurrence, and that the law of accidents does not swell its statistics to frightful proportions.

If we study a crowd as we would an individual, there are many interesting phenomena to note which may serve to explain the reasons for panics and the most rational means for their prevention. The very gathering of a large number of people implies a concentration of interest in a given and definite direction. There is an individual as well as a general aspect of the condition. The individual is so small a part of the whole that he becomes overawed by the impression of the latent and implied power of accumulated mental and bodily interests. It means stage fright to the one who faces it on the one hand, and on the other hand becoming respect by the one who merely forms a part of it. There is always a something about a crowd which manifests a strained and tense degree of mental activity, a hyperexcitability to casual impressions, and a corresponding lack of control of ordinary individual emotions. Thus, the flattest joke oftentimes produces an applause which is proportionate to the size of the audience rather than to its supposed intelligence. Contrariwise, the most trivial mishap awakens the most foolish terror. Excitement, irritability, and then fear rapidly follow each other on the slightest provocation. What would be trivial to an individual is terrible to a crowd. It is a question of degree merely, and is proportionate to the power behind. The mental tension, stupendous and formidable at best, is apt to give way with a sudden and dreadful snap. It is the spark to the magazine. The slightest exciting cause may start the train of the most unreasonable apprehension, which becomes intensified in proportion to the demonstrated difficulty of escape. The insanity of fear is both individual and general. The instinct of self-preservation becomes the one and only factor in the equation of desperate chances. It gathers strength from resistance, until its own exhaustion and despair strike the balance with death.

All these factors were present in the recent lamentable disaster. The crowd was worn out by excitement, irritated by strained expectation, ignorant of possible danger, hungry, tired, and impatient; every selfish interest was intensified by the promise of food and gifts, the struggle for preferment was pronounced and threatening, the terrible combination of lower human interests was charged to the full and awaited the signal for the inevitable explosion.

It is lamentable to think, in view of subsequent facts, that much might have been done to lessen the magnitude of the disaster, if not to prevent it altogether. As a large crowd is always a dangerous one, the gathering should not have been allowed to attain a magnitude beyond possible control. With sections properly guarded, a general and widespread panic would hardly have been possible. There should have been no single point of interest, no distinct focal direction of effort, but rather a judicious distribution of attractions. From all accounts the plain was seemingly large enough to allow space for tables, barbecue fashion, in properly separated places, with a well-organized system of rotation feeding and gift distribution, and a consequent prevention of a closely packed and dangerously sensitive mass of struggling humanity. As it is, the deplorable experience in

Russia may serve as a useful lesson for the more careful management of all crowds wherever assembled, and not only teach the authorities the urgent necessity for extraordinary alertness in properly preventing panics, but in promptly arresting them by the quickest possible methods of diversion and dispersion.

News of the Week.

Vacancies in the Medical Corps of the United States Army.—There are at present three vacancies in the medical corps of the United States army, and it is expected that at least three more will occur during the present year. As usual, an army medical board will meet in Washington early in October for the examination of candidates. The requirements for admission to the medical corps are stated in a circular which may be obtained by addressing the surgeon-general of the army, Washington, D. C.

Nebraska State Medical Society.—At the meeting of the above society, held in Lincoln, May 19th to 21st, Dr. F. D. Haldeman, Ord, Neb., was elected *President*, and Dr. George H. Simmons, Lincoln, *Secretary*. Lincoln is the place of meeting next year.

The Dinner of the Hospital Graduates Club.—The annual dinner of the Hospital Graduates Club of this city was held on the evening of May 29th, at the Hotel Hungaria. The president, Dr. C. H. Knight, welcomed the guests and introduced the toastmaster, Dr. W. K. Simpson. The following speakers responded on call: Drs. George F. Shrady, John W. Brannan, Landon Carter Gray, Frank P. Foster, E. M. Culver, and J. Riddle Goffe.

An Epidemic of Measles prevails at Flushing, L. I., at present, and notwithstanding the efforts of the local board of health and the village physicians, the disease is on the increase. Forty-seven cases were reported during May. The health officers quarantine all premises where the disease exists, and a large sign board, on which the word "measles" is painted, is hung over the front door.

The Morris County, N. J., Medical Society.—At the annual meeting last week of the Morris County Medical Society in Morristown, the following officers were elected: Dr. H. V. Day, of Butler, *President*; Dr. C. N. Miller, of Flanders, *Vice-President*; Dr. Levi Farrow, of Middle Valley, *Secretary*; Dr. John Stiger, of Mendham, *Treasurer*; Dr. E. P. Cooper, of Troy Hills, *Reporter*; Dr. Thomas P. Prout, of the State Hospital, *Essayist* for next meeting.

Dr. J. Henry Furman, of Tarrytown, died at his home in that place on May 26th, at the age of sixty-four years. He left a widow and two sons.

Professor Zacharjin, of Moscow, the eccentric physician of the late Czar Alexander III., will, it is said, shortly resign his chair in the university of that city. Dr. Tschirkoff, professor of therapeutics in the University of Kieff, is spoken of as most likely to succeed him.

The Medical Society of New Jersey.—The annual meeting of this society will be held at Asbury Park, Tuesday and Wednesday, June 23d and 24th. Dr. William Elmer, of Trenton, *President*; Drs. T. J. Smith, of Bridgeton, D. C. English, of New Brunswick, and Dr. C. R. P. Fisher, of Bound Brook, *Vice-Presidents*; Dr. E. L. B. Godfrey, of Camden, *Corresponding Secretary*; Dr. William Pierson, of Orange, *Recording Secretary*; and Dr. Archibald Mercer, of Newark, *Treasurer*.

The American Orthopædic Association, at the meeting held at Buffalo, May 19th to 21st, elected the following officers: Dr. Samuel Ketch, of New York, *President*; Drs. H. M. Sherman, of San Francisco, and W. R. Townsend, of New York, *Vice-Presidents*; Dr. John Ridlon, of Chicago, *Secretary*.

Post-Graduate Medical School and Hospital.—Dr. Robert Abbé has resigned from the professorship of surgery in the Post-Graduate Medical School and Hospital, and Dr. Thomas E. Satterthwaite has been appointed consulting physician to the hospital.

New York Eye and Ear Infirmary.—Dr. W. K. Simpson has been appointed surgeon to the New York Eye and Ear Infirmary, throat department.

The London Temperance Hospital has received a gift of \$250 from a friend of the cause, ninety years old, "as a thank offering for having completed fifty-six years of abstinence from intoxicating liquor."

Medical Association of Montana.—The officers of the Medical Association of Montana for 1896 are as follows: *President*, James M. Sligh, M.D., of Philipsburg, Mont.; *Secretary*, William C. Riddell, M.D., of Helena, Mont. The next annual meeting will be held at Helena, April 6, 1896.

Dr. Paul F. Mundé has been appointed consulting obstetrician to the Maternity Hospital of New York, and has accepted the position of one of the honorary presidents to the International Congress of Gynecology and Obstetrics to be held at Geneva, Switzerland, in September, 1896, which was tendered him by the president of the congress, the late Professor Vulliet, last February.

Sir William MacCormac is spoken of as the most likely candidate to succeed Mr. Christopher Heath in the presidency of the Royal College of Surgeons. He is one of the most hidebound of conservatives, and would probably exert every influence to prevent the introduction of any reforms during his incumbency.

Why We Oppose the Metric System.—Dr. Heywood Smith, of London, has found an eminently satisfactory and atavistic reason for the reluctance of English-speaking countries to adopt the decimal system of weights and measures. "The Anglo-Saxon or English-speaking race," he writes to the *Medical Press*, "is, without doubt, of Israelitish origin; that is, they are the descendants of the lost Ten Tribes of Israel, and thus they adhere to their tribal duodecimal notation; whereas, the other nations, having no sacred tradition regarding the number twelve, use the method that is perhaps more scientifically convenient."

American Climatological Association.—At the last meeting of this association in Lakewood, N. J., May 13, 1896, the following officers were elected: *President*, Dr. E. Fletcher Ingals, of Chicago; *Vice-Presidents*, Dr. S. A. Fisk, of Denver, and Dr. John C. Munro, of Boston; *Secretary* and *Treasurer*, Dr. Guy Hinsdale, of Philadelphia; *Council*, Dr. W. E. Ford, of Utica, Dr. Roland G. Curtin, of Philadelphia, Dr. Isaac Hull Platt, of Lakewood, Dr. S. E. Solly, of Colorado Springs, and Dr. James B. Walker, of Philadelphia.

Pennsylvania Epileptic Hospital and Colony Farm.—An official decree has been filed allowing and approving the merger of the Pennsylvania Colony Farm for Epileptics with the Pennsylvania Epileptic Hospital, under the title of the Pennsylvania Epileptic Hospital and Colony Farm. Dr. Wharton Sinkler has been elected president of the new corporation and has appointed Messrs. Charles M. Lea, Henry M. Dechert, and W. W. Frazier and Drs. Charles K. Mills and J. C. Wilson members of the building committee. Plans are to be at once prepared for the early erection of buildings upon the farm recently purchased at Oakbourne, Chester County. For this purpose Mr. H. C. Lea has contributed \$50,000. Previous subscriptions amount to \$27,350, of which \$14,000 have been used in the purchase of the farm; the balance will be devoted to the equipment in modest style of the institution and for its maintenance in an experimental way for the coming year. It is hoped that the movement will arouse the interest and support of the charitably disposed in all parts of the State.

The University of Pennsylvania has within the last few weeks been the recipient of a number of munificent donations at the hands of several public-spirited Philadelphians. Mr. Thomas McKean has agreed to contribute \$100,000 on condition that other citizens will swell the gift to \$1,000,000, the whole sum to be used for the development of the general usefulness of the university as a centre of education. Mr. Alfred C. Harrison has also made a contribution of \$100,000. Of this sum \$50,000 is especially contributed for the purpose of promoting the advanced work of the university, including the special preparation of teachers for their work and the equipment of a suitable building for graduate instruction and original investigation, with the necessary laboratories and apparatus. The remaining \$50,000 is contributed without limitation as to its use. Three contributions, each of \$10,000, have been received, one from Mr. John H. Converse, the second from Mr. William P. Henszey, and the third from a donor whose name is withheld.

Valuable Gift to the Philadelphia Academy of Natural Sciences.—Dr. A. Donaldson Smith, who returned a short time ago from an expedition through the northeastern portion of Africa, has presented the Academy of Natural Sciences with a large number of valuable specimens collected by him in his travels, including serpents, fishes, birds, mammals, a large number of entomological subjects, and a few shells.

The Walker Prize of the Royal College of Surgeons, for the best work in advancing the knowledge of the pathology and therapeutics of cancer, done either partially or wholly within the five years preceding the year in which the prize is awarded, has been awarded this year to Mr. Harold Jalland Stiles, of Edinburgh University. The prize consists of £100 accompanied by a certificate of award. It is open to foreigners as well as to British subjects, and the committee is not restricted in any way as to the selection of persons qualified to receive the prize, with the exception that members of the council of the Royal College of Surgeons are not eligible.

The Archives of Clinical Skiagraphy.—The modern tendency to specialism in journalism as well as in other fields is shown by the establishment of a periodical, with the above title, which will be devoted to a demonstration of the uses of the new photography in medical and surgical diagnosis.

A Possible Source of Infection.—The *New York State Medical Reporter* suggests that the promiscuous use of ordinary drinking-water for the extemporaneous preparation of solutions for hypodermic injections is possibly the cause of much disease the infection of which is capable of transmission through the medium of water, as malaria, typhoid fever, and diphtheria.

A Chair on the History of Medicine is to be established at the University of Würzburg.

Obituary.

SIR JAMES RUSSELL REYNOLDS, BART.,
M.D., F.R.S., F.R.C.P.,
LONDON.

SIR J. RUSSELL REYNOLDS, who died on May 29th at his home in London, was the son of the Rev. John Reynolds, of Westminster School, and grandson of Dr. Henry Revell Reynolds, physician in ordinary to George III. He was born in London in 1828 and was educated at University College, of which he was afterward, in 1856, elected a fellow. He began the practice of medicine in 1852, and almost immediately obtained a large clientèle. In 1878 he was appointed physician in ordinary to Her Majesty's household, and was created a baronet in 1895. He resigned the presidency of the Royal College of Physicians, or rather refused a re-election, this year, owing to ill-health. He seemed to be gradually regaining his strength when, on April 28th, as he was entering his house after having made some professional visits, he stumbled on the doorstep. The accident was trivial in itself, but in his weakened condition caused his confinement to bed, and in a short time pulmonary trouble developed, from which he did not recover. Sir J. Russell Reynolds was best known in this country as the editor of the "System of Medicine" which bears his name, though his best work was as a neurologist, and most of his writings were on neurological subjects. Among these works were "Diagnosis of Diseases of the Brain, Spinal Cord, and Nerves," "Tables for Diagnosis of Diseases of the Brain," "Vertigo, an Essay," and "Scientific Value of Legal Tests of Insanity." He was an honorary member of the American Neurological Society, and of many continental societies.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-First Annual Meeting, Held in the New York Academy of Medicine, May 26, 27, and 28, 1896.

WILLIAM M. POLK, M.D., OF NEW YORK, PRESIDENT.

First Day, May 26th.

Address of Welcome.—DR. WILLIAM T. LUSK, of New York, in an address warmly welcoming the members to New York, briefly referred to the valuable work of the society during its twenty-one years of existence.

Virginal and Senile Endometritis.—DR. PAUL F. MUNDÉ, of New York. Nearly all of the great amount of literature on endometritis, he said, referred to that disease during the child-bearing period in women who had been pregnant. Not long ago Dr. Sexton and Dr. Skene wrote on endometritis in the senile uterus, but there is little or no formal literature dealing with virginal endometritis. In 1881 Dr. Mundé saw a case of eroded cervix in a girl of fourteen, the condition being such as he would have taken for a puerperal lesion, had not the presence of the hymen precluded such a cause. Subsequent observation led him to believe that such cases are not very rare. The condition is not unlike that seen in chronic endometritis and cervicitis following some time upon the puerperal state. He had no experience with congenital fissure and erosion of the cervix, although he did not deny the possibility of their occurrence, as has been claimed by Fisher and others.

Dr. Mundé agreed with those who are opposed to vaginal examination of virgins without cause, but in some of the cases under consideration a correct diagnosis and cure could not have been arrived at in any other way.

After relating the case of a girl, aged twelve, who was also seen by Dr. Coe, he gave the history of a girl of eighteen who was anæmic and had hemorrhages. On vaginal examination the uterus, which was slightly anteфлекed, was found in nowise enlarged, but the os was gaping, and on this or a subsequent occasion it was found eroded. Medicinal treatment did not benefit the patient, and he thoroughly curetted the uterus. A number of adenoid vegetations were removed. All hemorrhage ceased, but he expected a return of the condition, and this took place after three months. He recommended another curetting and suture of the os, as in laceration. Some time subsequently this was done, nitric acid was applied to the uterine canal, and the uterus resumed its virginal appearance. He was unable to say what caused the endometritis.

Speaking of endometritis in the senile uterus, Dr. Mundé thought it unnecessary for him to say how suggestive of malignant disease is a discharge sufficient to soil the linen in aged women, yet he had seen not a few cases in which such discharge, even when very foul, was due to a non-malignant endometritis. Under no circumstances is hysterectomy indicated in these cases, and yet it has, no doubt, been sometimes performed under the supposition that malignancy existed.

In discussing this paper Dr. PENROSE, of Philadelphia, related a case in confirmation of his view that the erosion and ectropion of the cervix in virgins is sometimes, though rarely, due to a congenital state. Dr. LAPHORN SMITH thought it not surprising that endometritis should sometimes occur in virgins in view of the exposure to cold, etc., to which they subjected themselves. Dr. M. D. MANN thought a lithæmic con-

dition an important cause. DR. PALMER related some experiences showing the efficiency of constitutional treatment. DR. HOWARD A. KELLY thought an efficient ocular examination of the os could be made without injuring the hymen, and agreed with Dr. Mann as to the sufficiency of constitutional treatment in most cases. The discussion was continued by DRs. W. T. LUSK, J. T. JOHNSON, and the author.

Liability to Prosecution for Damages in Abdominal Surgery.—DR. CYRUS A. KIRKLEY, of Toledo, O., in this paper related two or three cases illustrating liability to suit for damages in abdominal surgery. He said that expert testimony is not regarded above ordinary testimony by the average jury and but little higher by the court; that the hypothetical question which is supposed to embody the facts in a case, in reality is often distorted, disingenuous, and is ruthlessly handled and more or less emasculated before the witness is allowed to pass judgment upon it.

DR. HOWARD A. KELLY confirmed the general views stated by Dr. Kirkley, but thought that usually the surgeon in a large hospital who takes ordinary precautions will have that moral support of the community which will prevent unjust suits for damages, or cause a verdict to be rendered in his favor.

Gynecology and General Medicine; Their Reciprocal Relations.—DR. CHAUNCEY D. PALMER, of Cincinnati, read this paper. He said there is no purely local disease; every organ of the body has its constitutional relations. These differ in intensity, quantity, and duration. The nervous relations were first considered. Many neuroses of a functional kind—chorea, epilepsy, hystero-epilepsy, hysteria, neurasthenia, neuralgia, and mental disorders like mania and melancholia—are often connected with or dependent upon female pelvic diseases or are aggravated thereby.

How does the female organism modify the manifestations of disease? He thought we must accept the view that menstruation is not a local function of but a few days' duration, but that it is a systemic change; a tide, the stages of which extend over twenty-eight days. Preceding the menstrual flow there is increased vascular and nerve tension, with increased bodily and mental function, while the reverse condition follows the flow. In consequence, there are phenomena which modify existing symptoms of disease, if they do not give rise to new ones.

Local diseases tend to become constitutional, and constitutional diseases to become local. Local diseases produce secondary constitutional changes or consequences, rather than the continuance of themselves. Local phenomena without adequate local cause mean bad constitutional condition, as do continuation of symptoms after removal of the exciting cause. There is scarcely a disease of the general system of considerable importance which does not influence the circulation and the innervation, and, of course, the functions of the pelvic organs. On the other hand, almost every gynecological disease requires some, a few need exclusive constitutional treatment. The inevitable trend of modern gynecology has been largely to surgery, yet the gynecologist must survey the system at large while recognizing the true significance of special symptoms. He who seeks the truth should be of no country and belong to no sect, for all truth is full, round, and complete.

The paper was discussed by DRs. JOHN BYRNE, WILLIS E. FORD, S. C. GORDON, and A. W. JOHNSTONE, all of whom were impressed with the necessity for recognizing the reciprocal relations between gynecology and general medicine.

The Clinical Importance of the Intermenstrual Wave.—DR. ARTHUR W. JOHNSTONE, of Cincinnati, in this paper referred to what in England has come to be

known, he said, as Stevenson's wave, as it was brought prominently forward by Stevenson, of Glasgow. This wave phenomenon manifests itself in all female animals, in birds the crest of the wave being seen before the molting period, in women before the menstrual period. Its trough represents the intermenstrual period. One who fails to recognize this wave and its clinical significance will at times be led to do things which are dangerous, while at other times he will be needlessly alarmed at trivial matters. Intermenstrual pain, which formerly was a conundrum, is now explained, as it takes place in the trough of the wave, and is due to shrinking of the ovary to its smallest diameter. For the laparotomist this law is more valuable than any other, and it teaches him never to operate just before a period if it can be avoided. During this time there is greater danger from hemorrhage. By this law are explained many cases of disordered digestion, vomiting, symptoms of gall stones, temporary glycosuria, and reflex manifestations. The menstrual wave undoubtedly has a good deal to do with the pathological metabolism of the body. Its influence on Basedow's disease is common knowledge. It explains the monthly loss or change of voice in some women. Many conditions in the specialties of rhinology, neurology, etc., are also explained by it.

The paper was discussed by Drs. A. J. C. SKENE, BUCKMASTER, ENGELMANN, PALMER, the author closing. The value of the law described by Stevenson was recognized by the several speakers.

Aids in Obstetric Teaching.—Dr. J. CLIFTON EDGAR, of New York. In his introduction Dr. Edgar stated his conviction that while the best method for a student to learn obstetrics is the personal care of parturient and puerperal women, still much of this experience will prove useless unless he has an intelligent appreciation of his work, based upon a previous thorough training in the principles of the subject. It is this training of reason and perception and the aids to it which have largely taken the place of the old theoretical lecture with which the author's attention is occupied. He is a firm believer in the advantage of models "possessing the third dimension of space" over elaborate description and illustration in the form of diagram. The rachitic pelvis, injuries to the pelvic floor, the relations of the uterus to surrounding parts are far better understood from casts and paper reproductions than from charts, however well executed. The models are particularly useful in the training of nurses. A further advantage in their use is the fact that they may be kept obstetrically clean and may be used at the bedside or in the obstetrical clinic. While something has been done in this field, much remains; for example, models of uteri of known periods of gestation and of pelvic deformities, which by their interchange do not a little to raise the standard of obstetric teaching.

Models are not in any sense to replace bedside instruction. They are purely auxiliaries to instruction in its various forms, and care must be exercised in their use. They undoubtedly lend a new interest to many points otherwise obscure and dry. The natural size of the object should always be reproduced or a wrong impression may be conveyed. Diagrams, charts, and blackboard illustrations are unsatisfactory and tiresome to the student, and can never be made to impart the practical knowledge obtainable with the aid of a few selected models.

The several varieties of aids to obstetric teaching are, for convenience, divided into five classes:

I. Plaster Models.—As such, these have a very limited field of application on account of weight and brittleness. Plaster is chiefly useful in securing impressions, which are then reproduced in other ways.

II. Paper Reproductions of Clay and Plaster Models.—The method of preparation used is that proposed by W. G. Thompson, which is briefly as follows: A clay or plaster model is covered by a layer of small strips of newspaper (two by four) previously moistened. On this single layer are rapidly placed successive coverings of the same paper dipped in glue. In large models strengtheners, such as wire, gauze, cheese cloth, etc., are introduced, and the top layer is laid smoothly to give an even surface. It is removed entire or in section, a backing added, and several coats of paint or varnish applied. Webster's frozen sections were reproduced in this way by enlarging photographs of the cuts on tissue paper, modelling through this in clay, and overlaying the paper strips as described. Transverse and sagittal sections and round objects may be modelled in this way, the latter to show the size and shape of the uterus in various stages of pregnancy. If casts can be taken from gravid uteri after death, so much the better, for they can then be exchanged among teachers and museums. A few of the uses to which paper models may be put are to show the height and shape of the fundus and lower uterine segment, placental insertion, physiology and pathology of pregnancy, mesial sections of the uterus, the curve of the parturient canal.

It is possibly best not to attempt reproduction in paper of any but the grosser frozen sections. A model of uterus and contained ovum was not altogether satisfactory. For such illustrations, as much can be accomplished by diagram. Models representing involution, position, and relationships of puerperal uteri from Webster's sections are, however, of use not only in demonstrating the physiology but the pathology of the puerperium. Rupture of the vagina and uterus, their relations, and the greater danger of infection when the tear involves vagina as well as uterus, may thus be shown.

III. Composition Models.—The author uses as a cheap substitute for rubber, modellers' and plasterers' composition of glue. Its application seems limited to a series of cervixes in different stages of dilatation. The mixture finally adopted was of Cooper's A1 glue and glycerin, the proportion determined by the flexibility desired.

The glue is soaked in water, the latter being removed by filtration, and the glue melted over a water bath. Glycerin is added and the mass boiled to expel the remaining water. The time required depends on the size of the mass and amount of contained water. When ready to pour the mass should be of thick, creamy consistency. Any desired color of aniline may be added in alcoholic solution. The mould is prepared by taking a negative model of the lower segment of the uterus (for example); this is covered with clay to the required thickness and a core is formed by running in plaster and allowing it to harden. The clay is removed, core and negative mould carefully shellacked, oiled, and fastened together. The glue, not too hot, is then poured in and allowed to cool. It may be removed in six hours.

In case the models shrink and become hard, they may be remelted and fresh glue added. They will then have less tendency to shrink. The lower uterine segment, mechanism of dilatation with gradual disappearance of the supravaginal part of cervix, are some of the conditions capable of reproduction in composition. (The author here took occasion to indicate his preference for bimanual over digital and instrumental dilatation of the os.) The models demonstrate the dangers of ordinary digital and manual dilatation and of breech extraction through an imperfectly dilated os, incomplete extension of the head, etc.

IV. Miscellaneous Models and Aids.—These include metal and leather models not classifiable under

other heads. The first offered is a vertical mesial section of the bony pelvis in aluminium, mounted by a hand screw on a blackboard, and the whole set on a tripod. There is scarcely an obstetric or gynecological condition that cannot be shown with it in connection with puppets, uteri, and chalk. The complete metal pelvis mounted on a tripod has already been described by the author. It is indestructible, adjustable at almost any angle, and fitted with movable sacrum and coccyx.

Chamois-leather models of puerperal uteri do duty in many ways, being made to open. With it the student may be taught to repair cervical lacerations, curette, and pack the cavity. It supplies an opportunity for manual training which may never occur to him again until in practice.

The perineum and pelvic floor should be reproduced in rubber, which is clean and portable. Casts are made from the living subject and rubber models made from them.

V. Electro-Plated Plaster Models.—For very small objects where minuteness of detail is required—*e.g.*, the non-pregnant uterus—electro-plated plaster models are recommended. A plaster cast is taken of the specimen, carefully dried, and copper plated. Bone, composition, and clay may be covered in the same way. Pelvic deformity, a subject usually dry and uninteresting to the student, is brilliantly illustrated by Tramond's series of twenty-four papier-mâché models from Paris museums. By copper plating they are made indestructible and may be constantly handled. This series is equally valuable to the teacher, practitioner, and surgeon.

Lacerations of vagina, perineum, and anterior rectal wall are permanently preserved in this way, the plaster casts being taken from the living subject at first. Proving unsatisfactory later, they were made from artificial lacerations in the cadaver. Sutures may be put in place by a drill afterward.

The paper was most profusely illustrated throughout by photographs and drawings of the specimens, models, and methods described.

The methods of teaching obstetrics described by Dr. Edgar received the commendation of Drs. KING, POLK, and REYNOLDS, provided, of course, they were intended only as aids, mostly preliminary, to bedside instruction.

Two Pregnancies Following Removal of Both Ovaries and Tubes; Two Cases of Extra-Uterine Pregnancy; the Effect upon the Vagina of Hysterectomy.—DR. S. C. GORDON, of Portland, Me., related some clinical observations in line with the title given. In neither of the two cases in which removal of both ovaries and tubes was followed by pregnancy, was it known that any ovarian tissue had been left, yet he supposed there must have been. But how could the ovum reach the uterus with the tubes tied off? Probably some stump of the tubes had been left and the ligature had disappeared. The third case related was one of tubal pregnancy which became abdominal. The fetus continued to live. Laparotomy was performed about the end of the fifth month. The fetus was removed alive, but soon died. The mother recovered.

Regarding the effects of complete hysterectomy upon the vagina, he said its opponents claim that it shortens the vagina and relaxes the arch. He believed the weight of authority is in favor of leaving a little of the cervix and closing the peritoneum over it in the abdominal operation, but since Jacobs' visit last year the fad seems to be to do the vaginal operation, whereby, of course, the cervix is also removed. Dr. Gordon prefers as a rule complete suprapubic hysterectomy, and claimed that by continuing the suture in the folded-over broad ligament down into the upper portion of the vagina, the latter is lifted up and

lengthened rather than shortened. He found no shortening except in two cases, and those were cases in which a portion of the cervix was left. He is disposed to think that leaving a portion of the cervix favors prolapsus of the roof.

Double Ovariectomy Followed by Pregnancy.—DR. R. STANSBURY SUTTON, of Pittsburg, read the history of a woman on whom he had performed double ovariectomy, removing on one side a multilocular ovarian cyst weighing twenty-five pounds, from the other side a similar cyst weighing six pounds. On the first side he seared the pedicle with the Paquelin cautery. This failed to work on the other side, and he tied close to the horn of the uterus and cut with the scissors. The uterus being in retroversion, he attached its fundus to the anterior abdominal wall. The operation was done on the 20th of October, 1892; on the 10th of June, 1894, she gave birth to a male child, weighing ten pounds and a half, which is still living. The 25th of February, 1896, she gave birth to another healthy child, weighing eight pounds. The mother is healthy.

DR. LAPHORN SMITH said he had removed the tubes and ovaries of a woman and she gave birth to a child two hundred and sixty-seven days later. She had probably been impregnated just before the operation.

Drs. CUSHING, ENGELMANN, A. P. DUDLEY, A. W. JOHNSTONE, and the author continued the discussion.

Second Day—May 27th.

The President's Address.—DR. WILLIAM M. POLK read his address as president of the society, giving a brief retrospect of gynecological progress since its foundation twenty-one years ago, as the first president, Dr. Barker, had done for the century before. Among the facts marking advance which he touched upon were antiseptics, which explains the former fatality of all operations involving the peritoneum; treatment and prophylaxis in laceration of the cervix, in which connection, he said, it is difficult to overestimate the value of Emmet's work; vesico-vaginal fistula; inspection of the bladder by light; catheterization of the ureters; detection of floating kidney and treatment by anchoring the organ; differentiation between tubo-ovarian disease and appendicitis, or their coexistence; surgical treatment of retro-displacement of the uterus—suspension and fixation; the discussion going on with relation to vaginal versus abdominal operations in pelvic diseases; recognition of infection as the cause of puerperal fever, and steps taken to avoid it; demonstration of the fallacy of the view that the uterus should not be touched during perimetritis, salpingitis, etc.

The President deprecated the conduct of those actuated by the feeling, "Get on! Get on!"

The Technique of Vaginal Hysterectomy.—DR. PAUL SÉGOND, of Paris, France, spoke upon this subject in French, Dr. Henrotin acting as interpreter. He wished to be understood as advocating the vaginal as only one method, suited to a certain class of cases, and not intended to supplant the abdominal in all cases. Whenever there is the least doubt as to the disease being bilateral, the abdominal method is preferable. In fibroids, assuming the two methods to give about equally good results, he would choose the vaginal in order to avoid the scar inflicted by the abdominal. The Péan method is still the Péan, no matter what slight modifications have been made by this or that man with regard to incision lengthwise, crosswise, etc. Much has been said of the advantage of having the work under one's eye in the abdominal operation, but Dr. Ségond claims that all operative procedure on the uterus through the vagina is just as much within view. It has been objected to the

vaginal route that adhesions can best be separated from above, but in reality in nearly all cases there is a line of cleavage which can be followed with entire success from below, and in the few rare cases in which this cannot be done it is found that the operation from above has also to remain incomplete. Regarding vaginal hernia, he has not seen it in a single case out of six hundred operated upon by him. In uterine prolapse vaginal hysterectomy is contraindicated, according to his view.

Dr. Ségond then directed attention to four possible complications of vaginal hysterectomy which made the operation so dreaded by some men, namely, lesions of the bladder, lesions of the intestines, lesions of the ureters, hemorrhage after the operation. These accidents are, he said, due chiefly to misuse of the retractors. He employs these to a much less extent than many operators. The most serious of the lesions is that of wounding the ureters, yet this accident has happened only twice in his six hundred operations. Dr. Ségond makes a circular incision, and from this a lateral incision up the sides of the uterus, forming two large valves, as it were, of the vagina—an anterior and a posterior one. As to secondary hemorrhage, it usually occurs at the end of forty-eight hours, and can be avoided by using good and proper instruments, all of which are simply modifications of Péan's. He is not in haste to let patients get up, but keeps them abed two weeks.

Dr. Ségond's paper was discussed in connection with that of Dr. Byrne's.

The Relative Merits of Total or Partial Hysterectomy for Cancer of the Cervix by Ordinary Methods and Supravaginal Excision by Galvano-Cautery.—DR. JOHN BYRNE, of Brooklyn, in this paper referred to one bearing upon the same topic which he had read at the meeting of 1892. He believed then, as he does now, that the question of primary mortality, though worthy of thought, is really of secondary importance. It is not so high in skilled hands but that hysterectomy for cancer of the cervix may be regarded as coming under the domain of legitimate surgery, if it were not for the fact that when one reviews the statistics of secondary results he becomes doubtful whether it would not be better for womankind had the operation never seen the light of day. To get at the true import of those statistics, it is necessary to study them critically. Being unable to secure such as would throw light on the ultimate results, about twelve months ago he made a personal appeal to many operators through letter, but only fifty-three replied, and many of these replies were such that no conclusions could be drawn from them.

The time having expired, Dr. Byrne could not conclude reading his paper, but he stated that the opinion expressed four years ago is that which he holds today, namely, that there is positively no place in legitimate surgery for colpo-hysterectomy or high or low amputation in cancer of the cervix except when performed through the agency of the galvano-cautery. He thought it would not be amiss for the president to appoint three fellows to investigate this subject, and to agree to treat a certain number of cases by galvano-cautery, say in the New York Cancer Hospital, and he would aid them in their labors if they desired.

A lengthy discussion followed these two papers, participated in by Drs. SUTTON, JANVRIN, WATHEN, KELLY, CUSHING, MANN, REAMY, A. P. DUDLEY, BACH, EMMER, FLORIAN KRUG, FORD, COE, GORDON, BAER, and BALDY. Few of the speakers touched upon the ultimate results of hysterectomy for cancer of the cervix except Dr. Janvrin, who gave his own experience as recently published in a report of the New York County Medical Association in the *MEDICAL RECORD*, and Dr. Coe, who said he had become doubtful as to the utility

of hysterectomy for cancer of the cervix, and wished to have the committee suggested by Dr. Byrne appointed.

Treatment of Extra-Uterine Pregnancy.—DR. HOWARD A. KELLY, of Baltimore, read the paper. He said it would be seen that he was going to carry conservatism into the most extreme domain of gynecological work. He would speak of treating extra-uterine pregnancy by evacuation through vaginal incision and drainage. Thirteen cases so treated were reported, all of which resulted in recovery except one, that of a patient who was in uranic coma at the time of the operation and died in that state several days later, death being in no wise due to the operation. As to the class of cases suitable for vaginal puncture, evacuation, and drainage, he said they are those of extra-uterine pregnancy with rupture in the early months, which include the vast majority of all cases, but not the recent ruptures, nor cases, whether recent or more remote, of advanced extra-uterine pregnancy. The opening is made into the sac between vagina and rectum, enlarging it in line with the axis of the pelvis by dilatation, avoiding wounding the rectum; the sac is cleaned out with the finger, and washed out with normal salt solution; this is done again as a final step before putting in gauze drain. The advantages over laparotomy were mentioned. In one instance he had diagnosed extra-uterine pregnancy, which he treated in this manner and found dermoid cyst; in another he found simple pelvic abscess. The chief danger is from hemorrhage, but this is little likely to take place, since at this period tendency to active hemorrhage in the sac has ceased. In one of his cases, however, there was such hemorrhage as to necessitate rapid opening of the abdomen and removal of the sac. He was unable to explain why there should have been hemorrhage in this case, since rupture had taken place some time before.

Dr. Kelly's paper was discussed in connection with the next one.

Early Rupture of Extra-Uterine Pregnancy and Its Treatment.—DR. FERNAND HENROTIN, of Chicago, said the object of this paper was to call attention to some of the peculiarities of early rupture—prior to the second month—and draw some deductions as to its management. There are two classes of cases: 1, what may be termed complete rupture, with free primary abdominal hemorrhage; 2, incomplete rupture in the tube, in which there may be secondary hemorrhage.

It is not claimed that these very early ruptures are invariably complete. There is reason to believe that many rupture into the broad ligament and are absorbed. Failure to observe discharge of decidual membrane is of little significance, for it may occur simultaneously with rupture, or follow it very closely. The physical signs are those of intra-abdominal hemorrhage. Failure to recognize tumor alongside the uterus is not important.

At this point Dr. Henrotin related a case of early complete rupture with hemorrhage into the abdominal cavity. The patient was in marked collapse, was cold, and seemed in rigor mortis, yet he operated, made use of saline solution, and she made an uneventful recovery. In like cases, in which hemorrhage is evidently going on, immediate operation alone can save life. The question of leaving a considerable quantity of fresh blood in the peritoneal cavity will depend upon the urgency of the case and freedom from septic contamination. If there is no sepsis, one needs only remove the larger clots, and the operation being thus done hastily the woman will stand a better chance of recovery.

The author then considered the differential diagnosis between tubal rupture and tubal abortion, after

which his paper was discussed in connection with Dr. Kelly's. Those taking part in the discussion were Drs. BOLDT, MANN, NOBLE, BAER, JANVRIK, GORDON, ASHTON, WATHENS, CURRIER, and the authors. Several of the speakers thought Dr. Kelly was only carrying out a generally accepted procedure, that of opening accessible hæmatoma through the vagina, for at this period the case had practically ceased to be one of extra-uterine pregnancy. Some of the speakers, however, expressed preference for the abdominal method even in these cases of rupture which had become quiescent, as well as in recent active cases, on account of danger from hemorrhage.

Suspensio Uteri with Reference to Its Influence upon Pregnancy and Labor.—DR. CHARLES P. NOBLE, of Philadelphia, had collected in this paper all the statistics as far as possible of operations for suspension of the uterus to the abdominal wall, both in this country and abroad, the number of patients who had subsequently become pregnant, and the influence of suspension upon the course of pregnancy and labor. The foreign and American statistics agree in the fact that when the uterus has been firmly fixed against the anterior abdominal wall there have not infrequently been symptoms during the course of pregnancy due to failure of the uterus to rise and develop in the normal manner, and causing at labor obstruction as if a tumor existed at the attached portion. In a considerable proportion of cases, greater in Europe than in America, the obstruction has been such as to require forceps, version, Porro's operation, or Cæsarean section. It is to be noted that these difficulties have not been observed in cases operated upon by the Kelly method in which the attachment of the uterus to the anterior wall has been only through the parietal peritoneum, followed by the formation of a pedicle or ligature composed of peritoneum, and allowing normal motion and growth to the uterus. Consequently Kelly's method is the one which he would recommend, though slightly modified, when on opening the abdomen it is thought necessary to lift the uterus. The complications named do not apply to the Alexander operation at all, or do so in very slight degree, and this is the method which ought to be adopted for uncomplicated retro-displacement of the uterus.

Vaginal fixation has given the worst results of all the methods in its bearing upon pregnancy and labor.

Third Day—May 28th.

The session was opened with a discussion upon Dr. Noble's paper on suspensio uteri with reference to its influence upon pregnancy and labor. DR. THOMAS ADDIS EMMET said he has found suspension of the uterus by any of the methods named, including Alexander's, unnecessary, as the condition could be corrected in a more natural way by plastic operations on the vagina. The discussion was continued by Drs. EDEBOHLS, KELLY, ASHTON, FRY, LAPHORN SMITH, and the author.

Some Aspects of Ureteritis.—DR. EDWARD P. REYNOLDS, of Boston, gave as the full title of his paper, "Some Aspects of Ureteritis, with Especial Reference to Diagnosis of the Disease as Bearing on Mistakes Between Ureteritis and More Serious Pelvic Diseases, and Some Reference to the Treatment as Determined by its Etiology."

The majority of cases which he has seen seemed to have been inaugurated by altered condition of the urine due to renal inefficiency. Among the symptoms were frequency of micturition, not wholly relieved by recumbent posture; bearing-down pain, increased by standing, usually completely relieved by a few hours' rest in bed; pain and tenderness on pressure on ureter with the finger introduced into the vagina. Cysto-

scopic examination is likely to reveal reddening and erosion at the mouth of the ureter, with eversion of mucous membrane of the outlet.

Treatment is palliative and curative. Application of solid nitrate of silver at the inflamed area mentioned will give more or less temporary relief. Curative treatment is hygienic and medicinal, but chiefly the former. The diet should be regulated by giving largely albuminate food, bland fluid, three pints or more daily of water, supplemented by alkaline diuretics. The condition is probably less due to functional vice of the kidneys than to imperfect metabolism in the body as a whole. So-called alteratives may prove of benefit, and he has given iodide of potassium and mercury a limited trial.

In acute cases there are symptoms not present in the chronic, relating to pain on pressure, referable at successive stages to the region of the pelvis of the kidney, then to the so-called McBurney point of appendicitis (on the right side), then to a spot about Poupart's ligament. He at first mistook two cases for appendicitis.

The paper was discussed by Drs. MANN and LAPHORN SMITH, who recognized constitutional treatment as especially important. Dr. Mann said his attention has not hitherto been directed to the tender points mentioned. He will hereafter look for them.

Implantation of the Ureter into the Bladder, by Abdominal Section, for the Cure of Uretero-Vaginal Fistula.—DR. H. J. BOLDT, of New York. Among the causes leading to the production of uretero-vaginal fistulæ, the most frequent at the present time is probably vaginal extirpation of the uterus. Formerly difficult parturition was the most prolific source in the etiology of this malady. It is the author's belief that injuries of the ureter from the performance of vaginal hysterectomy are of more frequent occurrence than is known, many cases not being reported. It is liable to occur relatively oftener in the hands of experienced operators than in those of less experience, because the former are apt to undertake more difficult cases, especially when operating for cancer, if the broad ligaments are thickened, and the operator works far away from the cervix while endeavoring to remove all particles of malignant infiltration. The ligature or clamp may prevent dribbling until necrosis has taken place. If a fistula is absent, the diagnosis is more difficult. In relating the history of a case, the author said the patient at times passed urine from the fistula, and on such occasions had more pain in the renal region radiating down the course of the ureter; after a short time a copious flush of urine would make its appearance with subsequent relief of pain. He believed the attacks of partial suppression of urine from the affected kidney are readily accounted for by the existence of this fistula, which at times probably becomes occluded: hence the severe pains in the renal region, which are relieved on the free escape of urine.

The patient made a good recovery after removal of the kidney on the affected side, although for a time there were signs of acute nephritis in the remaining kidney. This case taught that all uretero-vaginal fistulæ should be operated upon as soon as possible after the diagnosis has been made, on account of the great liability of the kidney to become infected.

If complete anuria is present there is reason to suspect that both ureters have been tied, especially when pain and sensitiveness to touch are present in the renal regions, with nausea and vomiting. Under such circumstances a cystoscopic examination should be made without delay. When injury has been shown to exist the question of treatment arises. A spontaneous cure can only come about if the ureter has been injured in its long axis. Such cases are more

apt to occur after parturition. Dr. Boldt then related a case which had led him to adopt uretero-cystostomy. It was one of vaginal hysterectomy for suppurative salpingitis, chronic pelvic peritonitis, and chronic metritis. The operation was very difficult, owing to the immobility of the uterus and intestinal adhesion to the pelvic organs.

The abdomen was opened and the lower segment of the ureter was found not mobile, yet it was possible to dissect it without injury by the aid of the ureteral catheter. This was done for a distance of about seven centimetres, leaving the peritoneal covering, which was already attached to it by the inflammatory process. This served a good purpose by maintaining vitality. At the vaginal junction the ureter was severed, but the catheter was allowed to remain in it. The bladder was now filled about two-thirds full of sterile water, so as to permit the selection of a proper place for implantation, which he desired to make as near as possible to the normal position. At this point he opened the bladder by an incision of about three-quarters of a centimetre, the water having been withdrawn again by catheter as soon as the knife touched the mucosa. After the bladder had been opened, a long pair of uterine dressing-forceps was passed through the artificial opening in the bladder per urethram, and the ureteral catheter was drawn from the viscus and out of the urethral opening, so that it protruded about ten centimetres; next the ureter was invaginated through the opening in the bladder to the extent of about one centimetre. Now three very fine silk sutures were placed at about equal distance, passing through the entire thickness of the bladder excepting the mucosa, and quite superficially through the ureter. The abdomen was closed. A permanent catheter was put into the bladder, alongside of the ureteral catheter, to keep the bladder empty and prevent pressure on the newly made opening. Recovery was uneventful.

After relating his own case, Dr. Boldt referred to the few reported in literature, and to the views of Krause, Kelly, Penrose, Krug, Veit, and others. He thought that among the methods adopted for intra-peritoneal implantation, the one applied in his own case deserved a trial, because of its simplicity, its facility of execution, and the favorable result which must follow under aseptic conditions.

To sacrifice a kidney for the abolishment of the fistula should be a last resort. Even if a nephritis or a pyelitis exists, other methods should be tried. Of course, should there be so much ureter lacking that it is impossible to do implantation, there is no help for the patient except nephrectomy.

Intestinal Bacteria as a Source of Infection Complicating Obstetric Operations, with Report of Cases.

—DR. EDWARD P. DAVIS, of Philadelphia, in this paper related two cases of infection about the time of labor, in which autopsy showed that the intestinal tract was the seat of infection. The first case was that of a colored girl with rachitic contraction of the pelvis. When admitted the abdomen was tense from tympany. When labor began Cæsarean section was successfully performed, and the child still lives. There was a tympanitic condition of the large intestine in the mother, but the gut did not protrude through the wound. The temperature remained below 100° F. several days. She then began to be annoyed by nausea and vomiting and persistence of the tympany. The abdominal wound had healed by first intention. She went on for a time with high pulse, clear brain, persistent nausea and vomiting. Finally high temperature ensued and death followed about six days after delivery. The salient anatomical points at post-mortem were immense distention of the small intestine and a mass of fibrin about the junction of the large and small intestine, at

which point the intestine was found studded with small ulcers, full of bacilli coli commune and micrococci pyogenes albi, which were also traced into the mass of fibrin over the intestine. Diagnosis: Lymphangitis with absorption of ptomaines and intoxication. The process had evidently begun before labor. It is the first case demonstrated by autopsy reported in obstetrics, so far as Dr. Davis knew.

The second case was that of an English girl, illegitimate pregnancy. She was constipated and showed anxiety about her condition before labor. She was delivered of a healthy boy by forceps; a slight laceration of the perineum was sewed up immediately. The temperature rose to 103° F.; pulse, 120 to 130; respirations, 36. She became maniacal. Washing out the uterus did no good. She died, and Dr. Bevin, who made the autopsy, found as the only cause of the mania and other symptoms an anomaly of the intestine, consisting of a loop of about two feet in the large bowel, which contained softened and inspissated faeces which had not passed in spite of calomel, etc. The pathologist made the diagnosis of auto-infection from anomaly of the large intestine, as there was no other apparent cause. The condition was new to him, said Dr. Davis, but Dr. Bevin has seen the anomaly in about eighteen out of three hundred autopsies, and the history in most of the eighteen was that of attacks of temporary mental disturbance and constipation. This extra loop, of from one and one-half to two and one-half feet of large bowel, gave a greatly enlarged mucous surface over which the contents of the bowel had to pass.

The differentiation from cases of wound infection seems to be want of chill, lower temperature, pulse rapid. Apparently all that can be done is to induce free purgation if possible.

The following gentlemen discussed the paper: DRs. R. A. MURRAY, E. H. GRANDIN, P. A. HARRIS, and E. CUSHING. Dr. Grandin and some of the other gentlemen thought it might be well to caution general practitioners against attributing to auto-infection those cases of sepsis attending labor in which their own hands or instruments were the cause. Cases of the kind related by Dr. Davis must be rare as compared with the number in which infection was introduced from without, and the cause stated should be if possible attested, as in these two instances, by autopsy.

Treatment of Intra-Ligamentous and Retro-Peritoneal Uterine Fibromyomata.—DR. WILLIAM H. WATHEN, of Louisville, said the purpose of his paper was to describe the method of operating when these tumors are too large to be removed by the vagina, and are so wedged in the pelvis as to make abdominal operation difficult if not dangerous. By the method described he ligates the uterine arteries from below, since if this is not done they cannot be reached from above by abdominal operation until after extensive enucleation. The operation is completed from above. Dr. Wathen thought no portion of the cervix should be left in performing hysterectomy in this class of cases, as it only invites future trouble.

The paper was discussed by DRs. CUSHING, HARRIS, GORDON, J. T. JOHNSON, and THE PRESIDENT. The President spoke of ligation of the arteries in abdominal hysterectomy, out at the side of the pelvis, far enough to prevent hemorrhage from all the branches supplying the field of operation—the ovarian, uterine, etc.

Cæsarean Section; Suture of the Uterus versus Total Extirpation.—DR. HENRY C. COE, of New York, read the paper. He related his experience with Cæsarean section in three cases and extirpation of the uterus following Cæsarean section in a fourth case, and gave reasons why he thought that in many instances, if not usually, it is best to remove the uterus after incising it and removing the child. Among the

women on whom he had found Casarean section necessary, it was of doubtful advantage to the patients themselves as well as to society to leave them in a state in which a subsequent Casarean section might become necessary. In the instance in which he removed the uterus he was led to this course from the fact that the patient's condition was such as to make it extremely doubtful whether she could survive any operation, and he regarded her chances as better after removing the uterus than after suturing that organ. The operation was shorter and there was less danger, of course, from septic infection. The woman rather unexpectedly survived. Among reasons for extirpating the uterus in similar cases are: Less danger of infection when there have been attempts at delivery; shorter operation; the fact that many of these people are pregnant illegitimately, are stupid, are liable to be away from skilled attendance in future labors, and have not the high motive to raise a child. Of course, there can be no universal rule to remove the uterus.

The following gentlemen discussed Dr. Coe's paper: DRs. GRANDIN, NOBLE, HARRIS, DAVIS, BOLDT, GARRIGUES, R. A. MURRAY, HARRISON. Dr. Davis agreed with Dr. Coe, but most of the other gentlemen thought he was too radical. They believed in removing the uterus only when there is a positive indication for it, particularly septic infection.

Drainage of the Stump in Abdominal Hysterectomy.—DR. HENRY T. BYFORD, of Chicago, in this paper described his method of draining when, after removing the uterus by the abdominal route, a little of the cervix is left. It consists in making an anterior vaginal incision and inserting a drain between the peritoneal folds and cervix, extending out through the vaginal opening.

DRs. HARRISON, NOBLE, and BAER made some remarks upon this paper. Dr. Harrison gave credit to Dr. Emmet for having done the first operation, removing the uterus except a small portion of the cervix by the abdominal route. Dr. Baer said he did not wish on this occasion to discuss the priority of this operation, as it had already been considered on former occasions. The point of importance was its value to humanity.

Myomectomy, Fatal Secondary Hemorrhage, with Rise of Temperature.—DR. HENRY D. FRY, of Washington, related a case of myomectomy in which the patient died after twenty-four hours of continuous bleeding due to slipping of the ligature. The point of interest was rise of temperature, pulse after some hours becoming rapid. While internal hemorrhage was suspected, he was in doubt because of the rise in temperature, as the books stated that in hemorrhage there was a fall of temperature.

The paper was discussed by DRs. GRANDIN, BALDY, and BOIES. They paid less attention to the temperature than to the pulse in hemorrhage.

New Instrument.—DR. CLEMENT CLEVELAND, of New York, showed a small electrode which he encloses in the ligature on arteries in hysterectomy cases, and after about thirty-six hours attaches to it the battery, passes the current, and severs the ligature (silk).

Surgical Injuries of the Ureter.—DR. J. M. BALDY, of Philadelphia, in this paper described the two methods of operating for repair of surgical injuries to the ureter, one consisting in uniting the severed ureter by uretero-uretero anastomosis, the other in inserting the ureter into the bladder, called ureterocystotomy. He thought the division was usually near enough to the bladder to allow of the latter operation, for which he expressed preference. It had been done but a few times, once by himself.

The discussion was by DR. BACHE EMMET, who said he had once performed uretero-uretero anastomosis, and by DR. BYFORD.

Resolution on Vivisection.—On motion of DR. GRANDIN a resolution was adopted opposing the passage of the bill before Congress intended to restrict vivisection in the District of Columbia.

Thanks to the Retiring Secretary.—On motion of DR. GRANDIN a vote of thanks was extended to Dr. Henry C. Coe for the efficient services which he has rendered the society during the number of years he has acted as secretary.

At an earlier hour a vote of thanks was tendered the president for the able manner in which he has presided over this very successful meeting of the society.

Officers.—The following officers were elected: *President*, Dr. Chadwick, of Boston; *First Vice-President*, Dr. Sutton, of Pittsburg; *Second Vice-President*, Dr. Garrigues, of New York; *Secretary*, Dr. Goffe, of New York; *Treasurer*, Dr. Baldy, of Philadelphia.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, May 19, 1896.

REYNOLD W. WILCOX, M.D., CHAIRMAN.

Intestinal Fermentation.—The discussion on this subject was opened with a paper by PROF. R. H. CHITTENDEN, of Yale College. Professor Chittenden said his paper would necessarily have to deal with the subject in a general way. In it he referred to the microorganisms, principally bacteria, present in the intestine, which brought about fermentation of foods; to proteids, as most liable to fermentation; to the retarding effect of sugar and of acid conditions; to the favorable influence of alkaline or neutral fluids; to the practical freedom of the secretions themselves from germs; to the evidence that bacteria themselves are not necessary to digestion and health; to the products formed by fermentation; to the measuring of intestinal fermentation by examination of the urine; to the power of bacteria to break down proteid matter with the formation of simple compounds; to the fact that the products formed by bacteria might at times combine with others under the influence of oxygen or other means to form more complex bodies of greater toxicity; to the fact that the absorption of the products of excessive intestinal fermentation might not only do harm by their direct toxic action, but also indirectly by increasing the susceptibility of the body to infection from other sources; and to the ailments connected with intestinal fermentation—diarrhœa, abdominal distention, anemia, so-called biliousness, many nervous manifestations. The question of how to prevent intestinal fermentation is one for consideration by clinicians. There are many drugs which unquestionably exert an inhibitory influence upon fermentation and putrefaction, but there is much diversity of opinion as to their efficacy when administered in such diseases as cholera, typhoid fever, etc. Professor Chittenden did not wish to question the possibility of applying antiseptic treatment efficiently, but he was inclined to lay special stress on the influence of diet. Other things being equal, it is obvious that the more digestible is the food, the less tendency will there be to intestinal fermentation. On the other hand, the accumulation of undigested food in the intestinal tract affords one of the best possible conditions for putrefaction. This explains the favorable action of a milk diet. Moreover, notwithstanding the ease with which milk is fermented, it is possible it has the power to retard somewhat putrefaction in other forms of proteid matter.

The Bacteriology of the Stomach in Relation to

Practical Therapeutics.—DR. J. H. KELLOGG, of Battle Creek, Mich., in a paper with this title, said that while much attention has been given during the last twelve years to the chemistry of digestion, comparatively little has been done in the study of the bacteria of the stomach in relation to practical therapeutics. In this paper he presented some conclusions which he has drawn from a careful comparative bacteriological and chemical study of the stomach fluid in three hundred and seventy-seven cases. The information sought by the mode of examination adopted was: 1, the number of microbes per cubic centimetre of stomach fluid; 2, the presence or absence of gelatin-liquefying bacteria; 3, the presence or absence of gas-producing bacteria; 4, the presence or absence of acid-forming bacteria; 5, the toxicity of the products of bacterial activity in the stomach fluid.

Within the past year three hundred and seventy-seven stomach fluids had been examined from more than three hundred and fifty persons. Of the fluids examined, one hundred and ninety-one were found to be absolutely sterile, while sixty-seven contained less than fifty bacteria per cubic centimetre, a number so small as to be considered accidental, so that these also could be regarded as sterile; while one hundred and two contained bacteria from a few hundred to more than two million per cubic centimetre. Dr. Kellogg was not surprised to find large numbers of bacteria, but was considerably surprised to find so large a number of perfectly sterile stomach fluids, especially since Cadeac and Bournay have recently asserted that the stomach and intestinal fluids are not destructive of micro-organisms as was formerly supposed, and since the assertion is commonly made by bacteriologists and physiologists that bacteria are not only present in the alimentary canal but are useful in the digestive process.

The fact that no bacteria whatever were found at the end of the first hour of digestion in 50.8 per cent. of three hundred and seventy-seven stomach fluids examined, seemed to be all the evidence required to demonstrate the proposition that the normal stomach is able to destroy those microbes which accidentally enter it through the mouth and nose, and that microbes play no part in normal stomach digestion. Kürhoff and Wagner and others were quoted for further confirmation of this view.

The method of chemical examination employed by Dr. Kellogg is based chiefly upon that of Hayem and Winter. In comparing the results of bacteriological examination with the results of chemical examination, he carefully noted the relation of bacteria to: 1, the calculated acidity, which represented the combined value of free hydrochloric acid and the combined chlorines diminished by the fatty acids present; 2, the acidity; 3, the free hydrochloric acid; 4, the combined chlorine; 5, the coefficient of starch digestion; 6, the coefficient of salivary secretion; 7, the coefficients of chlorine liberation; 8, the coefficient of absorption.

The summary was as follows: Of the one hundred and ninety-one sterile cases eighty-three were cases of hyperpepsia, eighty of hypopepsia, and in twenty-eight the amount of chlorine eliminated was normal. Of the eighty-three cases of hyperpepsia combined chlorine was in excess and free hydrochloric acid was normal or in excess in fifty-five cases; in twelve cases free hydrochloric acid was deficient and in one it was absent. Combined chlorine was deficient, or less than 1.55 milligrams per hundred cubic centimetres in sixteen cases. Of the eighty cases of hypopepsia, hydrochloric acid was deficient in sixty-eight, and normal or in excess in quantity in twelve. It thus appeared that a sterile condition of the stomach fluid might exist in hypopepsia as well as hyperpepsia, and it was indeed

a somewhat surprising fact that in forty-two per cent. of the sterile cases hypopepsia existed, whereas hyperpepsia was found in only forty-three per cent. of the cases. In forty-eight per cent. of the cases in which bacteria were absent free hydrochloric acid was less than normal in quantity, being below twenty-five milligrams per hundred cubic centimetres of stomach fluid, and in 23.5 per cent. it was absent altogether.

It was noticeable that anaerobic germs were found most abundant in cases in which the total acidity, the free hydrochloric acid, the coefficient of liberation, and the coefficient of absorption were the lowest. It appeared that the anaerobics flourished better in an acid medium, or rather resisted the influence of the hydrochloric acid better, than did the aerobic.

The coefficient of absorption in the class of anaerobic infected cases was .38 as compared with .34 in the sterile cases.

The author then considered the method of determining the relation of urinary toxicity to the bacteria in the alimentary canal. The normal urotoxic coefficient was .46. In the case of a lady suffering from a severe attack of migraine, stomach infected to a high degree, the urotoxic coefficient was found six times normal. In another case of marked infection, that of a young woman suffering from epilepsy, the urotoxic coefficient, as she was recovering from a series of seizures, was found to be more than double the normal. He said numerous similar cases could be cited.

A fact of considerable importance which his studies have established is that the tests for fermentation heretofore relied upon are of little value. Bacteriological examination is the only means by which it is possible to determine accurately the presence or absence of gastric infection.

For combating infection of the stomach the stomach tube is certainly the most efficient of all therapeutic measures, but most important of all is careful regulation of the diet. Foods already undergoing fermentation or decomposition must necessarily be avoided, and for a time at least those foods which readily undergo decomposition or fermentation—that is, such substances as furnish favorable nutrient media for the development of the micro-organisms found in the stomach.

In cases of excessive amount of free hydrochloric acid, suppression of foods containing ferments and perhaps for a time of foods which encourage the development of ferments is indicated. He finds a dry farinaceous dietary of greatest service in these cases, contrary to the practice of many others; but care must be taken that the starch so far as possible is converted into dextrin. In extreme cases he uses a starch-free dietary, or rather a dietary in which the starch is completely converted into maltose and combined with prepared nuts. Subnitrate and subgallate of bismuth, charcoal, and sulphur are useful. In hypopepsia and aepsia lavage is of vast service. Well-cooked farinaceous foods are digestible, but meats, butter, cheese, oysters, and fish must be carefully avoided for a few weeks or months in cases of mild infection. In dilatation of the stomach dry aseptic food should be given; in gastric catarrh, kumyss, buttermilk, or, better, koumyzoon. Several other measures, including massage, etc., received consideration, and illustrative cases were cited.

DR. W. H. PORTER was called upon to open the verbal discussion. He said it seemed to him, on looking at the subject from a purely practical standpoint, that the etiological factor in intestinal fermentation resolves itself into three conditions: People as a rule eat too much, and eat of material which is not best adapted for digestive and nutritive purposes; as a result, after months or years of such eating, their systems become very poorly nourished and germs innu-

merable appear in the alimentary tract. When called to the case the general practitioner has to deal with errors of diet, general malnutrition, innumerable bacteria, defective digestion. Studying the cases in this way, Dr. Porter thought it is comparatively easy to manage them pretty satisfactorily. On general principles he thought a well-regulated mixed diet gives the best results, but in the more aggravated cases his experience has been best with milk diet; preferably buttermilk. With the further aid of so-called antiseptics he thought we could subdue this intestinal fermentation as quickly as could be expected.

DR. H. D. CHAPIN thought a more important subject than intestinal fermentation could not be brought before the academy, for he believed that many wasting and also germ diseases, including tuberculosis, are at bottom due largely to failure in nutrition, and in restoring nutrition we go a long way toward stamping out the disease. Too great a variety at meals is to be avoided. Many persons who thought they could not take milk thrive best on it when instructed how to take it. Hot water is also valuable, and many cases of intestinal fermentation can be stopped by rare beef alone. In the summer many acute cases in children require that milk be cut off entirely for a time, giving, perhaps, only water, or egg water, or beef blood.

Dr. Chapin thought the value of antiseptic medicinal treatment of intestinal fermentation has been largely overestimated. He has tried mercury, salol, naphthol, etc., but has found them of little use in doses short of poisonous effects. The drug which in his hands had been most valuable is the least antiseptic, subnitrate of bismuth. He believed that by simplifying the diet, cutting off fermentative foods, and avoiding nauseous drugs, we get the best results in intestinal fermentation.

DR. H. POWER said that during the past five years he has attempted to trace the clinical connection between certain forms of convulsive attacks, including forms of epilepsy and disturbances of the gastro-intestinal tract. He thought he has been able to establish such a connection in many cases. The relation may be through peripheral irritation—intestinal—exciting the central nervous system, or by toxins lowering the resisting power. Both explanations are important. Following up this idea, he has placed a large number of patients on small doses of bromides and on intestinal antiseptics, such as salol, naphthol, borax, boric acid, etc.; but all of these antiseptics evidently produce disturbance in one way or another, and cannot be continued indefinitely. He thought benefit has come from flooding the system with water with a view to washing out the toxins.

DR. W. H. THOMSON said he has been accustomed to teach for years that there is a fundamental difference between organic nervous diseases and functional nervous diseases. In the former the patients are never without symptoms; in the latter they show no symptoms during the intervals. Examples of functional nervous diseases are migraine and epilepsy. Yet in the latter, especially, this view does not exclude special structural faults. He has for years treated epilepsy chiefly as a toxic disorder, on the line of intestinal antiseptics. The same is true of migraine and of so-called exophthalmic goitre—an inappropriate name, because the condition may exist without either goitre or exophthalmia. In such cases he believed that the thyroid gland is doing its best to neutralize the ptomain in the blood, which has its starting-point in the intestine, and that to extirpate it would be about as sensible as to extirpate the kidney for diabetes mellitus. Referring to Dr. Chapin's statement that bismuth is not an intestinal antiseptic, he thought he must have meant it is not a germicide,

for he, Dr. Thomson, has found it the best of intestinal antiseptics and gives the subnitrate of bismuth, from eighty to one hundred and twenty grains daily, in typhoid fever. Gastric ulcer is a frequent condition, and in this he gives antiseptics.

DR. KELLOGG said he had been impressed by the statement made by nearly all the speakers that they rely chiefly on diet. He himself relies almost exclusively on regulation of the diet, and does not believe that intestinal antiseptics are of great value. He thought we have heard too much of hydrochloric acid, and that probably writers have not touched sufficiently on the value of the intestinal mucous membrane as a means of destroying microbes and also of destroying the toxic alkaloids produced by microbes.

PROFESSOR CHITTENDEN believed there is a general impression that free hydrochloric acid is absolutely essential for fairly vigorous digestion. That is not so. There may be vigorous gastric digestion of the proteid matter when all the hydrochloric acid present in the stomach is in the form of combined acid. Combined acid has more or less germicidal action, though not so much as hydrochloric acid.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A NEW YORK PHYSICIAN AT THE MEDICAL SOCIETY OF LONDON—HIS VIEWS ON AUTOTOXIS IN INSANITY—LARYNGECTOMY—DISPLACEMENT OF HIP-JOINT—SUTURE OF VAGUS—FRACTURE OF NECK OF FEMUR—HEMATOZOON OF ASHANTI FEVER—HEALING OF VEGETABLE TISSUES—HEALTH OF IRELAND—IRISH WORKHOUSES—DUBLIN APOTHECARIES' HALL CASE—CHELSEA HOSPITAL AGAIN—THE NEW MEDICAL M.P.

LONDON, May 15, 1896.

VISITORS from your side are always welcome, and on Monday we had the pleasure of seeing Dr. Allan McLane Hamilton at the Medical Society meeting, where he read a paper on the "Connection of Autotoxis with Certain Forms of Insanity." He gave a careful account of the various forms of mental derangement which seem to be associated with gastro-poietic derangement, probably produced by fermentation or putrefaction in the alimentary canal. Your readers are doubtless too well acquainted with Dr. Hamilton's views to care for a brief statement of them from this side, and it will be more interesting to them to hear that the president, Sir Crichton Browne, himself an eminent authority on insanity, spoke very highly of Dr. Hamilton's work in this specialty, and said his own attention had frequently been attracted to the association of some forms of mental derangement with defective intestinal digestion or with diseased liver, which was unable to prevent intestinal ptomains from passing into the general circulation.

Dr. Haig argued that uric acid was the offender, but Dr. Andriezen could not see this and supported Dr. Hamilton. Dr. Hare thought the ancients were alive to the idea of autotoxis, as evidenced by such terms as melancholia and hypochondriasis, and Dr. Bower thought intestinal trouble more frequently the result than the cause of nervous disease.

At the Clinical Society meeting, after notes of a case of malingering in a boy of eleven, who had colored his urine to imitate hamaturia in order to escape school, three cases of laryngectomy were related by Mr. E. Ward, of Leeds, who had varied the usual mode of operating in order to effect the shutting off of the wound from the mucous canals opening into it, and

thereby securing union by first intention throughout. One of the patients was a man of sixty-four, operated upon for epithelioma; another, a man of forty-two, for general tumefaction producing dyspnoea and dysphagia for five months, deepening into orthopnoea, stridor, lividity, etc. These two cases were treated successfully. The third was that of a little girl, aged two years, with rapidly growing papillomata filling the larynx. She died of collapse sixty hours after the operation, and at the post-mortem the larynx was found again crammed with the growths. No preliminary tracheotomy is required where it has not already been rendered necessary by urgent dyspnoea. The first part of the operation was carried out on the ordinary lines, the larynx being, in preference, separated by division of the crico-tracheal membrane and dissection from below upward, enucleation of the upper part being thus facilitated. In cases of intrinsic disease the opening into the pharynx need not be more than a small vertical slit. After the larynx had been removed a large tube was passed from the mouth into the stomach, and the cut edges of the pharynx were carefully brought together over it by closely set sutures of fine silk, the pharyngeal wound being entirely closed. Then two discs of skin were cut out of the edge of the flaps opposite to the tracheal aperture, which was closely stitched to the circular opening thus made, and the skin wound was closed by suture throughout. Drainage tubes were inserted at each end of the cross incision at the upper part. By this method of closing the wound the trachea and pharynx are completely shut out from it, and the trachea is so held open that no tracheotomy tube is required. The oesophageal tube is removed or left *in situ* for feeding, according to the needs of the case and the difficulty with which it is passed. Mr. Ward claimed for this operation: (1) That it will reduce the mortality of the operation itself; (2) that it will considerably shorten the period of healing and convalescence; (3) that it will add immeasurably to the comfort of patients, both during convalescence and after recovery; (4) that it will justify attempts at radical treatment in some cases in which this is at present considered inadmissible.

Mr. Arbuthnot Lane said he had adopted a similar course in a case of his own, dividing the trachea and drawing it forward out of communication with the pharynx, and the result had proved very satisfactory. In a case of papilloma of the larynx, in which recurrence took place after removal of the growths, he had tried arsenic. By the time the dose of Fowler's solution had been carried to seven minims three times a day, the obstruction had altogether disappeared.

Dr. Semon protested against performing an operation so grave as total laryngectomy in a child for papillomatous disease of the larynx, a condition which had been shown to be amenable to milder forms of treatment.

Mr. E. Ward admitted that he would not be disposed to resort to laryngectomy again in a child with papilloma, though he knew of three cases in which the papillomatous growths recurred after removal and ultimately completely obstructed the larynx, and the condition of these patients was no better than after this operation.

Mr. Arbuthnot Lane showed a child on whom he had operated successfully for a deformity which consisted in a varying degree of outward rotation of the legs, due apparently to a slight forward and upward displacement of the hip-joint from its normal position. He divided each femur at the junction of the middle and lower third, and after rotating the lower fragment inward and the upper through an angle of 90° or more, he secured them together with wire. The result, as exhibited by the patient, both as regarded locomotion and appearance, was very good.

Mr. Makins recorded a case of removal of a secondary epitheliomatous tumor from the neck, in which operation the left vagus nerve was divided just above the centre of its cervical portion and at once sutured. No obvious results either immediate or remote, beyond the paralysis of the muscles supplied by the recurrent laryngeal branch, were observed. The case seems to support the opinion lately expressed by Boswell Park as to the comparative safety of dividing one vagus if necessary, and also offered some evidence as to the possible recovery of function if immediate suture be performed.

Mr. Raymond Johnson brought forward a case of fracture of the neck of the femur resulting from dry caries of the bone, in a boy aged seventeen.

Dr. Norman Moore showed at the Pathological Society meeting a hamatozoon from a case of malarial Ashanti fever. The parasite occupies a red-blood corpuscle and resembles *hamamœba præcox*. He thought it worth while to note the peculiarity of form, even if it indicated only a phase of development.

Mr. Shattock read at this meeting a communication on the "Healing of Incisions in Vegetable Tissues," comparing the phenomena to those of first intention and third intention in human tissues. His account of his experiments and the results at which he had arrived was followed with interest.

The public health of Ireland is in a satisfactory state according to the registrar-general, who reports that the death rate for the quarter was the lowest rate for the March quarter since 1864, except that for 1868, which was a little lower. Zymotic diseases were much below the average.

Speaking of Ireland, reminds me that the question of reforming the administration of Irish workhouses grows more and more pressing. The medical officers of some seventy of these have reported on the urgent need of changes. The association *Journal* has just concluded the issue of reports by its representative, one of them giving defects scarcely credible. But the *Medical Press*, the first professional authority in Ireland, remarks that "the statement is strong but true." There was a conference on the subject lately in London, and the revelations of some of the speakers were such as to excite disgust and almost despair. Beside neglect of the sick poor to the most shocking extent and corruption and jobbery rampant everywhere, it would seem that the central authority in Dublin has either lost control or sacrificed its duty for some political purpose.

The appeal of the Apothecaries' Hall of Dublin to the Privy Council came on last Monday and was practically referred back to the medical council for reconsideration. Their lordships suggested that the hall might address another application to the medical council, asking the appointment of examiners without restricting such appointments to surgery. Counsel for the hall agreed after consulting his clients to do so, but counsel for the medical council could not consult his clients. He therefore undertook to represent their lordships' suggestion in the most favorable manner, and the matter stands over until the next meeting of the medical council, when it must be brought up. The suggestion will probably be adopted.

The Chelsea Hospital for Women is not yet out of trouble. The lay committee, which, as I have previously shown you, is itself a discredited body, wants to make new by-laws to enable it to dismiss any member of the staff in the most despotic manner. I am told that most of the staff are willing to accept the proposed new rules, but we shall see. A meeting of the governors to consider the matter has been summoned.

Sir William O. Priesly, M.D., has been elected M.P. for the universities of Edinburgh and St. Andrews.

The seat has therefore fallen to a medical graduate. There was no opposition. Sir William is a supporter of the present government.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE ACADEMY OF MEDICINE AND THE CORSET—DISEASES CAUSED BY CORSETS—VACCINATION NOT COMPULSORY IN FRANCE—HOW PUBLIC VACCINATION IS CARRIED OUT—HANGING AS AN ART—SENSATIONS OF HANGING DESCRIBED BY ONE WHO EXPERIENCED THEM—DEATH OF PROF. GERMAIN SÉE.

PARIS, May 15, 1896.

"PARCERE subjectis et debellare superbos" is the Latin device which has been applied to all varieties of the female cuirass (to use a generic term) from 1590 to the year of grace 1896. The same is true, whether it is a question of the ticking corset worn by peasants, of that worn by the workgirl and made of shirting or wool satin, or that of the society woman, of multicolored silk tissues, stitched, embroidered, garnished with lace or ribbons—no matter, the effects are always the same.

The wasp waist so much sought after is too often paid for by incalculable harm. The wan face and the deformed thorax, seen every day on the street and in the ballroom, speak more eloquently than words to the physician of hepatic engorgements, dilated stomachs, and floating kidneys due to tight lacing. The evil is so widespread that the Academy of Medicine has devoted considerable attention to it. It is not altogether tight lacing either. In many cases the corset itself, by the manner in which it is made and the materials used in its manufacture, is alone and *ipso facto* the cause of all the mischief; as even if barely supported by the laces, joined however loosely, it must of necessity interfere with the free movement of the respiratory and abdominal muscles.

The lesions of internal organs due to this instrument of torture have been enumerated and described by all hygienists since the time of the metallic "busk" or cuirass, which was introduced into France under Catherine de Médicis. De Riolan, 1615 to 1640; Winslow, 1741; Michel, 1867; Chapotot, 1892; and Professor Hayem, of the Faculty of Medicine of Paris, during the present year, have demonstrated beyond the shadow of a doubt by indisputable facts the organic malformations acquired by the use of corsets, as well as the dangers of exaggerated compression upon the lungs, stomach, liver, etc. Dr. Poncet's valuable and instructive paper on the subject contains the following significant passage: "No authority, neither that of the parents, nor that of the husband, nor that of the physician, of course; no power, in a word, is capable of inducing a woman of nineteen or twenty years to abandon or even loosen a corset strangling the abdomen and false ribs."

Such has too often been our own personal experience, and when desiring to give a little more natural amplitude to the waist of a young girl of sixteen years, how often do we hear the reply: "But, doctor, I am not laced; the borders of my corset do not even meet. See, I can pass my hand easily under the corset." Vain delusion! The doctor's visit is almost always known beforehand, the corset is loosened accordingly, and five minutes after drawn up to the last notch.

The regular development of the body and marrow are in only an exceedingly small number of cases motives for renouncing these dangerous practices. Parents and friends know well and the physician repeats it often enough that serious diseases, sometimes incurable ones, result therefrom; but the exigencies of fash-

ion pass before everything else. Dr. Poncet reports clinically and in detail the case of a young woman of twenty-three, who died a victim of constriction caused directly by the corset.

Moreover, delivery could not take place normally. An operation was judged necessary, the Cæsarean operation, having for result the death of both mother and child.

It is really surprising that in all these discussions and writings no mention is made of floating kidney, or falling kidney as it is called here, one of the most frequent pathological conditions resulting from lacing; nor of hour-glass liver, a very frequent malformation attributable to the same cause. It is usually the right kidney that is displaced by the continual weight and pressure of the engorged liver upon it, due in its turn to the compression of the lower thorax and false ribs by the corset.

It is just one hundred years ago to-day—May 14, 1796—that Jenner discovered vaccine after numerous researches and patient observations in his native Berkeley Hills. The history of vaccine, from the date of the first public vaccination down to the present time, is too well known to need even mention, and we pass to the practical questions of the hour. Small-pox, said Professor Proust, at the meeting of the consulting committee of public hygiene of France, is a disease that is destined to disappear altogether from our nosological tables and one that will disappear the moment that the measures for its prevention so long since recommended shall be rigorously and completely carried out. That is so true that for twenty-five years past, with the prophylactic measures taken, the average of deaths from variola in France has steadily fallen. But we have not yet arrived at the results obtained in Germany, where vaccination has been obligatory since April, 1875, and is still, small-pox having become so rare that it is no longer mentioned in summary statistics. It appears that the number of deaths caused by variola in Germany is only about 3.3 in a million inhabitants. Among the French population the death rate is unfortunately very much higher, because the vaccinations and revaccinations are not practised regularly. It is on this account that the consulting committee of hygiene proposed three or four years ago to have enacted a law making vaccination and revaccination obligatory. To this the objection was raised that such a law would interfere with individual liberty, and it was not passed. But surely the liberty of spreading small-pox is one of the first that an individual should be deprived of.

The Academy of Medicine gives gratuitous vaccinations every Tuesday in the Salle des Pas Perdus, surrounded by the busts of medical celebrities. Yesterday the hall was crowded with mothers and babies. Over two hundred children were vaccinated between eleven and twelve o'clock. The culture and preparation of the vaccine lymph are made on the spot. At the end of a small garden between the buildings of the Academy of Medicine and the Geographical Society is installed a small stable, a model of cleanliness, in which are always kept four heifers.

In 1894 the vaccine service of the Academy of Medicine made 1,726 vaccinations and 10,766 revaccinations. In 1895 the figures were much lower—1,381 vaccinations against only 1,763 revaccinations. The mortality from variola, which is from thirty-five to forty per cent. among persons non-vaccinated, is from three to five per cent. among those that have been vaccinated, and only two per cent. among those who have been revaccinated. These heifers are kept for nine days in the stable of the academy. After which, the culture of the lymph made, they are killed the same evening. An autopsy is immediately made on every one of them, and in case of disease the lymph taken

from that animal is at once destroyed. While in the stable these heifers receive special treatment—stimulating drinks, alcohol in solution, infusion of tea, hay, and a general nourishment of excellent quality, milk, flour and milk, absolute rest, and a dry bed. The hygiene of the animal is the object of the minutest attention, for the quantity and quality of the lymph depend directly thereupon. Although the progress made in the domain of vaccination has been considerable, yet until vaccination and revaccination are made obligatory in France the population will never have a sufficient guarantee against small-pox, whether sporadic or epidemic.

A curious experiment has just been made by a man named Durand, who hung himself for thirteen days by the neck, taking only fifteen minutes rest (unhung) each day. He describes his feelings as follows: "I thought three days ago I was going to lose the large sum at stake. My fatigue was great, I had an intense fever, my extremities were congested, and my ankles made me suffer horribly. The most curious sensation is when, unhung, I attempt to walk: I have vertigo, my foot strikes the floor, and I imagine myself always in my stocking feet. Then I have a sensation of vast emptiness in my head, and seem to have just got up from a long illness. I cannot eat and only take from time to time a mouthful of bouillon."

When he rehung himself the strangulation was sufficient to cause protrusion of the eyeballs and tongue, the features became convulsed and cyanosed. This was followed by a state of stupor and semi-consciousness, which lasted until the next remission of fifteen minutes at the end of another twenty-four hours; and so on until the thirteen days were completed.

Dr. Germain Sée, who died the day before yesterday, at the age of seventy-eight, had been for thirty-five years past one of the most important physicians in Paris. Médecin des hôpitaux since 1852, professor at the faculty since 1866, member of the Academy of Medicine since 1869, he was during the last years one of the most sought-for consultants, one of the most occupied, and one of the most honored, both *causa honoris* and monetarily. A hard worker and profound clinician always, his best known works were: "La Chorée," "Le Sang et les Anémies," "Le Sal Gastrique," all now out of date. But his grand treatise on "Clinical Medicine," in twenty volumes, will remain a lasting monument to his worth. He was very unpopular with the students, and he said once to his class in our own hearing: "Go and buy your little manuals for three francs fifty. You will be refused at the examination, especially by me." In July, 1870, he was called in consultation in the Emperor Napoleon's case, and he it was who discovered that Napoleon III. was suffering from stone in the bladder, much to the chagrin of the other consulting physicians, who were Nélaton, Ricord, Fauvel, and Corvisart. He met with pecuniary reverses late in life, and was obliged to practise again like a young man, removing from his sumptuous home on the Boulevard Malesherbes to a comparatively modest apartment in the Avenue Montaigne, and climbing stairs to see patients as in his earlier days. Four years ago he retired absolutely, to await the long rest upon which he has just entered.

"APPENDICITIS FROM A MEDICAL STAND-POINT."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD of May 9, 1896, is published a letter from Dr. Robert T. Morris commenting upon my article, "Appendicitis from a Medical Standpoint," and regretting that I refer to

the fee as a motive for surgical work, in that it "lowers the caste" of my article. Viewing it from Dr. Morris' standpoint, I agree with him that it might better have been omitted. The reference to the fee, which he finds objectionable, was prompted by certain unpleasant experiences with one or two operative surgeons of a type that "lowers the caste" of the whole profession, and with whom unfortunately the fee is not entirely a secondary consideration. I am free to acknowledge that such men are the exception, in a profession noted for its unselfishness, not the rule, and the question of the "consideration" was intended solely for the black sheep in the flock whose anxiety is not for the relief of suffering humanity, but for fat fees and a "big record." It was neither intended as a fling at such men as Dr. Morris nor as a reflection upon operative surgeons in general. In regard to the major portion of Dr. Morris' communication I can only say that its courteous and gentlemanly tone, taken in connection with his well-known skill and the conservative spirit which he manifests, disarms criticism.

Dr. John A. Wyeth in the same issue reiterates his statement that "appendicitis is strictly a surgical lesion." The appendix, according to modern teaching, is a rudimentary herbivorous stomach. If we can have catarrhal gastritis, phlegmonous gastritis, gastric erosions, and gastric ulcers which may perforate and cause subphrenic abscess, local and general peritonitis, then gastric catarrh and gastric ulcer are surgical diseases, the treatment of which no physician should undertake without an operative surgeon at his elbow.

Dr. Wyeth quotes me as saying that "there is no peritonitis in the fulminant cases," and the statement thus appears in my article. A reference to the original draft of my article would show this to be an error either in copying or in the typesetting whereby a qualifying word was omitted. Taken in connection with what precedes and follows the quotation referred to, I think my meaning must be clear, and Dr. Wyeth will perhaps find it stated more lucidly in conclusions 3d and 4th. "That the proper treatment in non-operative cases is to favor the formation of plastic exudate and to secure firm adhesions; that the dangerous cases are the fulminant cases in which no warning peritonitis exists." By a warning peritonitis, I mean the localized plastic peritonitis which usually precedes perforation, not the general peritonitis which may follow it. Any physician worthy of the title knows that a diffuse septic peritonitis follows in the fulminant cases, but this is far different from the conservative, adhesion-forming, localized process of which I was writing, and which I believe to be not "the result of blind chance," as Dr. Wyeth terms it, but the deliberate effort of nature to wall in the diseased part. In certain cases, for some reason not fully understood, no plastic exudate is thrown out around the diseased appendix—no preliminary peritonitis—and then we have, if perforation or gangrene occurs, a fulminant case. I trust that this is sufficiently lucid for the average comprehension, for I hardly like to rest under the imputation that I have never seen, read, or heard of a septic peritonitis following perforation of the bowel.

Dr. Wyeth feels sure that I "erred in my diagnosis." He also states that "a surgeon of ripe experience or a physician of equal experience can tell in the vast majority of instances when operation is indicated." Contrast these two statements. The diagnosis is not ordinarily considered extremely difficult, while the question of operative interference is often one which will tax the best judgment. I trust Dr. Wyeth did not intend to be discourteous.

It is perhaps regrettable for the sake of argument that no autopsies were held, no laparotomies per-

formed, that the fluoroscope had not then been perfected, and that therefore I cannot prove my case. Inasmuch as it is not considered strictly ethical to enlarge upon one's own diagnostic skill—beyond a certain limit—it will be readily seen that Dr. Wyeth has me on the hip, or to quote from that classic work, "Decius Repetita Placebit," published by a certain chemical company, "he gat him the bulge on me." This question of diagnosis is after all merely a matter of opinion, and would mildly suggest that his absence of knowledge of my cases, and of my own ability or lack of it, detract somewhat from the value of a statement which coming from a man of his reputation would otherwise have more weight.

He refers me also to a paper—or rather to an abstract of a paper—by Dr. Samuel Lloyd, giving a mortality of seventy-seven per cent. in cases treated by medical means. In the absence of any information as to how many of these cases obviously required operation, how many were treated symptomatically, by salines, by the various other methods, or mistreated, and with no reference in the abstract referred to as to the proportion treated by opium, given, not empirically, but with the view of favoring the development of localized plastic peritonitis, the comparison is obviously unfair.

The doctor thinks it probable that the proportion which recovers under so-called conservative management would number about fifteen in every hundred. The vision of the operative surgeon is liable to be distorted by the fact that the graver cases are referred to him for operation, while the mild ones are likely to escape his observation.

The article was written not as a protest against the operative treatment of appendicitis, but as a protest against indiscriminate operating. I believe that nothing in it can be so construed as to interfere with operative procedures in any suitable case. Certainly, some of my own cases would have been operated on, had circumstances been favorable. Our text-books are largely written by hospital men from the hospital standpoint. This is in one sense a necessity, but it would be wise for "those in authority," before laying down cast-iron rules that all or even the vast majority of cases should be operated on, to remember that these text-books are read and taken as guides in the country as well as in the city, and that dogmatic statements, sweeping assertions, are not only capable of doing an immense amount of harm, and of distinctly increasing the mortality, but seriously impair and discredit the surgical side of the discussion. Recklessness of statement implies necessarily an equal recklessness in the selection of cases for operation, and a large number of letters now on my office table, from practitioners living in many localities in this country, would indicate that a reaction from the extreme views held during the past few years is taking place.

The time will never arrive when every patient with a diseased appendix will have it excised, neither will the profession as a whole ever endorse wholesale removal. Some cases cannot, some will not, and some do not need to be operated upon: therefore the sooner we recognize this and put the medical treatment on an established and scientific basis, the earlier will medical progress be benefited thereby. The specialist, including the operative surgeon, who is no exception to the rule unless he carefully guards against it, grows one-sided, like a house plant kept in one window—the leaves all face one way, and a view from the background may disclose defects not visible from the front. The extremes are dangerous, the truth lies midway, and there the pendulum—*est modus in rebus*—will eventually come to rest when some bright genius with sufficiently "ripe experience" can formulate rules when and when not to operate, for the guidance

of those fortunate ones among us who can make a proper diagnosis of appendicitis.

W. N. MACARTNEY, M.D.

FORT COVINGTON, N. Y.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The correspondents' column is very often not the least interesting and instructive portion of the rich contents of the MEDICAL RECORD. Here the writers put forward their impressions, opinions, and conceptions of facts, with a familiarity and *verve* that are necessarily absent from long and sometimes wearying systematic articles. These letters are similar to photographic snap shots. They reveal points and characteristics which the finished work of the artist lets slip in favor of a more harmonious general effect. Drs. Morris' and Wyeth's letters of recent date and Dr. Greene's letter in to-day's MEDICAL RECORD confirm what I have just said. Will you grant me the favor of joining them? I am, I hope, a not too immodest member of that highly-praised and indispensable band or portion of the medical profession commonly called "general practitioners." The general practitioner is the life and soul of the specialist, not only in holiday orations but in reality. If the general practitioner were out of existence, the specialist would be onscious of a very distressing want, namely, that indefinite glittering conglomeration of nobodies against which specialism parades its importance and distinction. But the nobodies—the great crowd of the voiceless—are the medical profession. All other practitioners are members of the "surgical profession," as Professor Wyeth phrases it, or of more limited specialties. It is with a certain sense of superiority that Professor Wyeth speaks of the surgical profession—he does not speak for the medical profession when he criticises Dr. MacArtney's remark on "fulminant" cases of appendicitis. Dr. Morris is somewhat condescending, but just as proud as Dr. Wyeth. Dr. Morris is so much of a surgeon that he seems to be ignorant of the existence of human nature. His reference to Dr. MacArtney's inability (a presumptuous assumption) proves this, as does his reference to time and money. "The general practitioner," says Dr. Morris, "must have so much information upon so many things"—and human life is so short! It was always short when art was the subject considered. Well, the general practitioner cannot, according to Dr. Morris, get the right point of view concerning appendicitis. "So many things of equal importance with appendicitis" keep hid from him the facts and phenomena of appendicitis as seen by operative surgeons only. Therefore some, not all, surgeons, with more charity than justice and wisdom, insist with more or less bluntness that the general practitioner is not a being with senses and a brain, but a simple tool good enough to prepare the way for antiseptics and the scalpel with. That seems to me to be the logical inference to be drawn from Drs. Wyeth and Morris' letters on Dr. MacArtney's interesting article, which has not been treated at all fairly by them.

When I compare my own experience, plus my impressions gathered from conversations and reading, I cannot suppress the thought that surgeons can learn something from the clinician and general practitioner. The surgeon may teach us, but he ought not to force his lessons on us. It will be a sad day for the medical profession, as well as for society, when general practitioners shall cease to present their protests as Drs. MacArtney and Greene have done. Professor Wyeth is not teaching when he says: "If all of a thousand suspected cases were operated upon, the mortality would be fifty per cent. less than in another thousand cases which physicians now let pass

without operation." As a practitioner of nearly twenty years' experience, I must say that Dr. Wyeth is laboring under illuſional prejudices which do not affect the phyſician. Surgeons are not, in this queſtion of appendicitis, free from "the failing common to ſpecialiſts of all claſſes—they are bent upon finding the entire theory of the phenomena they inveſtigate within their own ſpecialty, and they too often turn a deaf ear to any explanation of them drawn from other ſources."

Let us hope that the clinician and general practitioner will not reſuſe to take leſſons from the ſurgeon, but let us alſo hope that the members of the "ſurgical profeſſion" will treat the clinician and general practitioner as men and workers,

"Heart within and God o'erhead,"

and not as mere tools.

A GENERAL PRACTITIONER.

May 23, 1896.

"SHALL WE GIVE THE APPENDIX A REST?"

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Not while the majority of phyſicians admit that they cannot palpate a normal appendix, and that they cannot eaſily diagnoſticate true infective appendicitis.

Not while a coroner's phyſician can tell me that he ſtill finds deaths from unrecognized appendicitis to be "immensely common" in his poſt-mortem work in New York City.

Not while phyſicians who do not ſee appendicitis caſes continue to loſe caſes of peritonitis and inteſtinal obſtruction and acute gaſtritis.

Not while the medical death rate of appendicitis is nine per cent.—to uſe the figure choſen by Dr. T. H. Greene, in the MEDICAL RECORD for May 23, 1896.

Why is Dr. Greene willing to have nine per cent. of appendicitis patients die under medical treatment?

I have recently published a liſt of one hundred of my unſelected consecutive appendicitis operations, with ninety-eight recoveries and two deaths. Thirty-eight of theſe were abſceſs caſes, and the reſt were mainly adheſion caſes of the interval type. The two deaths were unneceſſary. Dr. M. M. Johnson, at the laſt meeting of the American Medical Association, reported on one hundred of his unſelected consecutive appendicitis operations, with ninety-eight recoveries and two deaths. Dr. J. B. Deaver has recently reported on a liſt of two hundred of his ſelected appendicitis operative caſes, with one hundred and ninety-eight recoveries and two deaths.

My own poſition is far from being an enviable one. I have aroſed the ire of fellow-ſurgeons by attacking the methods of thoſe who make long incisions, who commit taxidermy upon their patients by ſtuffing them with gauze, who fail to ſuture ſtructures of the abdominal wall ſeparately and accurately, who neglect to ſterilize abſceſs cavities while at work, and who do not make it a rule to remove adherent appendices. I am free to confeſs that they make it pretty hot for me. Men have been known to defend themſelves before. They excite my admiration for the piquancy of their ſatire, and they queſtion the accuracy of ſtatistics which are ſo different from the ſtatistics of their own experience. Strong men who have won high poſition through merit are in a poſition to put air brakes on progreſs if they wiſh to do ſo.

I have aroſed the enmity of general practitioners by inſiſting that they muſt make correct diagnoſes of infective appendicitis, and that they muſt be guided by a knowledge of the known pathology of appendicitis rather than by their own individual views. Dr. Fowler's book, Dr. Deaver's book, my own book, cover the pathology of appendicitis, and there are many

ſhorter monographs beſides. We know from the known pathology of appendicitis that if Dr. MacArtney did not err in diagnoſis in any of his twenty-four caſes, he muſt loſe about ſix of the number before he is through with them. We know that ſome of theſe twenty-four patients are not very well ſince their recovery. The "ſpectres of tuberculosis of the appendix, large enteroliths, ſtrangulating adheſion bands, and portal emboliſm that Dr. Morris fears" are not ſpectres. They are things that I have between my fingers in every-day practice. I know all about the difficulties that phyſicians have in managing their appendicitis patients, particularly in the country. Some of my moſt intimate friends are country doctors. We were ſchoolboy friends. We go fiſhing together and we go ſhooting together. We exchange confidences in camp, and I know all about the difficulties that Dr. MacArtney and Dr. Greene have in trying to do what is beſt for their appendicitis caſes, but that has nothing to do with the pathology of the diſeaſe. Phyſicians who treat appendicitis medically ſave moſt of their patient, and whenever one dies they are ſorry.

Thoſe who are perſonally acquainted with me know that I am not an extremist. I expend time and money and employ experts to determine the right of a ſubject, and when the right is clear it is my pleaſure to fight for the right. Many a man who fought me on appendicitis ſtandpoints five years ago has ſtopped. More than one of them has had the ſubject brought very cloſe to his heart by a calamity in the family. One by one they ſtop fighting me and turn to a ſtudy of the known pathology of real infective appendicitis. No one can ſay that I am not conſervative, unleſs he has liſtened to the arguments of men who are defending themſelves. My published work on other ſubjects ſhows my devotion to conſtructive, merciful, ſaving ſurgery. It is my pleaſure to ſave life and to prevent ſuffering, and I am morally bound to bear the brunt of ridicule from the general practitioner, and, what is harder, the ſarcaſm of my fellow-ſurgeons, in order to ſee the right prevail. I have never criticiſed any member of our profeſſion, but have fought for principles only. One of theſe days we may have a medical court with a judiciary to weigh evidence and to fix the value of teſtimony which is offered by advocates on both ſides of the queſtion of appendicitis, antitoxin, vaccination, and of all of the ſubjects which allow of ſcientific claſſification of data. Until we have ſuch a court men who are on the wrong ſide of a queſtion will ſubject patients to treatment according to their views.

A PROPOSED TAX ON PHYSICIANS IN HAWAII.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: North Carolina phyſicians are forced to pay a license fee of \$10 per annum. The Hawaiian legiſlature is now diſcuſſing a propoſed license tax of \$50 per annum upon phyſicians. There is no doubt that contagion will ſpread over other States and the queſtion of license becomes of general intereſt to the profeſſion. Perhaps it is time to conſider upon what grounds liberal profeſſions, the medical included, for centuries have been exempt from ſpecial taxation: what moral, hiſtorical, and economical arguments phyſicians of various parts of the country have to meet this novel tendency of legiſlatures. If the tax is juſt, we have nothing to do but to ſubmit in ſilence; if not, we have to come out of our political ſupineness provided with all the weapons at our diſpoſal. The queſtion of the amount of tax is ſecondary. It muſt firſt be decided

in principle whether a physician, a priest, and a lawyer can consent to pay any such tax without renouncing membership of a liberal profession and joining a trade. The tendency to make trades of these professions is so great and so general that having let go this last right of exemption from taxation, no reasoning man will be able to discover what the difference is between them. The liberal professions are called liberal because they enjoyed for centuries the privilege of exercise without special taxation. The abolition of this magna charta means equalizing of professions with trades. We do not think physicians lose anything morally or financially if henceforward they are considered among laboring and not among privileged classes. The doubtful morality of privileged classes is known too well for a man to feel much complimented nowadays in being classed among the privileged. The abolition of privileges must necessarily be connected with abolition of duties, and the duties of a physician toward his profession and society were always considerable and costly. Professional license seems in appearance only to be a direct tax. All such taxes are paid finally by the consumer; in our case by the sick, which in itself constitutes a great injustice.

So far as historical records show, the governing classes have always shifted the burden of taxation upon the laborers. The modern plutocracy hiding behind the formulas of liberty, equality, and what not, certainly could not do it openly and directly, but the same results have been obtained by the substitution of indirect taxation for direct. Indirect taxation is taxation of the consumer in proportion to his consumption. Nine-tenths of the indirect taxes are levied upon so-called staples and necessities of life, and the consumption of staples is out of any proportion either to wealth or revenue. A millionaire cannot, and does not, consume a hundred thousandfold more sugar than does a beggar.

In joining the ranks of laborers, the physician must protest against and oppose the whole system of indirect taxation as discriminating against the laboring classes. He must oppose all taxation of labor, whether in the shape of poll tax or license or otherwise. He must insist upon progressive revenue tax as the only just and adequate system of taxation. Only upon those principles and in union with other laborers, into whose ranks he is driven by the license taxation, is he sure to succeed.

HONOLULU, H. I., April 28, 1896.

THE SIZE OF A TEASPOON.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I recently addressed a note to the Gorham Manufacturing Company, silversmiths, of your city, directing attention to the wide variation in the capacity of teaspoons and asking if a pattern of uniform and definite capacity could not be adopted by the silversmiths of the country. This seems almost too much of a trifle to bring to the notice of your distinguished journal, but inasmuch as teaspoons are the universal standard, in domestic use, of measuring doses, and as they vary between the colonial spoon of one drachm and the modern spoon (tea) of two drachms, it might be of sufficient importance, as a matter of convenience to the profession, to invite some co-operation in an effort to obtain a teaspoon of standard capacity. It is manifestly unsafe, at present, to direct doses of a teaspoonful when there is so great a difference as a drachm in the contents. I have measured probably

three hundred teaspoons during the past two years and have found that most of those of recent design hold one and one-half drachms, some two drachms, and none one drachm excepting the very old and rare spoons.

ELIOT, N. Y., May 18, 1896.

"FAILURE OF CASTRATION TO CAUSE ATROPHY OF THE PROSTATE."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I wish to add my testimony to that of Dr. Kelsey as to the total failure of castration as a means of reducing prostatic hypertrophy. The case was seen by me last October in Dr. Wassidlo's polyclinic, in Berlin. The man, seventy-five years old, had been unable to urinate normally for a very long time, being obliged to use the catheter every two or three hours, both day and night. Lately he had also been suffering from severe cystitis. His prostate was found to be very much hypertrophied and the operation of double castration was performed on him by Dr. H. R. Wassidlo, then of Berlin, now of Dresden. No general anæsthesia was employed, only Dr. Schleich's local infiltration method, which excellent method, by the way, deserves to be more widely known and practised in this country. The man's bladder was washed every second day with a 1 to 2,000 argentic-nitrate solution and his cystitis was considerably improved. But in his urination there was not the least improvement when I saw the man the last time—about three months after the operation. He was as helpless without the catheter as before and had to use it quite as often. A digital examination per rectum failed to reveal any diminution of the hypertrophy.

THE TREATMENT OF SEASICKNESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD of January 28th I notice an article on the treatment of seasickness by Dr. Rockwell, and under date of April 11th a letter on the same subject by Dr. Boyd. In this connection I would like to call your attention and that of your readers to what might be termed the hæmatostatical treatment of this common affliction. For many years past I have had frequent opportunities of noticing the effects of seasickness upon different individuals.

While admitting the generally acknowledged theory at present entertained, that it is due to a disturbance of the cerebral centres by the vessel's motion, it is to be observed that a contraction of the peripheral blood-vessels occurs, inducing a sensation of chilliness, etc., and as the centres that control the calibre of the vessels, peripheral and otherwise, are the same, the vessels of the brain must at the same time become contracted, and upon this condition depends the cerebral anæmia which induces the emesis complained of. Provided this premise is correct, is it not reasonable to suppose that, by the administration of such remedies as will maintain the normal equilibrium of the circulation, with the normal qualities and frequency of pulse beat of the sufferer, we can, mechanico-physiologically, prevent the distressing conditions complained of?

Believing these requirements could best be met by the administration of nitroglycerin and caffeine, I employed them with most gratifying results, further

experience but corroborating my original expectation. A tablet of nitroglycerin, one-one-hundredth of a grain, has proven sufficient to so dilate the vessels; and, when followed by a tablet of caffeine, two grains, an approximation to the normal pulse in character and frequency has been maintained for from three to eight hours, to the complete exclusion of any seasick feeling.

These medicaments can be repeated as required, to the end that the normal pulse for the individual is assured. If a persistent retching prior to the administration of these remedies has induced an irritable condition of the stomach, it can be allayed by the ingestion of five minims of a four-per-cent. solution of cocaine in a wineglass of water—this to be repeated every four to six hours if occasion requires: but my experience leads me to the conclusion that with the aid of the former medication the cocaine need not be employed more than once or twice, if at all.

Although I have always used the nitroglycerin in one-one-hundredth grain doses, I will here suggest that it be given in half that quantity, thus obviating a sense of too great fullness of the head, sometimes for a few moments a subjective symptom of the larger dose. In my own case one-one-hundredth grain was used upon three different occasions, with two grains of caffeine, both being repeated at intervals of from three to six hours, depending entirely upon the pulse characteristics and the subjective symptoms of the malady. On neither occasion did it become necessary to resort to this medication after the second administration, following which all tendency to illness disappeared.

This line of treatment has been the means of my remaining on deck all day in perfect enjoyment of the surroundings in fair and stormy weather, when otherwise I should have been in company with the majority of the ship's passengers. When these drugs were administered to others, I have always had the satisfaction of noticing similarly good effects and the disappearance of the malady.

With such as have a daily alcoholic habit it is advisable to continue the same in moderation, using the caffeine as an adjuvant thereto. The nitroglycerin and caffeine might be even more efficaciously administered hypodermically, although I have not so used them.

It is unnecessary to refer to the advisability of proper attention being given to the primæ viæ before embarking.

FREDERICK C. RILEY, M.D.

48 EAST TWENTY-SIXTH STREET, NEW YORK.

"PONTINE" OR "PONTILE"?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of April 11th, p. 531, last paragraph but one of "Our London Letter," is mentioned a case of "Hemorrhage into the Pons." Since the use of "pons" for "pons Varolii" was advocated by me in 1880 (in a paper before the American Association for the Advancement of Science), and has been recommended by the nomenclature committees of that body (1890), of the Association of American Anatomists (1890), and of the Anatomische Gesellschaft (1893), permit me to congratulate the MEDICAL RECORD upon this example of the substitution of the mononym for the dionym, which latter is also objectionable as an eponym. Indeed, since there is but one pons, there is no more reason for continuing to name its discoverer than, supposing certain abdominal viscera to have been first described by Britons, for talking about the "stomach of Brown" and the "liver of Robinson."

On another point, however, my comment must be

the reverse of congratulatory. In the subtitle of the letter above mentioned the case is referred to as one of "pontine hemorrhage." This form of the adjective is not uncommon in medical literature, and "pontic" and "pontal" have found their way into the dictionaries.

Now, as may be seen from any Latin lexicon, "pontal" has no justification whatever. "Ponticus," the Latin antecedent of "pontic," is derived from "pontus," the sea. "Pontinus," the antecedent of "pontine," was originally "Pomptinus," and refers to a district of Italy. As already pointed out by me (article "Anatomical Terminology," Buck's "Reference Handbook of the Medical Sciences," VIII., 524, § 50), the only legitimate Latin adjective from "pons" is "pontilis," and its Anglo-paronym is "pontile." The use of any other form tends to cause confusion and to bring discredit upon medical scholarship.

BURT G. WILDER, M.D.

ITHACA, N. Y., April 28, 1896.

THE NEW SPECIALTY—GENERAL MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The only department of medicine or surgery not practised by any one in this city (so far as I know) as a pure specialty is general medicine. Nearly all of our physicians are specialists, *i.e.*, laryngologists, neurologists, etc.

I have decided to devote myself exclusively to the practice of medicine, and shall be glad to attend any patients you may intrust to my care, upon such terms as we may agree to. I will take full charge of the patient, except for conditions which may require attention in your specialty, or if you so desire I will see that the patient is returned to you with any complaint that may best suit your specialty.

In regard to my fitness for this work, I would state that I have had a hospital service, which, as you know, a great many specialists have not.

G. R. A. BALL, M.D.

NEW YORK, May 18, 1896.

Bacteria in Water from Deep Wells.—It has been a widespread popular opinion that the purity of water obtained from deep wells, especially from deep wells of the kind known as driven wells, might be depended upon. Of late, however, there has arisen a doubt of the accuracy of this belief, and scientific investigation has now shown it to be erroneous. Examination of waters from a considerable number of springs and deep wells by the bacteriologist of the Massachusetts State Board of Health has shown that bacteria are present in water taken not only from springs and open wells, but from carefully guarded wells of quite extraordinary depth. The results of the investigations prove that Sternberg, Abbott, and other high authorities were in error in believing waters from deep sources to be free from bacteria. Frankland, in his "Micro-Organisms in Water," evidently had doubts, but his investigations led him to believe that such waters, although perhaps not wholly free from micro-organisms, possessed a high degree of bacterial purity. It is difficult (says the report of the board) to find deep wells in uninhabited or country districts, and our results are all derived from populous areas. It is possible that other results might be obtained from wells driven in uninhabited regions. It is plain, however, that water absolutely free from bacteria is not ordinarily obtained from even deep wells, and that many deep wells contain as numerous bacteria as are found in many surface waters.—*The Engineering Magazine*.

New Instruments.

AN ARTICULATED KNAPP'S STETHOSCOPE.

By DICKSON L. MOORE, M.D.,

COLUMBUS, OHIO.

AFTER using Dr. Knapp's improved stethoscope, described in the *MEDICAL RECORD*, November 9, 1895, the writer was convinced that the claim made for it as a "high power" instrument, in which the "humming, buzzing sound so familiar to us all" was eliminated, was a claim readily substantiated. Convenience in using it, however, was lessened by the fact that it could not be taken apart and was therefore too bulky to be carried in the pocket. The problem was to ob-

tain an articulated instrument which would not violate Dr. Knapp's principle of a continuous metal tube protected by a non-conducting rubber covering.

At my suggestion Messrs. George Tiemann & Co. have made such a stethoscope with a bayonet adjustment which can easily be taken apart. The pin of the bayonet plays in a semicircular groove, the base of which is hard rubber; the metal attachments lock closely and are protected by hard rubber, so that when articulated the instrument carries out completely the original idea.

I have satisfied myself that none of its superior advantages has been lost in making it adjustable, and its increased convenience in transportation is my apology for this description.

As at times the physician, when leaning over a bed to auscultate, finds it more comfortable to drop his head slightly, Tiemann & Co. have kindly increased the width of the spring over that of the original model, in which the rigid tubes were too closely approximated for those who wear spectacles.

Surgical Tuberculosis.—Dr. Jeannel, in an article in the *Midi Médical*, writes as follows: For abscesses, ulcers, and joint affections, open freely, and excise if a joint be involved. Remove the caseous material by curetting, sponge the parts well, and arrest the bleeding. Fill the cavity through a thick rubber tube with salt solution kept at the boiling-point: fill and empty the cavity until it is thoroughly cauterized. Or fill the cavity with a cold or lukewarm salt solution, and raise the liquid to a boiling-point by introducing into it the blade of a thermo-cautery at a red heat. One minute is sufficient to heat the water in a cavity as large as a pigeon's egg. Do not touch the walls of the cavity with the blade of the knife. Give an anæsthetic if necessary, though usually cocaine locally applied will be sufficient.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 30, 1896:

	Cases.	Deaths.
Tuberculosis.....	226	120
Typhoid fever.....	10	3
Scarlet fever.....	83	9
Cerebro-spinal meningitis.....	3	4
Measles.....	281	11
Diphtheria.....	252	34
Small-pox.....	0	0

Limits of the Physician's Duty to the Dependent Classes.—Dr. Walk, writing in the *American Medico-Surgical Bulletin*, says that the physician as a man and as a citizen owes a great duty to civilized society, a duty which is conditioned upon his special knowledge. Acquainted as he is with the important laws of heredity and the reciprocal influence of mental and physical states, the responsibility rests upon him to lead the community in which he lives to a higher civilization and to better modes of life. He should be a teacher of the people, and not only by training men to cure disease but, pre-eminently, a teacher of preventive medicine, that department of our science now almost new, but destined to become its pride and glory. The question of his duty in regard to medical charities is much less simple. Here also an obligation rests upon him, as, for instance, in cases of sudden accident, etc. But this is a very small part of the so-called "charitable" work now thrust upon the profession. It is the common notion that the doctor should treat, free of charge, all the dependents in his neighborhood and should also give his services to both public and private institutions. Institutions supported out of the tax rate are, in no proper sense, charities. Their cost is levied upon all the citizens, in proportion to their taxable wealth, and there is no call for any one to serve them gratuitously. All others are paid for their services, but the physician is supposed to act upon some principle not applicable to other sensible men. Apart from the institutions supported by public taxes comes the yet wider field of the private charities. In these institutions it is right and fair that physicians should make contributions to them in service, if they see fit, but this right has its limitations. Free medical service, to come within the definition of a wise and judicious charity, should be rendered to those only who are unable to pay for it. To give it to others involves two wrongs: the first, to the younger men of the medical profession, who ought to have turned over to them those patients who are able to pay only small fees; the second, to the community, by the encouragement of pauperism and the undermining of independence. Twelve years ago a thorough investigation of the dispensary system of the city of Philadelphia was made, and quite recently the same ground has been traversed with a similar result by a well-known physician of that place. In thirty-two free dispensaries there were treated in one year one hundred and sixty-one thousand and twenty-nine cases, which was about twenty per cent. of the entire population of the city, or one-fifth of all the people. Carefully compiled statistics show that, in Philadelphia, the actual pauper class does not exceed one per cent. of the population. If medical men do all of this vast work from charitable motives, certainly they need to be converted to a more judicious and discriminating doctrine of charity. If this service is rendered

from selfish motives, the advantages derived from this free service have been greatly overestimated. No medical man should indulge the pleasing delusion that the patients he treats at the dispensaries suppose him to be doing a noble and philanthropic act, and putting them under a corresponding obligation. In their view the accommodation is generally the other way. The valuable experience that may be gained by dispensary practice is often lost from lack of time to make a really scientific examination. If, then, the duty of the physician to the dependent classes and also considerations of self-interest demand the restriction of free medical service, it is obvious that the existing system should be radically changed. Efforts made to restrict free aid to the indigent have, thus far, in almost every instance failed through the opposition of the physicians themselves, who desire to have largely attended clinics. The very enormity of the evil may, however, lead to a powerful revulsion of sentiment, when means will readily be found to discriminate between the poor and those able to pay for treatment.

Moral Insanity.—In the *Journal of the American Medical Association*, March 14, 1896, the subject of moral insanity is editorially referred to in the following words: "Recently a very reputable medical man was convicted of a heinous crime and sentenced to prison for life. In the effort to collect facts to be used in securing pardon the counsel discovered a most unusual life of hypocrisy. He had been cruel and harsh from boyhood. He enjoyed causing pain and suffering in others, and as a student he fairly revelled in the agony of animals in vivisections and the pain of persons diseased. To this was added great egotism and love of personal praise. He ruined his father's property in apparent speculation. He was a bitter enemy to his brothers and sisters, and was indirectly the cause of the death of his wife and drove his children from home. He was not miserly, but was, in his inner life, thoroughly dishonest and without the slightest conception of honor or duty to others. Yet he kept up a fair exterior, was a teacher in a medical college, with a large practice, and had no popular vices such as drinking or gambling. The more his history was studied the worse it appeared. Deception, fraud, and dishonesty marked every stage, and yet it was largely purposeless and without reasonable motive. The facts taken together had only one conclusion and that was moral insanity. Some condition of the brain was literally deranged and malformed. Some central part that had not developed had been steadily retrograding. However difficult it may be to explain and make clear this term, there are classes of facts that can be described by no other name. The common expressions, vice, wickedness, and depravity, used in the moral sense, become more and more confusing with each advance of science, and their use in any technical way is unfortunate for accuracy. The higher governing centres of the brain are clearly distinct from the lower, and what is moral, meaning the consciousness of duty and obligation to others and conceptions of right and wrong, is clearly a later development. Evidently these centres are governed by the same laws which work in harmony in the healthy person, but may diverge greatly in other conditions. The belief that these centres may be undeveloped and diseased is along the line and sustained by both the physiologic and psychologic laws of existence and growth. The legal fear that the recognition of this disorder will be an excuse for crime is purely theoretical and visionary. The greatest danger comes from the want of recognition of the actual physical states which are manifest in criminal immoral conduct, conduct that may not come under legal recognition, but is

nevertheless disease and wide departure from the normal standard. Every physician comes in contact with persons who show by their acts insanity of every element that enters into the higher mentality. The terms commonly used to describe this condition should pass out of all accurate language. Medical men should study the facts of these cases, confident that they will all be found to come under some general law of disease and degeneration. Had the actual physical condition of this doctor been known, the disaster of his life and the suffering of others might have been averted. Arguments over definitions and terms are absurd; the reality of moral insanity can be proven from facts which have no other meaning.

Rigor Mortis in the Fœtus in Utero.—A correspondent of *The Lancet* gives the following account of a recent observation of this kind: "Some few years ago I sent an account to a contemporary of a case in which rigor mortis in the fœtus in utero was the cause of difficult labor. During the last two years I have had three other cases, so that an event which I looked upon as rare must not infrequently occur; but it appears to have passed unnoticed by the generality of practitioners, as every one to whom I have spoken about the matter has confessed that he had never even heard of, much less seen, such a case, and the textbooks do not mention it. The following notes of my last case are, I think, worth placing upon record. On September 6th I was called in to a primipara, aged thirty-seven, by the midwife in attendance. The os was fully dilated, but no advance of the head had taken place for several hours. On applying forceps considerable resistance was experienced, and what I expected to find an easy forceps case proved to be quite the reverse. Progress was slow until I secured extension, when the head came down well; but further difficulty was experienced in extracting the body, which gave the impression of being much too large for the maternal passages. The fœtus, however, proved to be not large, but rather under the average. The difficulty had arisen at the various stages: first, the normal flexion had not taken place, and at a later stage the stiffness of the neck had prevented extension, and the lateral flexion of the body had been interfered with owing to the same cause. Rigor mortis was well developed all over the body, the arms and legs being stiff and in the flexed position. On balancing the child's body on one hand its back kept almost straight and the legs in the same flexed position, the heels not dropping below the nates. Owing to the forcible flexion of the neck, the head moved upon the trunk like a hinge-joint. At the moment of applying pressure with the forceps there was a crunching noise quite audible, sounding as if one were breaking a bone.

The Friends of Man.—To be the friend of man is not all gain. Whether by a process of evolution or degeneration, many animals have become truly domesticated. They have come to depend on man for food, for shelter, for protection. On the other hand, the more closely they have lived with him, and especially the more they have adopted the shelter of his roof, the more they have become exposed to his great enemy—tuberculosis. Professor Delépine, writing on this subject (*The Hospital*) has shown that—taking very large numbers as the basis of his estimate—at least sixteen per cent. of cattle are afflicted with this disease; and that, whereas in some districts it may be comparatively rare, there are parts in which a non-tuberculous cow is the exception. Pigs also are affected in the same manner, although not to the same extent, about one in every thirty-six being attacked by the disease. Cats and dogs also are subject to tuberculosis, and it is to be feared that from their exceeding

friendliness they may be a source of danger to children with whom they play. Although the form of tuberculosis with which poultry are affected differs in some particulars from that of man, it is a very common disease and commits great ravages in poultry yards. Having thus dealt with friends of man which have so far adopted his habits as to dwell under the shelter of a roof the writer goes farther. In the case even of sheep, which are rarely under shelter and in many respects live in more natural conditions, tuberculosis has been found; and, in fact, the only real friend of man which has almost entirely escaped the ravages of tuberculosis is the goat. But any animal which conforms with man's habit of dwelling under artificial shelter is apt to contract tuberculosis, and so it is that whether they be monkeys, camels, giraffes, antelopes, llamas, lions, tigers, foxes, tapirs, zebras, etc., they all, according to Professor Delépine, are liable to tuberculosis when they are kept in menageries. Clearly the friendship of man is not an unmitigated blessing.

The Wickedness of Advertising.—Our entertaining contemporary, *London Truth*, often devotes considerable space to matters medical. In a recent issue it says that the wickedness of professional advertising depends upon who does it. The anomalies, absurdities, and mysteries of medical professional etiquette with regard to advertising are strikingly and amusingly illustrated by an action which was tried recently at Manchester assizes. Damages for libel were claimed by Dr. Kingsbury, of Blackpool, against a medical journal which had charged him with conduct "wholly incompatible with the honor and dignity of the profession" and held him up to "medical reprobation" for allowing himself to be advertised as the physician of two hydropathic establishments. For the plaintiff several medical witnesses expressed the opinion that he had done nothing unprofessional. For the defence several other members of the profession took the opposite view, and it was in the cross-examination of two of these gentlemen that the fun came in. The first of them was Sir Dyce Duckworth. The plaintiff's counsel put to him the fact that Sir B. W. Richardson was advertised as consulting physician of an institution in Leicestershire. Sir Dyce disapproved of this. It was then pointed out that the witness's own name and his private address appeared on the widely circulated prospectus of an insurance company to which he was consulting physician. To that Sir Dyce could see no objection. The next witness was Sir W. T. Stoker. He was asked what he thought of a physician's name and address being given in an insurance prospectus. He said he thought it was wrong. So it will be seen that Sir Dyce Duckworth condemned Sir B. W. Richardson, Sir W. T. Stoker condemned Sir Dyce Duckworth, and both agreed in condemning Dr. Kingsbury. Having impartially considered the conflicting views as to medical etiquette with which the court was thus favored, the jury came to the conclusion that Dr. Kingsbury's professional character had been unjustly aspersed, and awarded him £150 damages. It has always seemed to the editor of *Truth* that there is a good deal of humbug about the objections of the bigwigs of the medical world to advertising. Nearly all are guilty of the practice themselves in one way or another, and some are as eager for a newspaper puff as the veriest quack. What an interesting revelation there would be, for instance, if the editors of my daily contemporaries were to disclose the sources of the paragraphs which appear whenever some more or less distinguished personage is ill and the name of his doctor can be insidiously given the benefit of a little publicity! But somehow the heads of the profession have got hold of the idea that what may be right and proper on their part may

be wrong and unprincipled on the part of humbler practitioners. The attacks which are made upon the latter whenever they are supposed to violate the proprieties of the profession by "advertising" will, however, be somewhat risky after this Manchester case.

Insidious Origin of Phthisis.—The most common mode of commencement of phthisis is insidious, and the usual history obtainable from such patients is that for a definite time—perhaps one month, more usually three or six months, or longer—there has existed a group of symptoms which we may fairly consider as indicative of the disease. Cough, for example, varying in degree; expectoration, at first slight and mucoid and later becoming yellow and purulent; associated, in some cases, with hæmoptysis, but in nearly all cases with the occurrence of wasting and of night sweats. The characteristic night sweats of phthisis are not those which occur in the earlier part of the night, soon after the patient goes to bed, and which may be due to varying causes, such as overeating, hot weather, etc., but are those which occur in the early morning, between 1 and 2 o'clock. These night sweats are usually a sign of nocturnal fever, but they are not proportional to the fever and frequently, after a few months of illness, they diminish or disappear. When a patient complaining of this combination of symptoms is examined physical signs varying in degree are discovered. These will be considered later. As regards the early symptoms, individual patients present some variation, although, if kept under observation, they nearly all show at one time or another an evening rise of temperature: this may be very variable after the disease has lasted one or two months. Other cases present symptoms of excessive wasting without much cough and only slight expectoration, and in these cases the presence of night sweats would indicate tuberculosis. In other cases the cough may be excessive: there is no expectoration, but wasting and night sweats are present. Both these classes of cases may present no hæmoptysis up to the time of the first examination and the physical signs found in the chest may be doubtful, so that as regards symptoms one looks to the presence of night sweats in association with wasting and cough as indicative of phthisis. I think it important to insist on the characteristic symptoms of pulmonary tuberculosis, inasmuch as not infrequently these symptoms are unappreciated, and a careful examination of the chest, which, when made, would indicate the disease, has been omitted. Turning to the physical signs which may be present in these early cases of phthisis, there is, first, a deficiency of movement at one apex and a difference in the percussion note below the clavicles, that on the side in which there is deficient movement being shorter and higher-pitched than on the other side, or is actually dull, while on auscultation and comparing the breath sounds on the two sides, it is found that expiration is prolonged and respiration is divided or that there is cog-wheeled inspiration on the diseased side. The signs of deficient movement at one apex indicate a deficient entrance of air into the upper part of the lung, and the difference in the percussion note, together with the prolongation of expiration, suggests slight consolidation. But in these early cases such physical signs are sometimes absent, are more frequently doubtful, and the chief signs to rely upon in the diagnosis of early consolidation are an increase in the vocal or tussive resonance at one apex or the presence of crepitations and rhonchi. As regards rhonchi it may be said that these alone may be present, and one may hear a sibilus at the end of inspiration or coming out on cough, which, if present at the same place on two or three different examinations, would be indicative of the apex being tuberculous. The crepitations

which are characteristic of consolidation are those which occur during inspiration, but also those which are produced by the act of coughing or are heard on the first inspiration following a cough. The procedure, therefore, of making the patient cough while the suspected apex is being listened to is of great importance, and the absence of crepitation is frequently decisive in a chronic case of illness as to the presence or absence of tuberculosis.—DR. SIDNEY MARTIN, *Clin. Jour., London*.

Neurasthenia of Nations.—At this time, says an editorial writer in the *Cincinnati Lancet-Clinic*, there exists a rather remarkable condition of unrest and irritability among the governing nations of the earth. Even the people of our own land, who have in their past history refrained from any active exhibitions of a desire to mould boundary lines or sit in the councils of other countries, are pluming their feathers for any contingency that may arise. In army and navy circles there are manifest activities of a very practical nature. By order of Congress the navy is being increased in efficiency as rapidly as possible. In observing what is going on, members of the medical profession are equally interested with their neighbors. An increase of men in the army and navy indicates a necessity for a corresponding addition to the medical staff, in each of which there are now several vacancies. There is much reluctance on the part of young physicians to enter the United States navy because of the inferior rank and pay that is accorded the medical staff. This is supplemented by an indisposition on the part of officers of the line in the naval service to give anything like a fair recognition to medical officers, on account of which there are at this time scarcely less than twenty vacancies in the medical corps. The recent increase of sailors will add to the number of surgeons needed for active service. Congress should recognize the fact that, while line officers in the army and navy are educated at the expense of the government, members of the medical staff must pay the entire expense of their professional preparation for service. Next, their service is equally arduous, and requires as high a degree of intellectual attainments, as that which is found to be necessary in any other of the war departments. This is easily shown by the character of examinations for entrance to the several services. For this reason medical men, while asking no special favors, do earnestly demand fair play. Active young recruits in the prime of life and health sometimes exhibit some contempt for the labors of the surgeon, but the time comes eventually when there is a high appreciation of the work of the doctor. So it is with young men from the schools at Annapolis and West Point; they are inclined to sniff at and look upon the surgeon as a very useless appendage in the service, which comes to some extent, no doubt, from there being no professorship of gumption in those institutions. There are some vacancies in the army medical staff as well as in the navy. In this service there is a better recognition of the value of medical men than in the navy. Congress should rectify the malpositions referred to. Millions of dollars are annually appropriated for instruments of precision intended to destroy life and property, while beggarly thousands are grudgingly given for the care and preservation of the lives of soldiers, sailors, and citizens. The nerve irritations of the great nations is not likely to be quieted by and-ones, but will probably seek relief in war measures. Weak spots will be uncovered and probed to the bottom, where, if necrosis exists, excisions and amputations, followed by vigorous aseptic treatment, will be enforced. In other instances transplantation of grafts of new tissue will be necessary for the preservation of the integrity of a nation's life; even then there may be

a weakening in some quarters so great as to cause the vital spark to forever depart from ancient kingdoms. There is a rise and fall, an ebb and flow, in the tides of nation life similar to that found in men, which, when taken at the flood, leads on to fortune and to victory. Sometimes the fight for existence is very hard and the days are very dark, but there comes a dawn, and the sun shines brightly in all of his glory over the victor. There is a survival of the fittest among nations. There are to-day nations which represent an effete civilization, that in the natural course of events will soon go to the wall and be numbered and remembered only in books of history. The rise and decline of great empires is a study of intense interest. In their consideration it is well to draw lines of comparison between such nations and those of an individual man. They are alike fed, nourished, thrive, and grow fat so long as nature's laws remain unviolated, but the moment vices of luxury and sensual dissipation are permitted to become fixed habits, there comes on a feverish condition that disturbs every function of the body. Degeneracy precedes the fall that is sure to come. Every nation and every man is just as strong and no stronger than his weakest part. Weak viscera may be strengthened by appropriate treatment, or utterly destroyed through corrosive environments.

Dr. Kelly's Utopian Suggestion.—Dr. Kelly, in the *New York State Medical Reporter*, advocates a national medical registration law and a repeal of existing law for punishment of malpractice. It is inconsistent to establish a law to insure competency in practice of medicine and surgery while the present laws for the purpose of punishing incompetency still stand. Dr. Kelly suggests as a remedy for existing evils that the medical profession should be an arm of the government service. The graduate should at once be assigned to duty and his salary paid by the government. In cities and large villages stations might be established equipped by the government with library, instruments, apparatus, medicines, and all requisites for research and experimentation. Service for the people should be obtained from these stations and there would be no individual fee. This would be of immense value to the people. With the doctor's bill removed we would see cases in their initial stages and the highest function of the profession would be realized, preventive medicine. The best professional talent would be within reach of the masses. There would be greater efficiency and united, harmonious professional co-operation. The benefit to the profession would be greater. A higher grade of qualification would be necessary and the beginning and conditions and circumstances affecting the individual member would tend not only to maintain that grade but to develop a higher one. The benefit to the government would be greater than to the people or to the profession, for the integrity of the nation depends on the superior physical condition of the people, which superiority would bring in its train higher intellectuality and morality. If we go a step farther and place medical colleges under government control, we could insure competency. This plan would bring a proper appreciation of scientific work. Under our present code physicians do not profit pecuniarily from their discoveries: all are published and given freely to the public. Thus the State often profits. Dr. Kelly's plan would no doubt result in the greatest good to the greatest number, just as would Edward Bellamy's ideal republic. But the difficulties are overwhelming. No doubt, a large majority of the medical profession would hail such a change, but is it probable that men who have practices yielding from \$10,000 upward would be magnanimous enough to sacrifice themselves? These, too, would be the ones who, in virtue of their reputations and wealth would have

greatest influence if the plans were seriously proposed. It is barely possible that the masses would not like to be deprived of the privilege of being humbugged. The government has limitations. International questions and disputes must be settled and appropriations to existing institutions must be cut down to the lowest cent. The time is far distant when the government will attempt to manipulate such a complicated piece of machinery as a national medical bureau. We will have to wait until Sir Robert Harton's ideal republic materializes. If he survives to acquaint us with methods by which supposedly impracticable reforms were there initiated, perhaps we can make them apply to the case in hand.

"Eye, to which all order festers, all things here are out of joint,
Science moves but slowly, slowly creeping on from point to point."

The Nose as a Germ Filter.—It would seem, from the researches of St. Clair Thompson and R. T. Hewlett, as reported in *The Lancet*, that the human nose is a nearly perfect filter for micro-organisms. These experimenters calculated that under very favorable conditions the lowest number of organisms contained in the inhaled air of an hour was fifteen hundred, and that oftentimes in the air of a great city there must be as many as twelve or fourteen thousand drawn into the nose during the same period of time. The fate of the thousands of microbes which thus enter the human body is a question of great pathological interest, and this increases when it is remembered that the expired air is practically free from germs. The fact that inspired organisms do not, as a rule, reach the air cells, was first pointed out by Lister. Later, Tyndall showed by his experiments with a ray of light in a dark chamber that expired air—or, more exactly, the last portion of an expiration—was optically pure; *i.e.*, that respiration has freed it from the particles of suspended matter with which it was laden. Since then numerous experiments have been made by bacteriologists which show expired air to be free from germs. Grancher has made many experiments with the expired air of phthisical patients, and has never found in it the tubercle bacillus or its spores. "Now, as the air is practically freed from all germs by the respiratory act, we have to consider where and how the thousands of organisms are arrested in the air passages. The experiments of Hildebrandt would tend to prove that the air is entirely freed from all germs before reaching the trachea. In verifying this we have examined the mucus from the trachea of all animals recently killed in the laboratory, and up to the present have found the mucus to be quite sterile. We therefore commenced with the nasal fossæ, and found that the mucous membrane of the healthy nose only exceptionally shows any micro-organisms whatsoever. The interior of the great majority of normal nasal cavities is perfectly aseptic. On the other hand, the vestibules of the nares, the vibrissæ lining them, and all crusts found there, are generally swarming with bacteria. These two facts seem to demonstrate that the vibrissæ act as a filter, and that a large number of microbes meet their fate in the moist meshes of the hair which tringes the vestibule. Germs which have penetrated into the nose are rapidly ejected by the action of the ciliated epithelium." The nasal mucus is an unsuitable soil for the growth of organisms, and hence is an important factor in that it does not further their multiplication. A pure culture of the bacillus prodigiosus was prepared, and a sterilized loopful deposited at a distinct point on the nasal septum well within the vestibule. Cultures were made from this spot every few moments for two hours, with the result of a continually diminishing growth in the culture medium, the sample taken at the end of two hours producing no growth whatsoever.

The foregoing facts emphasize the importance of nose-breathing, and the great danger which arises from the habit of breathing through the mouth and the resultant unfiltered stream of bacteria which is drawn through the pharynx into the trachea and bronchi.

Is Cremation Demanded by Hygiene?—It is urged with vehemence by the advocates of cremation that the present way of disposing of dead bodies by burial is unhealthful and the existence of cemeteries dangerous to those living in the vicinity. In this connection it is interesting to hear the results of the researches made by Professor Wolffhügel, of the University of Göttingen. As reported by the *Courier*, of Hanover, the author stated that this investigation had ended with conclusions shared by men working in the same department at Berlin, Munich, and Göttingen. At all these places special examinations by competent men had been made into the claim that the existence of cemeteries is dangerous. The conclusion in all these cases was that when cemeteries were established and managed in accordance with the laws, there was absolutely no danger to the health of the neighborhood and the principles of hygiene in no way demanded the change from burial to cremation. The author demands that to each grave be given the space of two cubic metres and that it be kept closed for thirty years, although in many cases a body becomes completely decomposed in six years. Then the cemeteries must be so situated that the lower stratum of water, even when it rises highest, must not reach the graves, in which cases drainage must be resorted to. In other respects there is no danger, as the ground absorbs everything, and not even the water which is one hundred metres from a cemetery is in any way in danger of pollution. It is simply ridiculous to claim that the air over the graves can in any way be contaminated by the bodies in these graves.

Exact Dosage in Exercise.—Housework, chores, gardening, walking, climbing, cycling, running, swimming, and many other sports give just the kind of exercise that is indicated in certain conditions, due regard being had to the physiological effects of varying dosage. Oertel has shown how the simple exercise of walking may be adapted to sufferers from cardiac debility by prescribing the distance and speed and the number and length of the rests on definite paths graduated according to their slope. His interesting and original work has not only given a new direction to the treatment of certain cardiac affections, but is destined to have an important influence in establishing accuracy in the prescription of exercise. Whoever has studied the map of the environs of Reichenhall, Bavaria, prepared by Oertel for the application of his method, will acquire a vivid idea of what precision of dosing in exercise means. In this map the different paths suitable for the work are marked in four different colors, to indicate those that are nearly level, those slightly sloping, moderately sloping, and steep, and figures are placed along each route to show the space that should be traversed in each quarter-hour. The locality itself is prepared for its remedial use by placing benches for resting at suitable distances, and by marking on certain trees near the path circles colored to correspond with the map, to indicate the difficulty of that particular section. By systematic practice on the easier paths heart and system are progressively trained and strengthened. Intelligent analysis may do the same work for cycling, horseback riding, and many other familiar exercises. In this way the dosage is practically reduced to a definite number of kilogrammetres in a given time, and a step has been taken in placing the prescription of exercise upon a scientific basis.—*Popular Science Monthly*.

THE DIAGNOSIS OF EARLY PHTHISIS.¹

BY LLEWELLYN P. BARBOUR, M.D.,

TULLAHOMA, TENN.,

PROFESSOR OF MATERIA MEDICA AND LECTURER ON DISEASES OF THE CHEST,
SEWANEH MEDICAL COLLEGE, UNIVERSITY OF THE SOUTH.

By "phthisis" I mean, of course, chronic pulmonary tuberculosis. By "early phthisis" I mean to indicate all that period of the disease previous to the breaking down of the tissues and the production of considerable constitutional depression or infection. Thus it will be seen that I include in the term the conditions usually defined as "incipient phthisis" and "first stage of consumption."

Concerning the importance of an early diagnosis there can be no dispute. Of the curability of consumption there is no longer a doubt. As in every disease, there comes a time in the progress of the case when death is inevitable. The earlier the diagnosis is made, the greater the chance of recovery. Therefore an early diagnosis is of the utmost importance to the patient. It is also of importance to others. That the disease is communicable is settled beyond question. A patient should not, and generally will not, go about spreading the germs of the disease broadcast if he is properly instructed after a diagnosis is made. Therefore an early diagnosis is of vast importance to the community. And here, as a corollary to the above, let me say: whenever we find that a patient has consumption he should be told the truth. Knowing the truth he will much more effectually co-operate, both in efforts directed toward his own recovery and in those directed to the prevention of the spread of the disease.

Notwithstanding the vast importance of an early diagnosis, and notwithstanding the great prevalence of the disease, an early recognition of phthisis is the exception. I am speaking well within bounds when I say that not one case in twenty is diagnosed while yet in an early stage.

This is largely due to the fact that many patients do not consult a doctor till the disease has made serious inroads. But it is also due to the failure of the profession generally to recognize the disease when they are consulted. This statement is an unpleasant, and it may be an unpopular one to make, but it is certainly true. Not long since I asked the supervising examiner of an insurance company how many of his local examiners he could trust to recognize an early phthisis. His answer was "Not one in twenty-five." I could sustain this statement by further quotations from many eminent diagnosticians, but I forbear. This failure of the profession is partly due to want of skill, but largely to erroneous teachings of the past and to carelessness and want of thorough investigation. When there is any reason to suspect phthisis, nothing short of a thorough, searching, exhaustive examination is justifiable.

Method is essential to thorough work in any line,

¹ Read before the Upper Cumberland Medical Society, May 5, 1896.

and as an aid to systematic work it is well to make a record of every examination.

Family History.—A careful questioning as to family history is first in order. While the disease is rarely inherited directly, yet beyond doubt certain families are more susceptible than others, and a history of a considerable number of cases of phthisis, scrofula, joint disease, or chronic diarrhœa should have weight in deciding an otherwise doubtful case. But the tendency of the profession is to attach too much importance to family history. This is the result of former erroneous teachings of heredity. An absence of tuberculous history in the family by no means precludes the possibility of the disease in the individual, and should never keep us from a careful personal examination.

Personal History.—After learning the history of the family, question as to the personal history should be made. A history of joint disease, scrofula, chronic cough, or any other tuberculous disease, increases the probability of phthisis; but the absence of any such disease, or of any previous sickness, does not exclude it. I was taught when a student that previous to phthisis there always exists a condition of ill-health—a pre-tuberculous stage. This was an error. Not only may the personal history of the patient have been good, but he may be in fair general health at present, and still have phthisis. For it is true that a considerable amount of tuberculous deposit may coexist with fair or even good general health.

Briefly, while a bad family and personal history and present condition increase the probability of phthisis, the reverse does not exclude it. Nor does age exclude it. Phthisis is much more frequent in childhood and old age than is generally supposed.

In considering the present condition of the patient, the height and past and present weight should be learned; the appetite, the digestion, the appearance of the tongue, the condition of bowels and kidneys, the amount and quality of sleep should all be investigated; and especially should we make a note of the quality and rate of the pulse, of the temperature, respiration, presence or absence of cough, expectoration, hemorrhage or spitting of blood, and of pains in the chest. With such a record, carefully made and intelligently considered, a correct diagnosis of phthisis can often be made, even without a physical examination.

We will return to a discussion of the rational symptoms after a review of the physical signs of early phthisis.

Physical Examination.—Before beginning a physical exploration of the chest, the patient should be stripped to the waist. I make this an inviolable rule. In an advanced stage the coarse râles, gurgles, cavernous respiration, etc., can often be detected through some clothing; but in early phthisis we have to deal with slight changes and slight differences, and even an undershirt is inexcusable.

With the patient thus stripped, he is directed to stand or sit erect and naturally. The chest is then measured about the nipples both at full inspiration and complete expiration; the opposite sides are measured and a note is made of the result. Next, he is inspected carefully, and then, in order, palpation, percussion,

and auscultation are practised. The presence of any scars indicating former glandular trouble about the neck is noted while inspecting, also the degree of muscular development, amount of adipose tissue, and the symmetry of the chest. When palpating, corresponding regions should be compared. It is well to do this also when percussing. But not too much stress is to be put upon comparison, as both sides are often equally involved. An expert ear must recognize the quality of the normal percussion note.

The finger or plessimeter should be applied firmly in percussion, and the stroke adapted to the condition of the parts. Just how much force should be given the stroke can only be learned by experience. The use of hammer or plessimeter is a matter of individual choice; one can be as accurate without as with them. But in auscultation the stethoscope should always be used. Accuracy is impossible without it.

Initial lesions are sometimes found in all parts of the chest, and all parts should be investigated; yet it is in the apices that the earliest infiltrations usually occur, and they should receive especial attention. I make it a rule to begin percussion at the neck, and to first determine the height to which the lungs extend on each side. The height and outline of the apices are surprisingly similar in normal chests and even a slight lack of symmetry is to be regarded with suspicion. The height of the apices can be readily seen by marking with ink or pencil the change from the dull note of the muscle, or the "band-box" note of the larynx, to the note of underlying lung tissue.¹

Pathology.—The pathological conditions of early phthisis are briefly as follows: In its incipency there is more or less deposit or infiltration and no general symptoms are present. We do not often see a patient in this condition except accidentally, as in insurance examinations. Sometimes this deposit becomes considerable, as I have said before, without giving rise to symptoms or in any degree impairing the general health. On the other hand, even a slight deposit will sometimes produce a localized bronchitis, a lobular pneumonia, or a circumscribed pleuritis. Before the area of infiltration becomes very large it usually does produce some one, or two, or all three of these complications. The bronchitis of early phthisis is usually of the smaller tubes. There may or may not be some hemorrhage from the first deposit. This depends upon whether or not there is much obstruction to the blood-vessels, and whether or not the vascular walls share in the tuberculous process. As the degree of consolidation becomes greater the tissues begin to break down and ulcers or small cavities form. This marks the beginning of an advanced stage. But sometimes this destructive process begins while the area of infection is yet small, and it may then be fairly included within the pathology of early phthisis, especially if the general health is not much affected. Usually the lung tissue is involved in the morbid process, but occasionally a tuberculous deposit forms on the walls of a bronchial tube and goes on to destruction with little or no involvement of the surrounding lung.

Physical Signs.—From this review of the pathology we can readily see what physical signs to expect. With but slight consolidation we will learn nothing by inspection, mensuration, or palpation, and only a trained ear can detect the changed percussion note—slightly duller, slightly higher.

It takes but little infiltration to weaken the air-cells and impair their elasticity. As a result we have the murmur lessened in intensity, and with a slightly higher pitch. From some cause—I believe because of

nerve involvement of the affected area—we frequently have a jerky or cog-wheel character of respiration. Of course the amount of infiltration may be so slight or it may be buried so deeply under normal tissue that even expert ears fail to detect any modification. One symptom worth something in the detection of early infiltrations, yet not often mentioned, is the transference of heart sounds. If with the stethoscope applied to the posterior apex, the heart sounds are heard with more than usual distinctness, we may well suspect a diseased condition of the intervening lung. Of course allowance must be made for violent heart action.

Even with considerable deposit we may learn nothing from inspection. Or we may, if one side is normal, notice lessened movement upon the affected side. Sometimes, too, there is noticeable flattening about the apex or apices, an appearance as if the neck rose straight from the flattened shoulders. Palpation will now give us noticeable increase of vocal fremitus. Sometimes the increased sense of resistance when pressing upon the apex or between the ribs is marked. The percussion note is decidedly duller and higher, and by auscultation we find the murmur not lessened but decidedly increased in intensity, higher in pitch, and harsher in quality—a broncho-vesicular murmur. If there is a bronchitis we find fine or coarse râles, according to the size of the tubes involved. With a lobular pneumonia, crepitant râles are heard. If there are circumscribed pleurisies, grating, creaking, or rubbing sounds may be heard. Pleuritic friction sounds vary considerably in quality and intensity even with the same amount of pleuritis.

Physical signs are modified somewhat in different parts of the same chest and by the different conditions of the chest walls in different individuals. Thin chest walls give more vocal fremitus, a percussion note more intense, and a respiratory murmur more distinct than chest walls overlaid with considerable muscular or adipose tissue. In the right subclavicular region the vocal fremitus is usually more marked, the percussion note duller and higher, and the respiratory murmur harsher than on the left side. The gland and muscles obscure the sounds in the mammary regions and the scapulæ in the scapular regions.

The value of the physical signs is very great. It is true that there are morbid conditions not of tuberculous origin which give some or all of these signs, but, excepting pneumonia, such conditions are rare, and croupous pneumonia is so easily differentiated as to need only to be mentioned. The other conditions, such as cancerous and benign tumors, hydatids, and syphilitic growths, may, so far as physical signs go, deceive the most expert. But there is usually some clew to the true cause, as for instance the locality. Hydatids are most frequent at the base of the lung. Cancer usually begins at the mediastinum. Syphilitic growths occur in the lower and middle lobe and even in the lower part of the upper lobe, but almost never in the apex. We may in some cases have to rely upon the personal history or finally upon the exploring needle and microscope. But any and all of these causes of consolidation are rare compared to tuberculous deposit, and, given evidence of more or less consolidation of lung tissue, it is safe to assume phthisis unless we can prove the contrary. The same may be said of moist râles, evidence of bronchitis. A chronic localized bronchitis of other than tuberculous origin is possible, but is very rare.

Expert work in physical diagnosis requires skill that can come only after considerable training. The ear must be familiar with all the normal chest sounds, and trained to detect the slightest variations, even as the musician must be familiar with his instrument and trained to detect the slightest jar or discord. It

¹ This method of determining the height of the apex, and the importance of it, were pointed out by Professor von Ziemssen in 1867. Yet it is scarcely mentioned by writers. It seems to me its value is not appreciated.

is different, however, as to a correct interpretation of the general symptoms. This is not a matter of skill, but of knowledge and judgment alone, and is within reach of all. I do not mean to state that a positive diagnosis can always be made in this way. Even an expert, combining physical signs with general symptoms, will often refuse to speak positively without the confirmation of the microscope. But the general practitioner who has a thorough knowledge of the pathological conditions of phthisis, and of its varying clinical history, ought to recognize the very probable existence of the disease at a much earlier stage than is now usual.

Symptoms and Complications.—Pulmonary tuberculosis occurs as a very acute disease, as well as a very chronic one, and with all intermediate grades; and cases in the same grade as to chronicity vary greatly as to symptoms and complications. An accurate description of the symptoms of one case will rarely fit another. No one symptom is always present in early phthisis, but there are not often lacking some two or three out of the group to indicate clearly their cause.

Cough.—As we should expect from the pathology of phthisis, cough is usually the first symptom to attract attention. Rarely, yet not so rarely but that every practitioner must meet them, cases advance quite far with practically no cough, deceiving the patient and his friends, who think there can be nothing the matter with the lungs of one who does not cough. The onset of the cough is as a rule very insidious, so that the patient does not know when it begins. Its character and course are very variable in different cases. It often begins as a slight hawking and clearing of the throat in the morning only. Gradually it becomes more frequent, and the throat clearing is noticeable during the day and night. Sometimes the local irritation of the nerves early produces severe and harsh cough. Again, a bronchitis occurs early and there is a viscid, glairy sputum with the cough. In other cases there is very early breaking down of the tuberculous area, and there is then early expectoration of a purulent or muco-purulent sputum. Oftener, however, the cough is for a long time of a dry, hacking character. It may at first be noticeable only when the patient is about to speak, and sounds like a short, jerky laugh preceding the words. This hacking cough may continue for weeks and months, or it may disappear entirely at times, to reappear now and then for a year or two. After a longer or shorter time expectoration begins.

Sometimes the history of a cough begins with a "severe cold" or an attack of "grippe." In many of these cases, a slight cough preceding the acute attack has probably been forgotten or has not been noticed. In others, the so-called cold was really an acute exacerbation of the early phthisis, and doubtless in some an attack of grippe has lighted up a dormant tuberculous deposit. In all of these cases the cough continues very persistent. The patient says he cannot get rid of his "cold." He may improve some, but the cough persists in spite of cough syrups and what-nots, and after a few weeks or months he consults a doctor.

Cases with such a history are frequently diagnosed chronic bronchitis, but the microscope has shown us that they are almost always of tuberculous origin. Even the absence of the physical signs of some degree of consolidation does not exclude phthisis. A bronchial tube may be the seat of a tuberculous deposit, which though small may cause harassing cough.

Other Causes of Cough.—Other causes of a chronic cough are pregnancy and abdominal tumors pressing upward on the lungs, laryngitis, tracheitis, cancer and syphilis of the lungs, and morbid growths of other parts of the respiratory passages. Not long ago I saw

a patient whose cough of several months' duration was caused by enlarged glands at the base of the tongue. It should be a part of routine work to examine the throat in all cases. By this means we determine whether the throat is a factor in the production of the cough; for the throat is often a complication when not the primary cause. Chronic laryngitis is not infrequent, but most cases of chronic laryngitis are tuberculous and are secondary to phthisis. Tracheitis, tuberculous or non-tuberculous, is rare. I have mentioned the differential diagnosis of cancerous, syphilitic, and other growths in the lungs. In the throat they are not difficult of recognition. Pregnancy and abdominal tumors are easily diagnosed, and their presence must not be accepted without investigation as the cause of the cough. I have not space to discuss coughs of a reflex origin from liver, uterus, or other organ. Such an origin is possible, but far from common, and such an opinion is never justified until every other source is excluded.

Expectoration.—I have said that the first appearance of expectoration varies greatly in different patients. In some the entire first stage is passed with none at all. Usually there is more or less. If there is considerable pneumonic disturbance, the sputum will be of a viscid, gelatinous character. Often it is a frothy mucus. This early sputum is not rarely streaked with blood.

Microscopic Examination.—Whenever sputum can be secured from a patient it should be submitted to a careful microscopic examination. And sputum can often be obtained from those who say they do not expectorate. Only a few days since I secured a sample of sputum and demonstrated bacilli in the case of a patient whose doctor had excluded phthisis because there was no cough, by directing him to clear his throat and spit on a clean piece of white paper when he first awoke in the morning. A sputum examination is of such importance in a doubtful case that the greatest pains should be taken to obtain it. The bacilli are often scant in the non-purulent sputum of early phthisis, and we cannot conclude positively that there is no tuberculosis after one negative examination. But if after several attempts by one skilled in the procedure no bacilli are found, phthisis may be excluded. A good microscope costs considerable money, its successful use requires much skill and takes a good deal of time. For these reasons microscopes will not very soon be as common as fever thermometers, though even more useful. But every practitioner can with little trouble collect a sample of sputum and send it to a microscopist. This should be done a hundred times where it is now done once.

Hæmoptysis.—Next to a cough hæmoptysis is the most frequent first warning of phthisis. Like the cough, it may come to one already in feeble health, yet frequently it occurs while the general condition is good. Not infrequently a case runs its course to a fatal end without hæmoptysis ever having occurred. Families differ in this respect. In some families every case of phthisis will have frequent hemorrhages, while in others there is none. The bleeding of early phthisis is usually slight, not more than one or two ounces. Often it is a mere streak or spot of blood in the mucus. A single attack may consist of only one or two expectorations, or it may continue two or three days, the patient spitting some blood every few minutes during the time. In some cases there is no cough preceding the hemorrhage and none follows. In others there is a dry persistent cough for some time before any blood is raised. Sometimes this cough is relieved by the bleeding, oftener it is not relieved, but continues its course as when no hemorrhage occurs. The color and appearance of the blood vary considerably; usually it is bright red and somewhat frothy;

if it is retained in the air passages any length of time it becomes darker and clotted. Thus we see that all forms and variations of hemorrhages occur in phthisis, and conversely any hemorrhage from the lungs or bronchial tubes is a nearly certain indicator of tuberculosis.

But there are other causes of hæmoptysis as follows:

1. The neoplastic growths before mentioned. None of these are so apt to bleed, even when present, as are tuberculous lesions. The sputa of cancer are of such a characteristic "prune-juice" appearance that they are easily recognized. Besides, cancer of lung is in most cases secondary.
2. A number of acute diseases, the most frequent of which is pneumonia. The history of these is sufficient for diagnosis.
3. Certain dyscrasias, as purpura, scorbutus, etc. Again the history is sufficient for diagnosis.
4. Organic heart disease. The chief forms of heart disease which cause hemorrhage are mitral obstruction and insufficiency, obstruction of pulmonary valves, fatty degenerations, myocarditis—any form of heart disease which leads to dilatation and enfeeblement of the right heart. As hemorrhage from heart disease does not occur until an advanced stage, with well-developed lesions, its recognition as a probable cause of hæmoptysis is easy. And phthisis must not be excluded because of the discovery of heart lesions; for those very lesions which are said to most frequently cause hæmoptysis are the ones that most frequently coexist with pulmonary tuberculosis. Given an equal number of the morbid conditions that cause hemorrhage, and phthisis is the one most likely to do it. But it is more frequent than any of the others. It is, as Flint says, "the cause of the hemorrhage in an overwhelming number of cases."

Spitting blood during the menstrual period—vicarious menstruation—affords just ground for suspicion of tuberculosis. I have watched three such cases for several years and two of them have already developed unmistakable phthisis.

Before making a diagnosis of pulmonary hemorrhage the throat should be excluded as the source of the blood. This is easily done by inspection during the bleeding. It is not so easy a matter after the subsidence of the hemorrhage, but the presence or absence of morbid conditions affords ground for a probable diagnosis. Hemorrhage from the larynx is rare; from the vault of the pharynx it is commoner, but from that locality at least part of the blood will pass through the nostrils. The appearance of the blood, whether clotted or not, does not help. The patient referred to above, whose doctor had excluded phthisis because there was no cough, had spit up blood, which, because it was somewhat clotted and dark, the doctor said came from the throat. Yet his throat is normal, and there is no reason to believe it would bleed. But there is dulness over the right upper lobe, with a harshened murmur, and the temperature rises every evening to $99\frac{1}{2}$ ° F. Such a condition of things, the rise of temperature, the evidences of infiltration, and the hemorrhage make a diagnosis of phthisis almost positive even without the microscope.

Pleuritic Pains.—Pleuritic pains occurring about the upper parts of the chest or beneath the scapula are significant of phthisis. They are symptomatic of the circumscribed dry pleurisies that may occur at any stage of the disease. These pains differ in character. Usually sharp and definitely located, the stitch pain, they at other times give a sense of soreness or of aching, and spread over a considerable area. While pleuritic pains frequently occur during early phthisis, they are by no means constant. Some cases pass through this stage with no pain whatever. Thus the absence of pain has little weight. And the diagnostic value of its presence depends largely upon the coincidence of other symptoms. Considered alone, a pain in the chest has no such significance as a hemorrhage

or a chronic cough, for the pain occurs much more frequently from other causes than do the other symptoms. The neoplasms already mentioned as sometimes producing cough and hemorrhage, may also produce pain. More frequent causes of pain in the chest are intercostal neuralgia and pleurodynia. The pain and tenderness of intercostal neuralgia are usually located at three points—near the exit of the nerve from the cord, in the axillary region, and near the sternum. Pleurodynia more closely resembles pleurisy, but usually occurs in those subject to rheumatism in other parts of the body also.

I have found intercostal neuralgia frequent in the phthisical and suggest it as of some value as an early symptom.

The Temperature.—The study of the temperature in phthisis is always very interesting. It has a variety of causes and shows all grades of intensity. The principal causes are, first, the absorption of the toxic products of the tubercle bacilli; second, the reactive inflammation of the lung tissue; third, the absorption of the septic products after infection by pyogenic germs. The first is the most frequent cause of fever in early phthisis, the second often uniting with it, but the third or septic cause is only added after the tissues begin to break down. Thus, the high temperature with chills, very marked remission, and profuse sweating so characteristic of advanced phthisis, never occur in the first stage. There are exceptional cases of phthisis in which the inflammatory reaction is so slight, and the bacillary advance so slow, that the system becomes accustomed to the toxins and no fever results until destruction and septic absorption take place. This oftenest occurs in the so-called fibroid phthisis. Absence of fever, therefore, denotes a slow advance or entire arrest of the disease. Periods of arrest are frequent during early phthisis and a diagnosis that excludes phthisis because of a normal temperature may be at fault. There are very few cases, however, in which there is not more or less rise of temperature at times during the first stage. Even in the very chronic conditions and during periods of arrest, the presence of tuberculous trouble is quite sure to cause some fever after physical or mental fatigue or worry. It is a good plan, in otherwise doubtful cases, to keep a record of the temperature taken at intervals of two hours, for ten or twelve days, and to require exercise to the point of fatigue several times during this record making. A rise in temperature of one or two degrees following this exercise, even though normal at other times, is, other diseases excluded, a reliable indication of incipient phthisis.

A daily fever, though ever so slight, denotes progress of the disease, and it is at such a time that the patient most frequently consults a doctor. And fortunately diagnosis is then easiest, as other symptoms are more pronounced.

In the great majority of cases there is a slight but persistent fever. The temperature rises only a degree or a degree and a half above normal, but stays there day after day, week after week, even month after month, with a steadiness not equalled in any other disease. There is some daily remission, usually in the morning. The amount of the remission varies in different cases. The range may be only from 99° to $99\frac{1}{2}$ ° F., or 100° F., or at times it may go somewhat below normal in the early morning, to surely rise again in the evening.

Accompanying the fever there is more or less loss of appetite, coated tongue, slow but progressive loss of weight, a feeling of languor, and general malaise. Sleep is broken and restless. The patient rises even more worn and haggard than upon retiring, and looks with dread upon the day's duties. Sometimes there are considerable exacerbations of the fever, the tem-

perature going to 101° F., or 102° F., or higher. Any such increase of fever should be looked upon as probably caused by destructive change and septic infection, and as marking the end of early phthisis. But sometimes these higher temperatures fail to show the marked remission of septic fever and occur when there is no tissue destruction. Such conditions are caused by considerable extension of the inflammatory action. These inflammatory fevers are frequently mistaken for light cases of pneumonia. They are diagnosed from croupous pneumonia by their lobular and not lobar extent, by want of crises, and generally by a preceding history of the lower fever and accompanying symptoms which I have described as so characteristic.

The mistaken diagnosis of malaria is often made of the fever of early phthisis. There are times perhaps when to one not skilled in physical examination the decision as to whether it is malaria or not must be doubtful. But such instances are very rare. Possibly in such cases the inexpert method of diagnosing by the use of quinine would be justifiable. The points of difference as to temperature alone are these: a fever of malarial origin almost always rises during its exacerbations at least to 101° F., while 99½° to 100° F. is the usual height in early tuberculous fever; the exacerbations of malarial fever usually occur during the morning, while the tuberculous fever reaches its highest in the afternoon.

And accompanying the temperature of phthisis there is cough, or hemorrhage or pain in the chest, or other symptoms which direct very plainly to a diagnosis. It is carelessness of investigation, or blindness to the significance of symptoms, that leads to so many failures of recognition.

Indigestion and Anorexia.—Loss of appetite is significant of phthisis only when it occurs in connection with other symptoms. Failure of digestion is of more importance. Indigestion, especially of the fermentative form, is a very frequent complication of early phthisis. More often than any other trouble it precedes phthisis.

Loss of weight has no absolute value in diagnosing consumption, but speaks in supposition of the disease when considered with other symptoms.

Pulse and Respiration.—Respiratory movements are not necessarily increased in early phthisis. When there is rapid respiration it is due to anæmia or to febrile action and not to the slight decrease in lung area. The circulation is more sensitive to the diseased condition and a considerable acceleration of the pulse is frequent, even with little or no fever. Especially is this true when there is coexisting anæmia. A rise of temperature is marked by a corresponding increase of pulse rate. There are cases in which a weak heart is a very evident predisposing cause of the disease, and in these the rapidity of the heart action is very marked.

Anæmia.—Anæmia is sometimes found in early phthisis. Writers have tried to prove that anæmia is a characteristic pretuberculous condition. That anæmia does increase the liability to tuberculous infection cannot be doubted, but too many cases occur without preceding anæmia to justify this view. Anæmia is usually a result rather than a cause of tuberculosis, and is a characteristic of an advanced rather than of an early stage.

Laryngeal Symptoms.—Laryngeal tuberculosis is in most instances a complication of advanced phthisis. It does sometimes occur early, and cases are reported with the primary lesion in the larynx. Such cases must be extremely rare. Expert examination has in the most of the reported cases revealed more or less pulmonary invasion. Laryngeal tuberculosis must be accepted as almost conclusive proof of preceding phthisis.

Other Symptoms.—Repeated chilly sensations, flashes of heat, proneness to "take cold," all these are symptoms which occur in early phthisis, and are of some value in connection with other evidence. With malaria excluded, a persistent coated tongue gives ground for a suspicion of phthisis.

While the different symptoms have greatly differing values, while some of themselves have little weight, yet all should be considered, as all are of value in relation to other evidence. Some standing alone are of great importance; a long-continued cough for instance, or a persistent slight rise of temperature, or a hemorrhage from the lungs, or a circumscribed pleurisy, each of itself affords good presumptive proof of phthisis.

But the value of any symptom is greatly enhanced by confirming symptoms, and even the minor ones may by their number become very conclusive. Thus, as I said in the beginning, by considering the totality of the symptoms a very probable diagnosis of early phthisis can often be made, even without skill in physical exploration. The physical signs are of course always very strongly confirmatory.

There is one evidence of tuberculosis that violates the axiom that a diagnosis is never to be based on a single symptom. It is the appearance of bacilli. No other evidence is needed when bacilli are found by a careful microscopist. This method of diagnosis is of such great importance that I want again to urge a resort to it in every suspected or doubtful case.

And again I want to plead for more watchfulness for the first appearance of this disease and for more care in investigating. Could every case be recognized in an early stage, this king of diseases would be robbed of most of its terrors.

NEURASTHENIA AND ITS RATIONAL TREATMENT.¹

By G. BETTON MASSEY, M.D.,

PHILADELPHIA.

NEURASTHENIA, or the "American disease," first described by the late George M. Beard, of New York, some twenty-five years ago, has since been the subject of much study and many treatises in several languages, as physicians the world over recognized that its occurrence was by no means limited by political boundaries, nor even by the existence of the environments of a new country. That it is peculiarly a disease of modern civilization, even though described to some extent by Burton in his "Anatomy of Melancholy," mainly manifested under conditions of mental high pressure, is but another way of saying that it is one of the penalties of that evolutionary development under which society is continuously progressing. A failure to attain a full correspondence with one's environment is shown by that momentous individual disaster, insanity, and though there is rarely any connection between true mental disease and neurasthenia, sufferers from the latter condition should note the hint it conveys of a lack of coequal exercise of the mental and animal capacities of the individual.

For there can be no question that neurasthenia is a symptomatic manifestation of an imperfect performance of all or nearly all of the organic functions of the animal life, causing perversion of the nutrition and functioning of the nervous system. Though it may be caused by a sudden mental shock, such a causation is unusual and the cases in which it occurs are more nearly related to hysteria. The common cause assigned to it—excessive mental occupation due to the

¹ Read before the Philadelphia County Medical Society, November 13, 1895.

claims of business or society—is but relatively true, for in a normal condition it is not work but worry that kills. In the abnormal conditions of alimentation and excretion which are probably the primary cause of neurasthenia, a persistence in any occupation requiring a high grade of mental work or irregular hours becomes a persistence in relative overwork, though the same exertions may be harmless under more normal conditions.

This view that assigns the many functional derangements of the nervous system comprised in neurasthenia to an auto-intoxication due to an imperfect performance of the abdominal functions is gaining ground, and is evidenced by the recognition of lithæmia in many cases in association with the nervous symptoms.

An enumeration of the symptoms of neurasthenia would occupy more time and space than are at my disposal. Considered as a whole, the subjective symptoms usually display in a most varied way a more or less pronounced inability to perform with personal satisfaction the various tasks imposed upon the individual by the necessities of a gregarious existence. Of objective symptoms the most pronounced are due to disordered action of the sympathetic system of nerves, disordered circulation, and general metabolic sluggishness.

In the treatment, the main purpose should be to arouse the defective activities of the sympathetic and of the organs under its control. The effectiveness of peripheral applications, such as the cold bath of momentary duration or applications of static electricity, in restoring circulatory and nutritive control, is no argument against the abdominal origin of the malady, as these agencies exert powerful afferent effects upon the sympathetic ganglia as well as upon the cerebro-spinal centres of innervation. Of this nature are also massage and electro-motor stimulation of the limbs and body surface, with the added advantage of a stimulation of the local circulation, nutrition, and tissue metabolism. But, unless the abdominal sympathetic system is directly reached, the worst of these cases will fail of complete remedial alleviation, and dissatisfaction will result to both patient and physician.

Rest and regulation of the diet added to these peripheral stimulations will do much for some of these cases, but will be lamentably ineffective in others. The importance of rest alone has been enormously overrated, so much so, indeed, that hundreds of patients who have done nothing but rest all their lives are put through a costly treatment by their physicians under an inordinate belief in this shibboleth, only to find their neurasthenic symptoms made worse by the burdensome effect of temporary additions of fat, or their melancholic symptoms intensified by a prison-like confinement. In this city alone a number of such patients have leaped from their bedroom windows. The fact that partial rest each day away from home and under the surroundings of a well-regulated sanatorium is a most valuable portion of the treatment, will not make rest at the patient's home or in a boarding-house of equal effect. Shorn of its institutional setting, change of surroundings, and the expectancy that occurs when a number of cases are treated together, this feature of treatment is more often harmful than useful. Rest and surface treatment alone in lounge-ridden cases is much like certain farming that is observable in the far South, where activity of soil cultivation is not a fault and where the surface scratching of superficial farming fails to supplement the rest in producing good crops.

In neurasthenia the causal conditions should be stirred from the foundation by appropriate medication and applications to the abdominal sympathetic. Electricity applied directly to the abdominal organs is a most valuable means for accomplishing this, and it

should be supplemented by appropriate doses of exercise as well as rest—the rest to follow each dose of electricity or mechanical exercise.

Electricity has been used for years in the treatment of this condition, particularly in Philadelphia, but it is to be regretted that its use has partaken so largely of the antiquated Duchenne methods as to be closely analogous to the soil-scratching methods of farming alluded to, and equally imperfect in results. Even when retained in the hands of the physician or an intelligent assistant, these methods are merely a peripheral excitation and fall far short of the possibilities that have been demonstrated by modern electro-therapy. Unfortunately, the battery is often relegated to the nurse under instructions, which lessens still further any good results it might give.

Aside from this assumption that an agent of this nature, which is just now being rapidly developed in all directions, can be employed properly by unskilled persons, the faults of the Duchenne methods are: Too great a reliance on the limited value of faradic currents; the use of electrodes of inadequate size; insufficient current strengths for an effective penetration; and failure to apply currents of proper density to the abdominal ganglia and viscera.

The excellent results derived from galvanic currents of fifty to one hundred and fifty milliamperes in the abdominal applications of the Apostoli method first directed my attention to the value of large electrodes and considerable currents in these conditions. As a result of these gynecological applications an increased general health is almost invariable, which is largely due to the necessary inclusion of the abdominal structures in the field of the current. Equally good results in the stimulation of the sympathetic may be obtained by placing the indifferent electrode beneath the back, in the shape of a very large wired-cotton pad, and the active one, which should be six or seven inches in diameter, on the abdominal surface. A greater effect is obtained if the active electrode is given a circular motion, being lubricated by soaping, as all portions of the abdominal contents are thus successively brought under powerful electric stimulation. The effect on secretion is often noticeable.

The peripheral applications are also best made by the galvanic current instead of the faradic, the patient continuing to recline on the large pad, while the smaller one, which is to be negative and well soaped for lubrication, is carried over the motor points of each limb and the trunk in a labile manner, all shock or unpleasant sensations being avoided by the free use of the controller. From fifteen to thirty-five milliamperes will be sufficient to produce ample contractions. A general motor stimulation of all the voluntary muscles is thus easily gained, as with the faradic current, with a greater excitation of the peripheral nerves and cellular activities. The sense of exhilaration is more marked than with the faradic current, and greater warmth of the extremities is produced.

With scientifically applied currents as the principal feature of the treatment, other measures are conjoined as required, including massage if the bodily condition is much below normal, and rest for at least an hour after each general treatment. In certain cases thus treated the diet requires but little attention, and even office treatment is often satisfactory, supplemented in either case by any indicated remedy by mouth. The final result is apt to be a far more lasting acquisition of healthy blood and flesh than if the main feature of the treatment were rest and overfeeding alone, which is so liable to cause a weakness of the heart muscle due to incipient fatty degeneration.

In some cases, however, in which the nutrition is decidedly at fault, absolute rest may be used with great advantage for a time in connection with the other rem-

edies, but if the electrical treatment be of the kind described, the duration of absolute rest need not be greater than two weeks, to be followed by two to four weeks of the electrical treatment under the rest-and-exercise plan before the patient returns to the active affairs of life.

The value of this modification of the "rest cure" has been attested by a number of years' successful employment without a single failure, though previous experience with the rest and overfeeding method resulted in a number of partial failures to permanently cure the patients.

On re-entering active life the former patients should remember that their indisposition was not one that had been acquired accidentally, but was the result of an imperfect response of the vegetative life to the particular environment, and while a continuance of the accustomed mental efforts may be conducive to a healthy will power, nature admonishes them to seek a broader physical life and to minimize the effects of artificial surroundings by spending a larger portion of each year in closer communion with themselves.

Conclusions.—1. Neurasthenia is a disease of abdominal origin primarily and evidences a lack of correspondence between the mental and vegetative life of the individual.

2. The treatment should embrace measures for arousing the defective activities of the sympathetic system of nerves as a principal feature.

3. Strong galvanic currents to the abdomen and general galvanic stimulation are preferable to the routine methods of using the faradic current now prevalent.

4. The tendency to overrate the importance of rest has led to a distinct abuse of this feature of the treatment of neurasthenia, which is of but limited importance with those who have led a sedentary existence.

SPRAINS OF JOINTS AND THEIR TREATMENT.¹

By JOHN F. CULP, M.D.,

STEELETON, PA.

MR. PRESIDENT AND GENTLEMEN: I have taken for my subject this afternoon one with which every practitioner of general medicine has more or less to do, though I venture to assert there are few injuries which meet with so little consideration in their treatment as do sprains. It is impossible to overlook open wounds because of bleeding and pain, and in fractures we know we must do certain things in order to get a good result. Because of their common occurrence, however, we are so apt to overlook the importance of sprains, though the amount of damage in these injuries is often greater than it is in fractures. A sprain has been defined as a temporary dislocation. As a matter of fact, in most cases this is just what it is. The only difference is that in the dislocation of a joint, muscle, or tendon, these structures which are torn apart remain displaced, while in a sprain they resume their natural relation after the injury. When we consider the amount of damage to the structures of a complicated joint as the result of a bad sprain, and then contrast the half-hearted, inadequate treatment which is so often given, we need not be surprised that our results are so frequently unsatisfactory to our patients and ourselves. Constitutional causes, such as gout or rheumatism, and in some people a feebleness of the power of repair, have, it is true, much to do with the final result; excluding these, however, there are few injuries which yield more readily to the proper treatment, if we only observe two things. These are,

first, to begin treatment at once: second, to see that our treatment is carried out in a thorough and systematic manner. One great mistake that is often made is to consider joints as made up of many different structures, all of them being separate and distinct from each other and with different and independent functions. Throughout the whole of life the very closest sympathy exists between the various component parts of a joint, so that it is impossible for one part to be injured without at the same time involving the other structures. As a natural result it must follow that sprains can never be the simple things which they are often considered to be. The immediate effect of an accident may, as it often does, fall on a joint; it can never, however, be limited to it. The capsule of the joint is opened up and its interior filled with blood. The cartilages are bruised and the ligaments are torn, while the muscles and tendons which surround the articulation are strained and lacerated; and together with all this there is such a general extravasation into the surrounding tissues that it is often weeks before the effused material will disappear. If by chance, however, only one of the component parts of a joint is injured, such as a ligament, it is impossible for the other tissues to remain unaffected during the changes attendant on its repair. It is only by taking a broader and more comprehensive view of the structure of joints and by regarding them as wonderfully complex structures that we can get a just idea of the true nature of the damage they suffer in sprains. When we acquire this knowledge, and then only, will our results of treatment be as they should. Before considering the question of treatment of these accidents, it might be well to consider the underlying anatomical causes which are responsible for most of these accidents. The development of the muscular system determines the strength and security of a joint. In quite an extended experience with this class of injuries, it can positively be asserted that the greater portion have occurred in those people whose muscular development was poor. One can almost assert as a positive fact that sprains never occur unless the muscles are either weakened or tired out by prolonged exertion, or caught by some sudden slip unawares before they can recover themselves. Speaking generally, it may be said that sprains are the result of a twist so rapid and sudden that recovery cannot take place in time. Naturally, this condition one would expect to find in one with weak muscles or in those in whom the muscles have been tired out by prolonged exertion, and who from fatigue have lost their instinctive vigilance and power of recovery so essential to the safety of a joint. The muscles are really as much a part of a joint as the bones and ligaments. The function of a joint is movement. Considering the way in which sprains interfere with this, the muscles which direct and execute these movements are as much concerned as the ligaments, which have only the passive mission of checking them when they become excessive. The question of diagnosis is, generally speaking, not difficult, though in sprains of some of the complicated joints it is often by no means easy.

Dislocations.—Fractures near joints and in children the separation of the epiphyses of the bones must all be excluded. Without an anæsthetic in the severe sprains of the larger joints it is often impossible to make a positive diagnosis. More than once have I etherized with the idea of reducing a complicated fracture and have found a sprain instead. The pain of a sprain is of a peculiar sickening character. Indeed, it is so sudden and often so severe as to cause strong men to faint. Muscular sprains are, as a rule, distinguished by a peculiar sensitiveness of the skin, most marked over the joints or at the point of attachment to the bones or tendons. Very often after the

¹ Read before the Dauphin County Medical Society at Harrisburg, Pa., March 3, 1896.

joint has almost recovered from a sprain, and an imperfect diagnosis or no diagnosis has been made, we can clear up the matter, with some joints at least, by carefully observing the tender points. A tender spot just back of the greater trochanter nearly always affords valuable information as to a hip-joint sprain. In the knee this tender spot is toward the under side of the knee cap slightly below the joint centre. With the ankle joint, while the sprain is constant, its location is not so constant, though it is usually toward the inner side of the external malleolus. The tender spots probably generally mark the location of adherent bands or perhaps roughened synovial fringes, or sometimes spots where there has been extravasation of blood into the joint capsule.

We now come to the question of treatment, and our results will depend on the earliness with which we see these cases, and on the thoroughness with which we carry out certain fixed indications. These indications are just three:

- 1st. To limit the extravasation of blood and lymph.
- 2d. To promote the absorption of effusion.
- 3d. To promote the healing of the torn structures, and to restore the usefulness of the joint.

We can best control the extravasation due to broken blood-vessels by local applications, by placing the joint in the proper position and by the use of judicious pressure and thus securing rest for the joint. One of the best local applications is cold water, but strange to say in most cases we do not usually get satisfactory results from its use. This is because we do not see our cases early enough. Unless they are seen within one or two hours after the injury, or unless later in the case inflammation sets in as a complication, cold applications do not answer as well as do hot ones. Soaking the part in very hot water in these delayed cases not only relieves the pain better, but it seems to produce a more permanent impression on the swelling. The various other local applications almost invariably owe whatever virtue they possess to the spirits they contain. We can, however, make an exception with the old time honored lotion of lead water and laudanum. Much may be done to check the bleeding from torn vessels by placing the articulation in such a position that the joint cavity is diminished. If left to itself, in most sprains we find the joint in a condition of considerable flexion. While this position gives the most comfort temporarily, it conduces to a continuance of the bleeding, because it enlarges the joint cavity to its full extent. We can rely on the judicious application of pressure, however, not only to limit the amount of effused material, but to relieve the pain as well. Pressure as usually applied by bandaging does more harm than good. The bony prominences which do not need it receive the support, while the hollows and irregularities about the articulation do not get any at all. It has been my practice to loosely envelop the joint with a couple of layers of absorbent lint which has been saturated with a lead-water and laudanum solution. Over this a good thick padding of cotton wool is applied, care being taken to make it thicker over the hollows and irregularities. Well-picked oakum is a good substitute for the cotton. A bandage carefully applied over such a dressing will make the ideal compression and support. Sprains of most joints, when treated with proper local applications, position, bandaging, and rest, do not require a splint. It is good routine practice, however, to exclude from this the knee and the elbow, the two most complicated joints. It is well in these sprains to apply a felt splint if the injury is at all severe. Just how long we should give these injured parts rest without disturbance is often hard to determine. Probably most joints are rested too long. Rest in these cases is a necessity, and while it is the first indication in this class of injuries, as well as in all

others, yet a time comes when rest can be carried too far. After the subsidence of the swelling, in most cases we can begin movement within three or four days. Unless we have to deal with a rheumatic or gouty subject, this, as a rule, is not too early. Acute inflammation, so often dreaded as a complication, rarely comes on as a result of early movement. We must, however, know just what damage has been done before we begin to move a joint, or we may make matters worse. For example, in making passive motion in a sprain of the ankle, where the external lateral ligament is so often torn, it would be bad practice to adduct the foot. If, after cautious and well-regulated movements, the joint swells and becomes tender, it is well to wait at least a week or more before resuming movement. The second indication in treatment, *i.e.*, to promote the absorption, is to be met to a great extent by bandaging and rest. After two or three days, soaking the joint in hot water, or, better still, a strong solution of vinegar and salt applied just as hot as can be borne for ten or fifteen minutes, three times a day, does much to soften and absorb the coagulated effusions. These baths should be followed by frictions with some good stimulating liniment, the rubbing being done firmly but gently in the direction of the return current of the lymphatics. It is a most excellent practice to begin these frictions above the seat of the injury in order to empty the absorbents, so that they may the better accommodate the lymph from the injured tissues. This lymph is probably more viscid than that found circulating in normal vessels. If after ten days the thickening about the joint has not disappeared and there still remain tender spots in moving the articulation and on making pressure, counter-irritation by iodine, or, often better still, by a fly blister, is indicated. In two weeks' time, with the treatment outlined, we will nearly always find the joint which has been quite severely sprained in good condition and ready for work. At this period sometimes, however, owing either to the severity of the injury or to some constitutional peculiarity, it remains painful and insecure, and even the slightest movement may cause acute suffering with swelling. The joint structures are in a condition of subacute congestion. What is now needed is absolute rest, and rest must be had or there will be a long history of disability, which may become permanent. A plaster-of-Paris splint will nearly always give the required rest. Put on properly, it will last at least a month, when, as a rule, it should be taken off and the joint examined. It may be necessary to reapply this splint one or more times, though usually four to six weeks of this treatment is enough. We are now in great danger of carrying our rest too far, and it often requires the nicest discrimination to tell when to begin forcible movements. Forcible movements are movements made with some force, let us understand, and when we are of opinion that they are necessary to break up any adherent bands and to restore motion to the joint, they should be carried out in a thorough manner. Half-hearted, inefficient attempts do more harm than good, and, by producing pain and swelling without getting motion, often doom the joint to still further rest, when rest does positive harm. The trouble at this time is to a great extent in the muscles, which really are the true ligaments of the joint. Frictions with stimulating applications, together with the use of electricity, are extremely useful in restoring their tone and strength. The faradic current in these conditions is probably more generally useful than the continuous current, especially if there be simply muscular wasting and stiffness without much pain. When there is marked tenderness accompanying atrophy, the galvanic or constant current meets the indications better, not only improving the nutrition of the muscle, but removing the pain as well. Thus does the joint, which is other-

wise perfectly normal, often remain weak and uncertain simply because of this lack of muscular tone. Our attention cannot be too strongly called to this state of the muscles, which it seems is so frequently overlooked. The various elastic appliances which are so frequently worn after sprains, have much to do very often with keeping them weak and uncertain. They are of unquestionable value at times, but their indiscriminate use without the proper medical supervision does much harm. Constitutional treatment, as has been intimated, is often necessary: rheumatic and gouty patients often require colchicum and the iodides and the salicylates. Where there is a peculiar feebleness of the power of repair without any special diathesis, iron and strychnine are of great value.

In looking over the accident records of a large industrial establishment, the Pennsylvania Steel Company, with which I am connected, I find in thirty-eight hundred cases of accidents, two hundred and sixty-one sprains of all kinds, or an average of one sprain in about every fifteen accidents. These are by no means all that have occurred during this time, this record having been made up only from those which were considered worth recording. The least time for treatment was three days; the longest time eight months. The general average was a trifle over nine days. Sprains of the wrist, the ankle, the back, and the knee were the most common: there being forty wrist-joint sprains, which were under treatment about six days. Knee sprains, while common, are not so numerous as those of the ankle, there being twenty-six cases in this record, which were under treatment on an average of about twenty-three days; of ankle-joint sprains there were seventy-two cases, which got well on an average of about thirteen days. Sprains of the back were most numerous, there being eighty, with an average of eight days for treatment.

These back injuries were with few exceptions markedly cured on the record, though as a matter of fact there are, it seems, few bad sprains of the back which are ever really cured permanently. Time will not permit my taking up the treatment of these back injuries. In the total of eighty cases there was not one in which the spinal cord was seriously involved. The muscles or their tendinous attachments, or the investing membrane of the fascia, were almost invariably the parts to suffer. There were but two cases of sprain of the elbow, and the same number of the hip-joint, while there were thirteen of the shoulder-joint.

New Intubation Instruments.—After reviewing the inventions of Bouchut and O'Dwyer, Dr. Tsakiris gives the results of his efforts in this direction in the service of Chantemesse, and describes the modifications which he has applied to the various instruments (Société d'Éditions Scientifiques, Paris, 1895). These consist in a holder for introducing the tubes and a new extractor. He prefers tubes made of aluminium because they are not so apt to force back the false membrane, are not so readily obstructed, do not interfere with swallowing of liquids, keep in place better than the heavy tubes, are better tolerated by the larynx, do not produce lesions, nor oxidize by remaining in the larynx.—*La France Médicale*, February 21, 1896.

Symphiseotomy.—Among the secondary complications non-consolidation of the symphysis is the most important. It causes functional impotence and lumbar pains; at times, however, it may be followed by no inconveniences.—*Union Médicale*, 1895, p. 489.

THE NECESSITY OF ECONOMY IN NERVE EXPENDITURE.

By EDGAR R. IVATTS, M.R.C.S., L.R.C.P.,

EVANSTON, ILL.

THE various forms of nervous exhaustion or prostration included under the term neurasthenia are so familiar to every physician, and have been so thoroughly investigated by Beard, that it seems somewhat superfluous to say anything further on the subject. It has occurred to the writer, however, that, as in so many cases this condition could be avoided by a little timely care and precaution, it may be worth while once more to point out the real condition of affairs, and to emphasize the absolute necessity of rest, both as prophylactic and cure. A consideration of the dynamic laws of the nervous system in relation to waste and repair helps one in detecting the early indications of exhaustion, and thus in warning the patient at an early stage of the folly of disregarding the obvious rules of health. As pointed out by Herbert Spencer¹ and others, there are in the nerve cell, as in other cells, two opposed processes in continual operation, termed by the physiologists anabolism and katabolism. The relation between the two is of course not a constant one, but fluctuations occur on either side, according to the necessities of the organism. During periods of great activity, the katabolic changes are greatly in excess of the anabolic, and proceed at their expense. During the period of growth in youth, the anabolic greatly preponderate, as also in adult life during times of repose and rest. There is apparently a point of extreme divergence on the katabolic side, an approach to which is compatible with health. That is, the individual can pursue his ordinary vocations to an occasional extremity, and recover expended energies during the ordinary periods of repose.

This point no doubt varies with different individuals, according to their constitutional strength, and also no doubt in the same individual somewhat according to the condition of health at the time. Evidence points to its being less extreme in the case of women than men. As a general rule, most people know when they are tired, and this point is not passed.

The bicyclist goes up the hill until he feels too fagged to go farther, and wisely gets off. The sensible man of business comes home tired, refuses to go out again, and goes to bed early. The busy overworked housewife gets extra help, or her husband sends her off for a holiday to recuperate; and then a working equilibrium is maintained.

But if under stress of business, or from other causes the natural checks or deterrents to excessive expenditure are disregarded, what happens? The supreme inhibitory force called the will, or self-control, is first exhausted, and then follows what might be called a "hyper-katabolism," or exalted action of the subordinate nervous centres, with which every physician is familiar, and which is the first indication and sign of the threatened disintegration. It is analogous to the heightened irritability of the spinal centres, in the absence of cerebral control which occurs in descending sclerosis of the cord. A person in such a condition has for a time an unusual sense of well-being and elation, with increased capacity for work. His ideas flow rapidly and without effort, and his conversation is unusually fluent. Work that at other times would seem a great deal to accomplish seems easy of accomplishment. A prospect that was previously not very inviting now seems rosy.

Such a condition is of course common to ordinary healthy people, but there are indications which show that the normal equilibrium has been upset. The true

¹ "Principles of Psychology."

relation of such persons to their surroundings is to some extent lost, as in a person under the influence of alcohol, and they are borne along involuntarily on the current of their own ideas. There is sometimes a wild restless look in the eyes, reminding one of what is seen in acute mania. There is also an exalted action of the motor centres to be noticed, with some loss of muscular sensibility. Such persons find a difficulty in sitting still, and the ordinary co-ordinated movements are exaggerated so that they move rapidly and continue walking and running up-stairs without feeling tired. When sitting down, a constant shifting of position, or agitated chair-rocking, and general fidgetiness may be noticed. Their only complaint at first is a disagreeable feeling in the epigastrium, probably due to hyperæsthesia. It will be found on inquiry that this display of energy is not being compensated for with food and rest. On the contrary it will be found that the usual sleeping-hours are reduced to three or four, or very commonly there is complete insomnia. They have no appetite for food, and take only a little, perhaps, to relieve the uncomfortable feeling at the epigastrium. Such a condition of affairs precedes many cases of mental disintegration, and is familiar in a more exaggerated form as the early stage of general paralysis and acute mania.

If at this stage the patient comes under a physician's notice, and can be persuaded to alter his or her mode of living by adopting the only rational measures that lead to recovery, rest and food, the end may be averted. Unfortunately this advice is too often disregarded, and as the inevitable reaction sets in, recourse is had to the various so-called "nerve tonics" "to fix themselves up"—too often alcohol, morphine, or cocaine. These are no better than spurs to a jaded horse. Nature has her revenge, and after a certain time, according to the strength of the individual, the reserve is exhausted and there is a progressive depression of the nervous system, spreading from the higher nervous centres downward. All work becomes impossible; a settled melancholy succeeds the previous exaltation; the presence of intimate friends and even of nearest relatives becomes a burden; various forms of emotional weakness, with hysterical disturbances manifest themselves; muscular weakness with fibrillary twitchings, cardiac weakness with fainting, are some of the symptoms of prostrate nervous system.

This is a bare outline of the condition with which we are all familiar under the name of nervous prostration. The progress of events may be rapid or slow, according to circumstances. When it extends over some time, the symptoms displayed are more numerous and often difficult to account for. They have been described very fully by Dr. Beard. It is only my object to emphasize by reference to the dynamic laws of the system, how inevitable the reaction is, and how impossible it is to impede the downfall so long as the exciting causes continue to operate. In a large proportion of cases, as the result of an extended rest, the normal equilibrium is re-established and the patient returns to his or her usual occupation. This means that a considerable rest has to be taken, extending in some cases to a couple of years or more. Every Atlantic liner leaving New York has some of these afflicted ones on board. Most of them are men who have shattered their energies in business. Their very natural excuse is that "time is money, that opportunities cannot be thrown away, and that money would be lost through not pushing business." That is true enough; but they do not seem to consider the time lost in Europe recuperating their health, the opportunities for pushing business that are then lost, and the increased expenditure incidental to travelling. It is quite open to doubt whether they do

not in the end suffer a loss all round. There are some unfortunate cases in which the normal equilibrium is never re-established, and a permanent unstable condition of the nervous system results.

The same law applies to all forms of nervous exhaustion, whether it be that resulting from the general exercise of faculties in business, or the excessive use of any one department of the nervous system. Common examples are seen in the overtaking of children, especially girls in school, too much attention being given to mental development during a period which should be largely devoted to physical growth; or sometimes there is an excess of exercise in both directions. Another form is seen in people of leisure and intellectual attainments, who do too much abstract thinking and self-analysis. Others read too much imaginative literature, especially poetry to excess, and hear too much music, pursuing whatever gives the largest emotional element. The resulting exhaustion can be observed in the gradual deterioration of their taste, which undergoes a gradual decline, seeking for satisfaction finally in the literature of the French decadent school and also in the continual complaint of "ennui" and "boredom."

In reference to this form the following law laid down by Alexander Bain¹ is of interest. "Every emotion whatsoever both exercises and exhausts some one portion of the physical framework of mind. Certain circles of the brain, certain muscles and organic processes are involved in each case, and these are liable to weariness after a time, while by repose they become charged with new vigor. Hence any department that has been severely drawn upon ceases to support the associated mental condition, and every department that has been long dormant is ready to burst forth on application of the proper stimulus."

Dr. Beard attributes the tendency to nervous exhaustion to two causes more than to any other; first, the nineteenth-century competitive feeling, and secondly, the stimulus given to the nervous system by electrical discharge in dry conditions of the atmosphere, when conduction in the air is diminished.

The second is probably more operative in America than is generally supposed. As regards medicinal treatment, he places ergot and the bromides in the first rank, and they are certainly very useful in the stage of excitement. Arsenic he also regards as a very useful remedy in some forms of neurasthenia, as it diminishes sensibility and reflex irritability. There are great obstacles in the way of devising methods of treatment in some of these conditions. The judicious selection of methods is fraught with difficulty to the physician, and it sometimes requires a considerable amount of tact and ingenuity on his part to divert the energies into other channels. Considerable space would be occupied if one were to attempt to describe all the forms of exhaustion in detail. My object is only to emphasize, as has already been done by Beard, Weir Mitchell, and others, the necessity of rest. Proportion is everything in life, and the art of living is to husband our resources, and by distributing our energies to avoid excess in any direction.

Operations on the Impregnated Uterus.—Dr. John A. Murphy says that any one who has seen an operation on the impregnated uterus must admit that there is less difficulty than in the non-impregnated. This is due to the fact that the vessels are larger, the uterine body is lifted out of the pelvis, and the ligaments are more easily reached in the impregnated than in the non-impregnated uterus. The danger following operation would be less if more care were taken to remove all of the placenta and membranes.

¹ "The Emotions and the Will."

A STUDY OF HIGHLY MINERALIZED THERMAL WATERS IN THE TREATMENT OF DISEASE, BASED ON EXPERIENCE AT THE GLENWOOD HOT SPRINGS, COLORADO.¹

By HENRY H. SCHROEDER, M.D.,

NEW YORK.

AMONG the people who crowd the decks of the Atlantic liners seeking pleasure abroad are thousands of invalids who hope to regain health and vigor at the various European spas, notwithstanding that, as Baruch observes, "this country boasts of mineral springs rivalling if not surpassing in virtues the most celebrated ones in Europe, and that if more attention were paid to the hygienic and social conditions at our health resorts, the results obtained would be fully equal to those observed on the continent."

At Glenwood you will find a conscientious and liberal management endeavoring to fulfil these conditions, and, in addition, certain advantages in the climate and in the character of the springs not to be found in any other European or American resort. The results obtained while acting there in the capacity of resident physician have encouraged me to give a brief description of these springs, with their physiological and therapeutic action, which may prove useful to the members of the profession at large, as an aid in deciding where to send their patients. Hayem believes that the treatment at bathing-resorts is capable of producing profound and lasting modifications of the general nutrition, but that the success of the therapeutical effect renders the choice of a suitable place a problem of great gravity. In order to choose wisely, a thorough knowledge of the value of the different resorts is indispensable, as well as a clear conception of the diagnosis and a complete knowledge of the patient.

While the treatment at every resort is usually applicable to a variety of diverse conditions, it is none the less true that it will be found especially appropriate to a certain form or phase of some chronic disease. It may not be out of place to suggest that the family physician, having selected a place which from actual knowledge or from the experience of others he deems appropriate to his patient, may render the utmost assistance to the resident physician and materially aid in the success of the treatment by sending a full history of the case, the diagnosis, and any personal characteristics or idiosyncrasies. Needless to say, he should for the time being surrender the case *in toto* to the resident physician, and impress the patient with the fact that only by confidence in and obedience to the new medical adviser will he be able to receive the full benefit of the treatment.

One of the first questions presenting itself to our minds when called upon to recommend a suitable resort is the climate, for the preservation of health and the treatment of disease by climate go hand in hand with other curative measures. The medicinal properties of a mineral spring, otherwise of great value, may be so modified by meteorological conditions as to be inefficient in the treatment of disease, while the health-giving qualities of a bathing-resort are very materially augmented by the general prevalence of good weather. Generally speaking, dry air is more bracing than moist. It favors tissue changes, improves the digestion and other functions. Moist air, especially if combined with cold, predisposes to gouty and rheumatic affections; or, if combined with heat, the effect is relaxation—the appetite fails and the

functions of the digestive organs and nervous system become impaired.

Glenwood is situated at an altitude of fifty-six hundred feet, in a valley in the midst of the foothills of the western slope of the Rockies. The dryness of the atmosphere in that region is well known, the annual rainfall, including snow, being only fifteen inches. (In the Alps there is a yearly precipitation of thirty-one inches at the Engadine and thirty-nine inches at Davos-Platz.) The surrounding mountains give protection from high winds and the consequent dust, which are so irritating to invalids sojourning on the eastern slope in close proximity to the great plains. Its sheltered position also makes of Glenwood an admirable winter resort. The valley widens at this point so that the precipitous hills do not deprive it of an abundance of sunshine, and the patients find it quite comfortable to exercise out of doors, and even to swim in the great salt-water pool throughout the entire year. At the altitude of fifty-six hundred feet the air is not so rarefied as to cause discomfort or any symptoms of distress. On the contrary, though there is at first a slight increase in the pulse rate and the respirations, the sojourner presently experiences a sense of comfort and ease in his movements. Invalids suffering from non-complicated diseases of the heart and lungs bear the change of elevation as well as do those in normal health, and are able to take physical exercise with increased elasticity and force.

Weber sums up the physiological effects of mountain climates on invalids as follows:

1. Increased action and better tone of the skin; improved nutrition.
2. Increased tone of the heart and of the contractile fibres of the vascular system.
3. Deeper respirations, strengthening of respiratory muscles, increased determination of blood to the lungs.
4. Increase of the quantity of watery vapor and carbonic acid emitted from the lungs.
5. Increase of appetite and improved assimilation of food.
6. The formation of more blood and better nourishment of the different organs.
7. Stimulation of the nervous and muscular systems to greater activity.
8. Improved sleep.
9. Increased tissue change.

The climate, then, although only an adjunct to the other therapeutic agents, is a most desirable one in the treatment of those disorders which it is claimed are relieved at Glenwood, because the qualities of the atmosphere which might be disadvantageous are almost entirely absent during the whole year, while those other qualities, the proper use of which raises the bodily strength and facilitates the restoration of the affected organs and functions, are present.

The mineral springs are about fifty in number, but only a few of these are utilized. These few, however, yield about two thousand gallons of water a minute, a supply seen to be most generous, when we consider that all the numerous establishments at the Hot Springs of Arkansas have to depend on a flow of three hundred and sixty gallons a minute (Walton). The natural temperature of the water is 127° F. Great quantities of H_2CO_3 and H_2S are evolved. $NaCl$ constitutes a large proportion of the salts in the water, but the degree of mineralization is so high that were all the $NaCl$ eliminated there would still remain a sufficiently large percentage of saline ingredients to make it rank with the strongest of mineral waters.

The following is the analysis of the water of the Yampah Spring at Glenwood, made by Charles F. Chandler, Ph.D., New York, June 12, 1888.

¹ Read before the American Climatological Association, at Lakewood, N. J., May 13, 1896.

In one U. S. gallon of two hundred and thirty-one inches of water:

Chloride of sodium	1039.8307 grains.
Chloride of magnesium	13.0994 "
Bromide of sodium	0.5635 grain.
Iodide of sodium	trace.
Fluoride of calcium	"
Sulphate of potassium	24.0434 grains.
Sulphate of calcium	82.3661 "
Bicarbonate of lithium	0.2209 grain.
Bicarbonate of magnesium	13.5532 grains.
Bicarbonate of calcium	24.3727 "
Bicarbonate of iron	trace.
Phosphate of sodium	"
Biborate of sodium	"
Alumina	"
Silica	1.9712 grains.
Organic matter	trace.

1250.0411

Carbonic acid and sulphuretted hydrogen are given off in large amount at the springs.

In addition to the springs there are the natural vapor caves found in the cliffs at the mouth of the beautiful cañon of the Grand River, a few minutes' walk from the hotel. Springs boil up from the floors of these caverns and pour out vapor laden with sulphuretted hydrogen and sulphurous anhydride. A temperature of 112° F. is maintained in the caves by the heat given off from the water. The presence of large amounts of sulphur in the vapor is demonstrated by heavy deposits of that substance in a free state on the walls of the caves, this being probably effected by the mutual decomposition of sulphurous anhydride and sulphuretted hydrogen.

Physiological Action.—It is often claimed that quite as effective results can be obtained from baths of plain hot water as from the use of the water of hot mineral springs, and that the apparent superiority of the latter is due mainly to the change of climate and mode of living. Although change of climate and mode of living are certainly valuable and sometimes necessary adjuncts in the treatment of certain diseases, I am convinced by my experience at Glenwood that there are virtues in highly mineralized thermal waters that the plain baths of hydropathic institutions do not possess. The improvement noted in patients who were residents of Colorado and accustomed to an out-of-door life and fresh air, and in others who had received treatment in hydropathic establishments of high standing without relief, would seem to justify me in coming to this conclusion.

I am unable to give a satisfactory reason for any difference there may be in the relative merits of artificial and natural heat. The experience of Dr. Keyes, from personal observations made at the Hot Springs of Arkansas, may be of some interest in regard to this point. He says: "My own investigations showed me that a foot-bath at 110° F. was impossible. The feet could not possibly be retained in the water at that temperature, a thing perfectly possible (but not pleasant) at home in Croton water. A thermometer held in the mouth while making the attempt to take this foot-bath was raised to 103° F. An ordinary bath at 98° F. was unpleasantly hot, and caused perspiration to trickle from the forehead in streams. The immediate after-effect of the bath (unlike that from an ordinary bath) is one of exhilaration, followed in a couple of hours by reaction and a desire to sleep. The appetite improves under their use and the ordinary functions seem to be performed better than when they are not used by the visitors to the place." If a mammal be placed in a hot bath which is three or more degrees higher than its own temperature, the excretion of carbonic acid and the consumption of oxygen are increased, owing to the stimulation of the metabolism (Pflüger), while for the same reason urea is also excreted in larger quantities (Schleich). It will also be

observed that this increase of urea continues for several days after taking a series of such baths.

It is now well understood that the foregoing effects of prolonged hot and vapor baths are produced by the stimulation of the sensory cutaneous nerves, which exercise an important influence on the most complicated processes of the organism by means of the reflex actions transmitted through the central nervous system. Anything which tends, then, to intensify the stimulation of the peripheral nerves will favor greater activity of the different vital functions. That saline ingredients act as additional excitants may easily be demonstrated by noting the greater redness of the skin after a hot brine bath as compared with its appearance after a plain hot bath. Paalzow's experiments prove that a strong stimulation to the skin produces a reflex conversion of tissue indicated by an increased consumption of oxygen and excretion of carbonic acid. Brunton recommends the addition of common salt to the water to increase the stimulation of the skin and the amount of after-reaction. The gratifying results obtained at Glenwood I fully believe to be largely due to the decided stimulation of the skin occasioned by the extraordinarily large amount of mineral ingredients in the water. Liebermeister, Rembold, Paalzow, and Leichtenstern have been convinced by their experiments that the stimulus of the salts and gases usually employed in balneotherapy is commonly too weak to increase reflexly the conversion of tissue and the production of carbonic acid. "There is no perceptible influence on the beats of the heart," says Leichtenstern, "and no effect worth mentioning on the distribution of the blood, from the use of thermal indifferent baths (those containing a low percentage of salines), to which class most of those applied in balneotherapy belong. On the other hand, thermally indifferent baths (those with only a temperature of 93° to 95° F.) containing salts and gases in quantity may by their stimulation of the skin act as mild epispastics and occasion a slight expansion of the vessels of the periphery." Röhrig and Guntz found that when they immersed a rabbit in a three-per-cent. brine bath with a temperature of 96.8° F., there was a greater consumption (15.3 per cent.) of oxygen and a greater formation (twenty-five per cent.) of carbonic-acid gas, as compared with an equally long stay in a simple water bath of the same degree. These percentages rose higher and higher as the salt bath approached the point of saturation. Thus, the acceleration of oxidation kept pace with the increasing skin stimulation, due to the larger amount of saline constituents of the bath. In the light of such investigations by men of known ability, we may not unreasonably look for the best results, other conditions being equal, from treatment at those springs the water of which has a temperature considerably over 100° F. and a very high percentage of mineral ingredients. The regular immersion in such water in conjunction with vapor baths, by stimulation of the cutaneous nerves, influences the finer processes of metabolism, as well as the secretions, distribution of the blood, movement of the lymph, etc. It is during these changes that pathological products, exudations, hyperplasias, new formations, and toxic agents are drawn into solution and eliminated from the system.

Before leaving this part of the subject, a few words are in place in regard to the action of the sulphur. In the majority of books it is claimed that, in spite of the strong impression made upon the sense of smell by the sulphuretted hydrogen evolved, the amount of sulphur in sulphur springs is really very small. Unfortunately, the volume of sulphurous and carbonic-acid gases escaping from the Glenwood waters has never been measured, but eye-witnesses are always impressed by the large amount which continually escapes,

and the extensive deposits of free sulphur on the walls of the caverns would seem to indicate that the waters of these interesting springs are heavily laden with this constituent. Woods believes that "sulphur baths act by producing an excitant effect throughout the ultimate organic structure, substituting a new and self-limiting action for that previously existing; perhaps, as in the case of mercury and iodine, changing the very structure itself by stimulating the disintegrating process and causing a healthier nutritive deposition in the place of the diseased tissue removed. In other words, they are an alternative remedy." Sulphur baths also lower the morbidly increased irritability of the nerves, and a simultaneous use of the water for bathing and drinking purposes promotes the flow of the secretions, especially the bile.

The vapor in the caves is used to accomplish the same objects as those obtained by the hot baths. The skin stimulation from this vapor is very marked, probably on account of the large amount of sulphurous and carbonic-acid gases contained, as well as from the heat. These gases, with the aid of the watery vapor, are in the best possible form to be absorbed by the skin, and come directly in contact with the terminations of the nerves, producing a powerful stimulating effect on the glands of the skin as well as the rest of the economy, and a most profuse perspiration is the result. In the case of several persons who complained that Russian baths had not been able to excite the sweat glands to a desirable state of activity, a profound diaphoresis was effected by means of this vapor. This effect is found to be very useful in diseases of the skin and in those diseases in which it is desirable to eliminate lactic, uric, and fatty acids, urea, and other products of metamorphosis.

As a Drinking-Water.—The ingredients of the water which are of value for internal use are carbonic acid, sulphur, sodium chloride, and the laxative bicarbonates and sulphates.

The carbonic acid causes a feeling of warmth in the stomach and acts as a stimulant to the mucous membranes, nerves, and muscular fibres of the stomach and intestines, causing an increase of the gastric juice, exciting peristalsis, and improving the appetite. There is also an increased excretion of urine, due to the fact that carbonic acid accelerates the absorption of water by the mucous membrane of the intestinal canal (Voit).

Sodium chloride stimulates the mucous membranes of the body, especially in the gastro-intestinal tract, dissolves mucus in the stomach, increases the secretion of the gastric, intestinal, and pancreatic juices and bile, favors the formation and absorption of peptones, and excites peristalsis. It plays an important part in the diffusion of fluids through the membranes, and its presence is necessary for the solution of the globulins (Landois and Stirling); it also increases the excretion of urea (Voit, Bischoff, Brunton). By the last-mentioned processes the structures of pathological products become loosened, and their albuminates are carried away and converted into the ultimate product—urea (Voit, Flechsig).

Sulphurous mineral waters containing earthy and alkaline sulphates are more or less laxative and diuretic when taken internally, while the sulphurous acid disengaged from them in the body promotes diaphoresis. Stiff (quoted by Baruch) believes that sulphuretted hydrogen has a specific excitant effect upon the sensory fibres of the pulmonary branches of the pneumogastric and upon the cardiac and vasomotor centres, its prolonged use giving rise to paralysis from overstimulation. In this way he explains the action of sulphur water on the respiratory and circulatory systems, on tissue metabolism, and on the secretory and excretory functions.

A study of the effects of the climate, vapor bath, and the internal and external use of the water of Glenwood, shows that these various agents possess qualities in common which render them of value in the treatment of disorders in which the general condition of the patient is torpid, the tissues changes sluggish, the functions difficult to stimulate, and in which the absorption and elimination of pathological products and deposits are desired.

Contraindications.—In the use of such powerful agents caution is always advisable in selecting cases for treatment. Generally speaking, the patients who would be apt to do badly at Glenwood are those suffering from organic disease of the kidneys complicated with degenerative changes in the arteries or hypertrophy of the left ventricle, valvular lesions of the heart by poor compensation or diseased blood-vessels, epilepsy, acute inflammatory diseases, recent hemiplegias, menorrhagia, and metrorrhagia. Patients with valvular lesions with simple hypertrophy and good compensation, unaccompanied by renal or vascular complications, suffer no inconvenience whatever.

Therapy.—The various resources of modern hydrotherapy and balneotherapy have received full attention at Glenwood, the different forms of douches, massage, tub and vapor baths, and a mammoth swimming-pool being resorted to as the occasion requires. Excellent meals and special kinds of diet are provided at the hotel.

Uric-Acid Diathesis.—Ebstein and others have shown that the introduction of urates in solution into the tissues produces local irritation, and that urates in solution give rise to even more irritation than when in the solid form. In the condition generally known as the uric-acid diathesis, it is usually considered that the excess of uric acid is due to some morbid process and that it is not the primary cause of the disturbance; but it is also recognized that the uric acid itself is capable of exciting irritation and doing harm to the tissues, and that it should be removed from the body and its production restricted. That the treatment at Glenwood is most appropriate to such cases seems to be borne out in my own case. For six or eight weeks before my arrival at Glenwood, though my previous health had been good, I had been the victim of the various symptoms that go to make up an attack of uricacidemia, *i.e.*, frequent headaches, acid eructations, coated tongue, constipation, an insurmountable sleepiness after meals, mental depression, and irritability. The treatment consisted of a visit to the vapor cave every other day, the drinking of a glass of the water every morning before breakfast, and frequent swimming in the pool. The daily quantity of urea and uric acid was estimated for twenty days, using the hypobromite test for the former and Salkowski's method for the latter. The food before and during the treatment was about the same, consisting of a simple mixed diet. According to these analyses, the ratio of uric acid to urea at the beginning was 1 to 32. This must be considered an excessive amount of uric acid. To be sure, Haig puts the normal ratio at 1 to 33, but the consensus of opinion appears to be that his methods are at fault. The ratio after irregular fluctuations became 1 to 56 on the twentieth day, this really being about the normal relation of the two nitrogenous compounds. The improvement in my condition after the first week seemed to keep pace with the changes in the ratio, so that by the fourth week I felt as well as usual.

It has been affirmed that some mineral waters have a solvent action upon uric-acid calculi. This I cannot believe, unless the uric acid is in the form of very minute particles. It is quite probable, however, that they interfere with the formation of fresh gravel. When the existence of the stones has been recognized,

the simplest way of dealing with them is to adopt surgical measures for their removal, and after the operation the patient may resort to mineral springs to prevent a repetition of the disorder.

Gout.—The indications to be met in the treatment of this disease are the correction and prevention of the necrotic processes by the establishment of a more complete metabolism and by the elimination of uric acid, as well as the absorption of deposits about the joints. According to Roberts, Garrod, Duckworth, and others, the deposition of crystalline urates is not merely a concomitant to, but is the actual cause of the joint troubles. There are others, however, who dispute this theory and believe that uric acid is the result and not the cause of the morbid processes. Nevertheless, both recommend the time-honored measures to hasten the elimination of uric acid. The treatment of this disorder by means of mineral waters is most suitable and effective, for at the bathing-resort the habits are regulated, the patient willingly submits to irksome treatment, lives in a pure and invigorating atmosphere, and enjoys abundant exercise. There is a remarkable unanimity of opinion in the literature of the subject as to the good results obtained at a suitable resort, and especially at hot sulphur springs. Senator believes that sulphurous waters containing sodium chloride and alkaline and earthy sulphates tend to remove the various disorders which stand in a more or less close degree of causal relationship to gout, either as precedents or concomitants, such as irregularities of digestion, gastric and intestinal catarrh, tendency to acidity, constipation, portal congestion, disorders in the urinary secretions, etc. He is also of the opinion that such waters exert a more immediate influence upon the gouty diathesis and uric-acid dyscrasia, and that permanent benefit is derived from their influence on the exciting disturbances. E. Pfeiffer, of Wiesbaden, having subjected some healthy persons to a series of twenty hot mineral baths, found no essential difference in the amount of uric acid eliminated. After treating gouty patients with the same course of twenty mineral baths, he found that the quantity of uric acid excreted by them was usually diminished fifty per cent. or more. He concluded that thermal waters have a very marked action in the prevention of gouty manifestations, and thinks that the saline constituents in them exercise an important influence distinct from the effect of heat itself, as ordinary hot baths have not the same influence. The mineral waters which exert the most powerful stimulant effect on the secretions and most vigorously promote the absorption of morbid products will render the best aid in attacking the deposits in and around the joints, the inflammatory thickening of the tissues, and consequent articular stiffness, dislocations, and contractions of tendons. The following is a fairly illustrative case:

L. K.—, aged thirty-eight, of Telluride, Col. Two years ago the large toe of the right foot was swollen, painful, tender, and red. The condition disappeared in about two months under medical treatment. A year later the same symptoms came in the great toe of the left foot, then invaded the other toes, and finally the entire foot. The patient was worse in spite of treatment. June 14, 1895, he came to Glenwood with the condition unchanged; he was barely able to walk with the assistance of crutches.

Treatment, tub baths daily at a temperature of 105° F.; all medicine stopped.

July 5th he walked about with some slight help from a cane.

July 10th he went away almost cured, not being able to stay longer away from home.

Chronic Rheumatism.—This disorder has usually progressed so far in patients who seek the help to be found at bathing-resorts that structural changes at-

tended by proliferation and thickening of the synovial and periarticular connective tissues have taken place as a consequence of the chronic inflammatory irritation. The membranous elements of the articulations in many of the cases have become rigid and perhaps coalesced with the soft parts lying over them. In old and obstinate cases the disturbances of nutrition may have extended to the bones and soft tissues surrounding the joints. Motion is interfered with and the adhesions have occasionally given rise to complete ankylosis, which has persisted in spite of all ordinary treatment. According to MacLagan, lactic acid, although not the cause of rheumatism, is present in excess even in the chronic forms of the disease, and causes great irritation of the tissues, which have become more liable to disturbances on account of the inflammatory changes. As a general rule, the disease drags on for months and years, terminating in even the most satisfactory cases in a very imperfect recovery. The general health of these patients is often poor and calls for tonic remedies to improve their nutrition. The most efficacious treatment in correcting the extensive changes just referred to are the mineral baths, which have a good influence on the nutritive processes by dilating the blood-vessels and by increasing the excretion of lactic acid and other products of metamorphosis.

The natural springs capable of producing these effects are always noted for their high temperature. Senator was convinced of the greater value of waters rich in mineral matters, especially the concentrated brine springs, for stimulating absorption. Massage and douches are important factors in the treatment of this disease.

Mrs. McF.—, aged thirty-three, of Fruita, Col. Feet became swollen, tender, and inflamed eleven years ago. At different times almost every joint of her extremities has been affected. Her trouble always became aggravated in the spring, and has grown steadily worse. She came to Glenwood one year ago and took forty-five vapor baths in the cave. She received more relief from this than from any previous treatment, and has been almost free from the disorder until the following spring, when it again recurred. The attack was not so severe as previous ones, although she attended to her duties with difficulty.

June 12th, 1895. Physical examination: Joints of fingers, hands, wrists, and ankles swollen; otherwise normal.

Treatment, vapor baths in the cave every other day for the first week, and then daily; water internally before breakfast.

July 12th she had taken twenty-five baths. All swelling had disappeared from joints; very little pain. She probably felt even better after her return home, as that was her experience before.

Miss P. R.—, aged nineteen, of Denver, in March, 1894, began to have swelling of hands and feet. In the summer of 1895 the joints were very much swollen and painful, but were somewhat better in the fall. The trouble grew worse than ever during the following winter. She was treated in a hospital in Denver without any improvement, so she came to Glenwood, April 29, 1895. At this time her feet and hands were much swollen and very painful, and her muscles were stiff. Locomotion very difficult; bowels constipated; appetite poor. She took tub and vapor baths regularly, and drank the water before breakfast.

June 17th the swelling of joints was much less; she walked better; the bowels were regular and the appetite was good.

July 15th she could walk a long distance without pain; all swelling had disappeared.

Mrs. E. S.—, aged forty-nine, of Philadelphia.

Her present trouble began nine years ago, with swelling of left arm and lower extremities. During the course of the attack large nodules appeared in various parts of the body. This was accompanied by mild febrile symptoms, a good deal of pain, and a red rash. The condition lasted about four weeks and was followed by considerable pain on exertion. Was improved at Clifton Springs by means of baths and wet packs. Since then she has had many attacks, affecting the muscles and joints all over the body. While coming West she had a severe attack at Denver about one month ago, and was confined to bed for three weeks. This time the pain was severe in the region of the sciatic nerve, and the knees and feet were swollen and painful. The patient became improved enough by means of medicines, massage, and electricity to continue her journey to this place, but she was still almost completely disabled.

Physical examination: Aortic insufficiency; otherwise negative.

Treatment, vapor cabinet baths daily, followed by hot douches over the affected parts; water internally before breakfast.

July 12th she went away, feeling almost well. She walked during the last two weeks without assistance.

July 20th a letter was received from the patient stating that she continued to improve.

Rheumatoid Arthritis.—The erosion of the cartilages, the exuberance and abrasion of the bones, the osteophytic formations around the articular surface, and the lesions of the synovial membranes, with the attending deformities, contractures, ankyloses, and atrophies which characterize this disease will fully test the efficacy of any form of treatment. It is safe to say that the majority of patients suffering from aggravated attacks of this ailment, who are able to bear the expense, sooner or later find their way to some bathing-place, after searching elsewhere in vain for relief.

When the patient is comparatively young and the disease has not run too long a course, proper treatment by means of appropriate mineral baths, if persisted in for a sufficient length of time, will be rewarded by gratifying results. In advanced cases, after the patient has reached middle age, the most favorable prognosis we can offer is that the progress of the disease may be retarded and that some of the complicating contractures and other deformities may be relieved. It is important to remember that in this disease the patient is apt to be in a "run-down" condition, and that in such instances drastic measures cannot be too strongly condemned. Local douches of hot mineral water combined with massage are still at our disposal in the treatment of such cases. Rademaker, of Aix-la-Chapelle, has found marked benefit to follow treatment by this means even in advanced cases, the general bath being used when not contraindicated. My personal experience with this affection was confined to advanced and hopeless cases, and although the disability from contractures, etc., was considerably alleviated, they were not long enough under my care to note whether the improvement continued. Some very remarkable results obtained by my predecessor, Dr. Hobhouse, in younger patients with a less obstinate form of the disease, have been reported by Dr. L. R. Morris, in the *New York Medical Journal* for September 28, 1895.

It is of importance to instruct the patients suffering from rheumatism and gout that they will be liable to experience an increase of the pain in the joints while taking the baths. This pain soon departs, as a rule, though in some cases it persists during the entire course. When it does come to an end, however, it leaves the patients in better condition than before, and they will probably enjoy immunity from attacks of

rheumatism and gout during the following winter at least.

Gastro-Intestinal and Hepatic Disorders.—The waters of Glenwood taken internally, aided by their external use, worked well in gastro-intestinal disorders due to catarrh of the mucous membranes, torpor of the muscular coat, and deficient secretion. In obstruction of the portal circulation and catarrh of the bile ducts the drinking of the water, combined with the mineral and vapor baths, bracing air, and exercise, gave the most satisfactory results. Frerichs, in speaking of some of the European spas, says: "They are with difficulty replaced by any other remedies in cases where the jaundice owes its origin to chronic congestion of the liver, with obstinate catarrh of the bile ducts and mucous membrane of the stomach and duodenum, to gall stones, etc."

Although it must be confessed that the evidence of the efficacy of mineral waters and alkalis in dissolving gall stones is inconclusive and their value overrated, there can be little doubt that they improve the general health, lessen the tendency to acid dyspepsia, reduce congestion of the liver, and produce such changes in the bile as to lessen the chances of the formation of fresh concretions.

Murchison believes that solutions of the crystallized salts from natural spring waters do not when dissolved in ordinary water have the same effect as the mineral waters themselves, which contain other substances left out in the process of crystallizing. The same writer is of opinion that the waters are more efficacious when drunk at the springs than when used at home, and that they should be slowly sipped rather than swallowed at a draught. Zowilski (quoted by Murchison) found that sipping liquids not only increased the quantity of the bile, but caused it to be secreted under greater pressure, so that the secretion still occurred when its flow into the duodenum was obstructed. Following are a few of the cases treated:

J. L. S.—, aged sixty-one, Buffalo Springs, Col., is a cattle ranchman accustomed to outdoor life; yet in August, 1892, he became the subject of attacks of dizziness and vertigo. This was accompanied by eructations of gas and acid regurgitation. He vomited from one to three times a day. Insomnia from epigastric oppression was marked and constipation was very obstinate. His weight was reduced from one hundred and twenty-seven to one hundred and eight pounds. Coated tongue, bad taste in mouth, poor appetite, sallow skin. He came to Glenwood in December, 1894, took cave baths and drank one pint of the water before breakfast daily. His bowels soon became regular and after twenty days' treatment he could eat anything. He gained twenty-six pounds in fifty days. He then slept well and all depression and anxiety had disappeared.

Mrs. S. R.—, aged twenty-three, of Denver, has had indigestion since a child. It began to be severe when she was fourteen years of age. Her symptoms were eructations of gas, acid regurgitation, flatulence, rumblings of gases in the bowels, bad taste in the mouth, constipation, frequent abdominal pains, distress after eating, and insomnia. Sometimes she passed stringy mucus from the bowels. She came to Glenwood on June 1st, drank the water daily before breakfast, and took tub baths.

June 3d all symptoms of her trouble had gone, and she had a good appetite and slept well.

Mrs. W. E. C.—, aged thirty-five, of Boston, has suffered every spring from attacks of catarrh of the bile ducts and intestines. The attack for which she sought treatment began in latter part of March, with constipation, loss of appetite, mental depression, lassitude, fermentation of food, and headaches. The patient did not improve in spite of medicinal treatment

and daily exercise consisting of walking and horseback riding. She arrived at Glenwood on June 9th, somewhat jaundiced. Treatment consisted of drinking the water before breakfast, daily cabinet baths, douches over the region of the liver, and massage.

June 18th the patient left entirely well. Her sallowness was all gone, and she had regained her natural cheerfulness.

D. C. S.—, aged thirty, of Philadelphia. His trouble began in August, 1894, with severe pain in the right iliac region and constipation. The stools contained a great deal of mucus and flatulence was marked. He had lost thirty pounds. He had tried lavage and had taken hydronaphthol, bitter tonics, and laxatives, yet there was no appreciable improvement.

Treatment at Glenwood commenced on July 3d, and consisted of two glasses of the water before breakfast, cave baths every other day, and moderate exercise.

August 10th the bowels were regular; he had had no flatulence for some time and felt invigorated and healthy; the complexion was clear.

Diseases of the Skin.—The waters and vapor of Glenwood possess to a remarkable degree the property of unctuousness. While immersed and for some time after taking the baths, the skin has a peculiar feeling of smoothness, as if it had been anointed with some very fine bland oil.

Hot sulphur baths should never be used in acute cases or in acute stages of chronic cases. The best results are obtained in the torpid or terminal periods of chronic cutaneous disorders. Sulphur seems to have a real influence over the functions of the skin. Aside from its use as a parasiticide, it is beneficial in those affections in which general excitement is wanting and the local disorder has subsided into the obstinacy of habitual wrong action with very little or no tendency to acute inflammation. The hot baths soften, macerate, and cleanse the scales and crusts of the epidermis, stimulate the production of healthy skin, and improve the functions of the tissues. Not only are the local disorders relieved, but the functional and other disturbances causing them are removed or improved by the general tonic effects of the treatment. Senator especially recommends hot sulphur baths when the gouty state is complicated with affections of the skin. The cutaneous disturbances which have received most benefit at Glenwood are chronic eczema, acne vulgaris, psoriasis, seborrhœa, and the chronic scrofulous exanthemata.

Mrs. J. F.—, aged fifty-three, of Des Moines, Ia., had had occasional slight attacks of rheumatism and periods of nervous depression. Last winter the skin of her hands became red, scaly, thickened, and cracked, and continued so, notwithstanding many attempts to overcome this condition. She was constipated and subject to flatulence.

June 3d she came to Glenwood and was put under treatment which consisted of a tub bath daily at a temperature of 105° F. and the drinking of the water before breakfast.

June 29th she said this was the first time she had used any water that would regulate her bowels, although she had spent some time at Carlsbad.

July 15th the skin of her hands had become smooth and soft and her general complexion was much clearer than when she came.

Dr. Hobhouse when resident physician suffered from a prolonged attack of boils, lasting over two months, which he thinks was due to the neglect of some small acne pustules. He finally resorted to the baths himself and was thereafter free from the trouble. According to his experience, treatment by the baths and vapor was most valuable in the severer forms of chronic acne, associated with the formation of large comedones

and a good deal of surrounding inflammation, as well as in other morbid processes affecting the sebaceous and sweat glands.

Bulkley believes that many cases of psoriasis have been greatly benefited by the use of remedial waters, but in order to obtain relief the visit must extend over a considerable length of time, as such treatment for a brief period, though possibly of temporary benefit, will not so modify the system of the patient as to prevent a return of the eruption when active measures are no longer employed.

Syphilis.—This disease cannot be cured by the water and vapor alone at Glenwood: nevertheless, they are powerful adjuncts to the regular forms of treatment. All the experience at Glenwood tends to prove this statement and coincides with the views of Leichtenstern, whose conclusions concerning the action of hot sulphur waters are as follows:

1. They excite the retarded eruption of roseola.
2. They give support to the specific cure and increase the power of the skin to take up mercury that is rubbed in. They raise the temperature of the body and assist the action of the mercury by increasing the decomposition of the albuminates.
3. They have a favorable influence in hastening the cure of certain affections of the skin, and also favor disappearance of affections of the glands, periosteum, bones, and nerves.

4. They are useful in cases of inveterate syphilis when patients are suffering from injudicious administrations of mercury and iodine, too long continued cures, chronic mercurialism and iodism, and in those cases in which there is not constitution enough to respond further to mercury and iodine.

We may add to the above conclusions that these waters and vapor have been very useful in those cases in which mercury and iodine were not tolerated in sufficient doses. The efficacy of the Glenwood waters, and more especially of the vapor, in eliminating metallic poisons have long been known to physicians in all parts of Colorado, who have been in the habit of sending their intractable patients suffering from lead-poisoning incurred at the numerous smelters to these springs, where they invariably obtain relief. Mironovitch has experimented to ascertain the amount of excretion of mercury through the sweat glands, and has found it much greater than was formerly supposed. He believes that when it is necessary to relieve the system of an excess of mercury, a relatively larger amount can be eliminated by means of the perspiration than through the kidneys. The powerful excitation of diaphoresis and the consequent excretion of mercury probably explains some of the beneficial effects obtained by the treatment of syphilis at Glenwood. Dr. Hobhouse secured some gratifying results in treating obstinate cases, one of the most interesting of which has been reported by Dr. Morris in his article. There are no cases on my books that would be appropriate as illustrations, as the patients who came under my care were all suffering from tertiary forms and unfortunately could not remain long enough to get the full benefit of the treatment. But from the improvement noted in these instances, I felt certain that the disease would have been completely overcome if they had remained for a reasonable length of time.

In presenting this article, I have confined myself closely to those diseases with which I have had personal experience at Glenwood, but good results have been reported by others in the treatment of certain nervous troubles, naso-pharyngeal catarrh, some forms of kidney disease, diabetes, obesity, and alcoholic and tobacco poisoning. All medical men occasionally meet with aggravated and obstinate cases of chronic disorders which baffle every attempt, no matter how

skilful, directed toward the restoration of health. Let me conclude by urging the discouraged physicians to send a few of their discouraged patients to this sanatorium of nature, and decide for themselves as to its merits.

THE VIS MEDICATRIX NATURÆ.¹

By ALEX. C. EWING, M.D.,

SALT LAKE CITY, UTAH.

God having made man, he gave him this earth for a habitation and at the same time placed within him countless workshops wherein is manufactured material designed for his growth and preservation. These workshops are nothing more or less than minute cells, a grand aggregation of which make up the human body.

That there is in man a vital principle, a something by which life is preserved if not prolonged, is, I think, not questioned. None who have familiarized themselves with disease and solution of continuity can fail to note the rapid repair of bone injuries, the closing of an incised wound, and the overflushed and fevered cheek assume in a short time the color of returning health. That we may not lose sight of this remedial impulse of nature in our treatment of disease is the object of this paper, and of what this wonderful power is and how brought into action shall be my province to essay an explanation during the few moments kindly allotted me in this convention.

Disease is the absence of or deviation from health. Some one has termed it "the lack of adjustment between the body and its environments." From time immemorial man has been endeavoring to find out the secret of health and disease, and from the early dawn of medical history physicians' minds have been busy unravelling the mysteries relating to the nature and cause of diseased conditions. In primitive times disease was attributed, as you well know, to causes the most absurd, e.g., that the body was possessed of an evil spirit, the cure consisting of certain incantations; it was also believed that the remedy should as nearly as possible resemble the special organ affected; that, and later on, the blood was undergoing fermentation, with the formation of acids and alkalies in the body, etc. Of course, as would be expected, the most diverse means were used for relief, and if the patient recovered in spite of the empirical, if not to say dangerous treatment, it was heralded as a "cure."

But for absurdities in the treatment of diseases one need not revert to the ancients, for almost in our own day Hahnemann, the founder of homœopathy, ascribed the therapeutic effects of drugs to the "spiritual power which lies hid in the inner nature of medicines." He taught that medicines became more powerful the more they were weakened, or "attenuated," as he called it, and did not hesitate to make the assertion that he had treated many cases with perfect satisfaction solely by means of "olfaction"—even if the patients so treated were destitute of the sense of smell! Was this medication the cause of the cure, or was it the *vis medicatrix natura*?

It was not until a much later period that physicians recognized that there is something, and they know not what it is, aside from drugs, which plays an important rôle in the eradication of disease; and the brightest minds of the present day are earnestly seeking a solution of this mystery. Have they found it and can it be explained by the "exhaustion" theory of Pasteur; the "excretory" theory of Chauveau; the "ozonized oxygen" theory of Traube; the "tolerance to poisons" theory of Sternberg; the "phagocytic" theory of Metschnikoff; or the "immunizing nuclein" theory of Vaughan? I shall let them answer.

Pasteur, having noticed that when an animal recovered from a "germ-caused disease" the germ could no longer be found in the blood and tissues, accounted for the death of the germs and consequently the cure of the disease by the exhaustion of some substance in the blood necessary for their subsistence. Chauveau's theory was that the bacteria causing the disease died from the effects of their own excretion—an antitoxin. It was this antitoxin-excretory theory which led Koch to use tuberculin in tuberculosis, Klebs to expect favorable results from diphtheridin in diphtheria, and, since Friedlander's discovery of the pneumococcus, pneumotoxin is being used in pneumonia. I will say here in parenthesis that I am not overconfident in the belief that a substance which causes a disease will ever prove to be a remedy for the same. If so, Pasteur's hydrophobic matter should be used in the treatment of hydrophobia and vaccine virus in small-pox. Neither can I believe that there is such a thing as an antitoxin in the sense that poisonous bacteria excrete or secrete a toxin which produces a disease, and then at leisure set about to manufacture or secrete an antitoxin designed to counteract the effects of their former secretion. I do not wish to be understood as not favoring the use of antitoxin, for the wonderful reduction in the death rate since its discovery and use in diphtheria has proved it to be a veritable godsend to suffering childhood. I am only criticising the supposed manner of its production in the system. Lewis and Cunningham found that bacteria injected into the blood current rapidly disappeared, and concluded therefore that the blood or something in the blood is destructive to germ-life. Traube observed the same phenomenon and attributed their disappearance to the blood's ozonized oxygen. Diligent research has been made along this same line by such noted men as Behring, Foder, Gschiedler, Haliburton, and many others; their conclusions being that the blood possesses germicidal properties outside as well as within the body.

All of you are familiar, no doubt, with the phagocytic theory of Metschnikoff, who, when his theory was first enunciated, believed that the white corpuscles which collect in such great numbers wherever pathogenic germs are gaining access to the system, are gathering for the purpose of warfare, and that they accomplish the destruction of the germs finally by a process of deglutition! The definition of inflammation according to Metschnikoff's theory is a very simple thing; indeed, nothing more nor less than an encounter between the leucocytes or phagocytes on the one side and micro-

¹ Read before the Utah Medical Society, October 2, 1895.

organisms on the other. The fiery red cheek of pneumonia, the 106° F. temperature in typhoid fever, and the swollen and painful joint as a result of injury, are but evidences that a struggle for supremacy is going on in the system between the invaders from without and the defenders within.

And, indeed, if one but watches from day to day the closing of an external wound, he will become almost converted to this theory, for we do see unmistakable evidences of strife. How they do repel the invaders which are clamoring to get in through the open wound by throwing up their breastworks within the gap! And should we fail to come to their assistance with our antiseptics, how very many of them die upon the ramparts, the dead bodies falling off in the shape of pus corpuscles, showing how fearless and earnest is the struggle.

That there is an increased number of white corpuscles in and around the point where the body is struggling against disease or injury is a well-known fact, but just how the increase is brought about is not as yet fully understood. It is supposed to be due to a certain "psychical activity of their own," whereby the nucleolus becomes a nucleus, and the nucleus in turn is transformed into a leucocyte; or to a stimulus imparted to them by the nervous system, by which "they are swept out from the capillaries and tissues into the circulation," and then, I suppose, are transferred as a reinforcement to the parts most needing their assistance. The latter theory might explain their great increase after a cold bath, as first observed by Winternitz. But if we explain the raising of the arm for the defence of the body in response to a nerve telegram, why can we not as readily understand that the influx of white corpuscles at a given point, also for defence, is in answer to a similar communication from the brain? This theory, defining the office of the white corpuscles to be that of the defenders of the system against animal and vegetable parasites, was a great stride in the right direction; but a greater one was the discovery of "nuclein" by Vaughan, demonstrating beyond a doubt that it is this substance (evidently a product of the leucocytes) which gives to the blood its germicidal power. Metschnikoff had already shown us how the *vis medicatrix nature* was brought into action, but it remained for Vaughan to reveal to us the long-hidden mystery—what the *vis medicatrix nature* really is.

His discovery was to us as the brightness and warmth of the sun on a foggy morning, clearing the atmosphere of our minds from the accumulated mists of centuries. It seems there can be no doubt but that nuclein, proto-nuclein, spermin, antitoxin, or whatever you choose to call it—all being, I aver, one and the same substance—whether secreted by the leucocytes or not, is at least carried by them to the *locus lesionis*, or point of attack, and there used as powder and ball against the invasion of poisonous germs; that when given as a medicine it increases the number of white corpuscles and stimulates as well their natural alertness and aggressiveness. Added to this, our knowledge that leucocytosis is the first physiological step nature takes in defence of the body against pathogenic organisms certainly gives us reason to hope that the days of scientific treatment of at least zymotic diseases is at hand.

That a temporary leucocytosis is observed also during digestion would lead to the supposition that the white blood-cells, owing to their amoeboid propensities, enabling them to traverse blood-vessels and tissue without disturbing their integrity, are designed to perform a double office, viz., as domestic laborers, to carry the nutriment from the digestive tract to all parts of the body in such quantities as are needed for growth and repair; and are, in a certain sense, warriors, in that

they secrete or supply a germicidal substance called nuclein, which is antagonistic to, and protects the system against, the toxins emanating from poisonous bacteria.

In this connection you might ask, if leucocytosis is absolutely necessary for successful termination of the bodily struggles against disease, why is it that one does not speedily recover from that most obstinate of diseases, leucocythæmia, seeing that the white corpuscles are present in such superabundance? I shall try to answer by saying that a "leucocyte must be in full physiological activity before it can become a phagocyte"; that leucocythæmia should be looked upon only as a symptom of a systemic glandular disease, the white corpuscles representing a once mighty army, but now, alas! only a straggling host of vanquished heroes—being left with scarcely enough nucleinic strength for sluggish motion. They are here, in a word, mostly as dead or dying cells, incapable, in consequence, either of defensive action or of exercising their office as carriers of nutriment to the tissues—the inevitable result being general malnutrition, with pyæmia and abscesses in various parts of the system. As Metschnikoff has abandoned his "deglutition" theory, or so modified it as to agree with that of Vaughan, it is only in the sense of supplying the nuclein to the seat of disease that the leucocytes are to be looked upon as warriors. The only personal encounter likely to take place would be when the delicate cell membrane, being irritated by a bacterial cell, bursts and scatters its contents in the shape of nuclein into the very eyes, as it were, of the rapidly increasing enemy. By the personal encounter of the elements of the opposing cells, various diseases may not unreasonably be accounted for; thus, when the toxin of the bacterial cell is of sufficient strength and quantity to neutralize the nuclein of the leucocyte, disease sets in, and the place where the barriers give way and the line of defence is broken gives a name to the disease; e.g., should microorganisms gain access to the uterus after parturition, and the nuclein-carrying leucocytes guarding the apertures of the veins and lymphatics, laden with toxins, be overpowered, we have puerperal septicæmia; and should the typhoid bacilli with their toxins be of sufficient strength and virulence to repulse the leucocytes colonizing in and around Peyer's patches, typhoid fever is the result, etc.

The discovery of the past and present in etiology, pathology, and prophylaxis certainly gives a roseate hue to future medicine, and the time may come even in our own generation when Pasteur's prophecy shall be realized: "It is possible," said he, "for man to eradicate every contagious disease from off the face of the earth." Yet, methinks, the day is still far distant when we shall be able to dispense with morphine in pleurisy and renal colic, to discard mercury and iodide of potassium in syphilis, to treat malarial troubles with anything else so successfully as with quinine, to apply any remedy that will so relieve the painful symptoms of acute rheumatism as do the salicylates, or to find anything that will so modify arterial pressure, and give to a panting, dying soul the breath of life, as does the subcutaneous injection of nitroglycerin in the red hepatization stage of pneumonia.

You will readily see by the foregoing that this subject was not selected because I have lost faith in the efficiency of medicine. Nature does sometimes throw off disease, but how liable are we to have fibrous consumption as a result of an unassisted pneumonia and cardiac affections follow in the wake of rheumatism and diphtheria! There is no science in the "expectant" plan of treatment, except "Christian science."

Looking at the various infectious and contagious diseases from an etiological standpoint, we get an encouraging view of a scientific line of treatment by the

exhibition of an artificially collected nuclein, the chief object being to reinforce deficiencies in the *vis medicatrix nature*, and thus turn the battle from probable defeat to positive victory.

The millennium, however, will not be ushered in by the discovery of scientific medication. But it will come. A faint illumination is observable on the eastern horizon, and when the day finally breaks and we "behold the gates of light unbarred," we shall see standing therein a maiden, dressed in spotless raiment, as old as "She," yet young and far more beautiful, and her name shall be the beautiful name, "Hygiene."

In the preparation of this paper I have derived much help from the perusal of articles written by Drs. Charles G. McClintock, of Ann Arbor; Roswell Park, of Buffalo; and Frank C. Wilson, of Louisville.

THE CLIMATE OF NEW MEXICO.

By FRANCIS W. GALLAGHER, M.D.,

LAS CRUCES, NEW MEXICO.

THE conditions throughout the arid regions of the Rocky Mountains generally are such as to promote constructive metabolism, and for this reason are adapted to various debilitated states of the system, but it will probably be a long time before many physicians in the populous centres think of this section in relation to any except tuberculous cases and those exhibiting a tuberculous tendency. This article will, then, only consider the climate of the Rocky Mountains with reference to the amelioration or cure of consumption and conditions of ill-health favoring the development of this disease. Let us briefly consider, in the first place, what attributes of climate are by the best authorities considered essential in the climatic treatment of consumption; and, secondly, where are these requisites best supplied. The climatic conditions which the experience of years has confirmed as giving the best results in the treatment of phthisis are atmospheric dryness, altitude, and sunshine. I will not undertake to more than state this proposition, as, so far as I know, no one of authority and observation attempts to dispute it.

Where in the United States, then, are these essentials to be found in the greatest bounty? The observation and experience of years have demonstrated that the great rainless plains and tablelands of the Rocky Mountains alone adequately fulfil the indications. Anywhere within this region the invalid is under infinitely better conditions than in the Mississippi Valley or the valley of the great lakes, but in this vast territory—an empire in extent—some sections seem particularly selected by nature for the rescue of organisms attacked by the bacillus, and I would like briefly to direct attention to that land of perpetual sunshine, New Mexico, within whose boundaries is found almost every variation of climate which the taste and physical state of the health seeker may suggest. The possibilities of New Mexico for recreation and health are scarcely at all appreciated.

Lying within easy reach of busy little cities and comfortable and homelike villages scattered here and there in the valley of the Rio Grande, stretch chains of towering mountains, here snow capped and there clothed with picturesque cedars and tall pines, down whose rugged sides tumble snow-fed streams. The hunter, the fisherman, and the student of nature in her solitary moods, is each here afforded opportunity according to his kind. Unfortunately, the tuberculous patient, either from obstinacy or faulty diagnosis, does not seek change of climate while he is physically able to court the goddess Hygeia by brook and moun-

tain trail, where she is most exuberant in the bestowal of her favors. For such the towns and villages must suffice. New Mexico has many charming places where every comfort is easily procured. Individual taste as to expense and social surroundings must govern choice of location. From a social point of view, the larger towns afford, of course, greater advantages.

Las Vegas has an altitude of sixty-five hundred feet. It is a busy modern city and the largest town in the mountain country between Denver and the Texas line. It is in the area of least rainfall and its conveniences for the entertainment of visitors are necessarily greater than those of any town within the territory named. Las Vegas is a city of pleasant homes, and many people of means have, because of its salubrious climate, made it their place of residence. There is winter in Las Vegas, and snow, which, however, does not last, but, on account of the porous and sandy soil and the dry air and sunshine, disappears rapidly, leaving the streets dry—a surprise to those who, accustomed to Eastern experiences, associate snow and sunshine with slushy streets and mud. The summers here are delightful, and I do not think any spot in America can offer a July and August to compare. With cloudless skies, delightful coolness, trees, lawns, and flowers, Las Vegas needs only to be better known to be appreciated. Six miles of a mountain ride brings one to the famous Las Vegas Springs, renowned for its baths and the excellent quality of its waters for internal use. This spot has been called the Carlsbad of America by an eminent chemist who analyzed the waters. The hotel accommodations here are excellent.

However, from any other than a social aspect, Las Vegas is no better than other towns to the south. Mention may be made of Santa Fé, Albuquerque, Socorro, Las Cruces, and others, in the order in which they are reached as one proceeds south along the Rio Grande.

One night out by railroad train brings one to Santa Fé. It is situated on a tableland at an elevation of eight thousand feet. It is a delightful place for summer residence, and for many cases of early lung involvement with apex infiltration and collapse of air-vesicles affords the condition required for restoration of function. The many historical associations and extant monuments of Aztec and early Spanish life will elicit interest and help to make the time spent here entertaining and instructive.

Not far from Santa Fé lies the busy little city of Albuquerque. Its elevation is five thousand feet, said by some authorities to be the ideal elevation for the best development of the human form. It is a city with all modern comforts and affords first-class entertainment for visitors, and during the fall, as the winter farther north grows colder, invalids go there in numbers and profit by the many advantages it offers.

One hundred and twenty-five miles south of Albuquerque lies the neglected and almost unknown Mexican village of Socorro, which, I believe, has the possibilities of the finest health resort in the Southwest. The town is situated on a plain which slopes from the base of the Socorro Mountain a mile distant to the Rio Grande. The water supplying the town comes from two hot springs in the Socorro Mountain, with volume sufficient to supply a town of thirty thousand persons with water for household use. The water is free from mineral ingredients or organic matter, and is delightfully soft. The elevation of the town is forty-five hundred feet. Only an occasional health-seeker goes to Socorro, because its advantages are unknown and it affords no adequate accommodations. Capital will some day discover Socorro and its exceptional possibilities, and it will grow to be for all the West and South what Colorado Springs is to certain sections of the East.

About one hundred and thirty miles south of Socorro we enter the beautiful Mesilla Valley and its capital, Las Cruces. Las Cruces already has a reputation which brings each winter many health seekers to its doors. It is delightfully situated in a most fertile valley at an altitude of four thousand feet. It is already quite famous for the abundance and quality of its fruits and a large quantity of excellent wine is also made here yearly. It is beyond doubt the best winter point in the Territory. The town is surrounded at some distance by mountains which protect it from the winds, and winter here is a long, delightful autumn, which permits constant out-of-door country life, free from many objections incident to residence in a city.

I have attempted only a very hurried and cursory view of New Mexico and some of its towns, with the object of affording some information which may help the invalid. I wish merely to direct the attention of those of the profession who may be seeking information about the Rocky Mountains to the incomparable advantages of this land of perpetual sunshine, and particularly to its southern half, where the summers are pleasant and the winters without the sting of the colder North which drives the invalid from out-of-door life to the confinement of ill-ventilated rooms. Other States and Territories have their distinguishing qualities, but New Mexico stands unrivalled as nature's great sanatorium for the consumptive, where she dispenses with the hand of bountiful providence those blessings of altitude, dry air, and sunshine, without which the climatic treatment of consumption would join the procession of rapidly coming and rapidly going laboratory failures.

May 19, 1896.

SOME ANCIENT SANITARY AND HYGIENIC RULES.

By F. OVERHOLT, M.D.,

DES MOINES, IOWA.

It has ever been the struggle of "science," since its birth, to search for something new. It has ever been the policy of "dogma" to adhere to tradition.

Science is always searching for new facts, new theories, and new plans, and is constantly changing the order of things in an effort to better conditions.

Dogma, on the other hand, is always pointing to the record of the past and saying that the fathers knew better than we, hence we should follow the teachings of the fathers.

Science is showing us the influence of germs in health and disease and adding to that knowledge day by day. Germs, it says, explain all phenomena of disease except perhaps tumors, syphilis, and rheumatism, and it is likely that at no distant day these will also be explained on that hypothesis. But now comes another school of investigators, who insist that predisposition and natural resistance to disease germs form a large element to be reckoned with. These investigators are looking to heredity, atavism, and reversion for a basis of predisposition and immunity. They tell us that the new growths are the result of the atavistic change in the cells whereby they take on the characteristics and functions performed by the particular tissue they form a part of in its more primitive state; that rheumatism for instance, is a reversion of our functions of metabolism to the bird or reptile stage of our development, when we excreted uric acid instead of the more elaborate product of our more highly developed organism, urea.

Of a necessity science must change her sanitary rules to meet change in theory, but dogma sticks to her tradition and insists that the old rules were estab-

lished by a higher authority than science and must be right. The Jews have followed the one dogmatic set of rules in matters sanitary and hygienic for six thousand years. The results arrived at and the mass of evidence as a result of this action cannot be ignored, and it seems to me cannot help being of considerable value to sanitary and hygienic medicine if approached in the right spirit.

True, the rules are founded on anything but scientific grounds, and yet many of them can be defended with the facts and theories of the very latest scientific research. The Jews claim greater immunity from syphilis and tuberculosis and a less percentage of sterility than other races. I say they claim it. I don't know that this claim rests on any true scientific basis, but it is reiterated by some of the best medical authorities we have.

One of the lecturers at Owens College, Manchester, asserts that no Jew or Jewess ever has been known to suffer from cancer and that the immunity is due to their abstinence from swine's flesh; but this explanation cannot hold even if the first part of the statement be true, for the Mohammedans have cancer, and they also abstain from pork, though whether they are as often attacked as others or not, I have no information.

The essential part of the Jewish law, so far as this subject is concerned, has to do with circumcision, the rules of the relations of the sexes, the sorts of food allowed and proscribed, and the method of slaughter.

The male Jew is circumcised at eight days, and he ascribes his comparative immunity from venereal disease largely to this cause.

The Jewess is forbidden to have intercourse until seven days have elapsed since a "show" of blood. This rule I am told is strictly adhered to, and not to the effect of reducing the size of the family, as would naturally be supposed from a common notion on this point. "If a woman have borne a man child then she shall be unclean seven days and she shall then continue in the blood of her purifying three and thirty days. But if she bear a maid child then she shall be unclean two weeks and she shall continue in the blood of her purifying threescore and six days (Lev. xii. 2)."

Adultery was punishable with death according to the old law.

A Jew may eat of any animal which has a cloven foot and chews its cud, provided it has been properly slaughtered, or of any fish that has fins and scales. I shall now quote from Leviticus:

"Ye shall eat no manner of fat, of ox or of sheep or of goat" (vii. 23).

"Ye shall eat no manner of blood, whether it be of fowl or beast" (vii. 26).

"Whatsoever parteth the hoof and cheweth the cud among the beasts, that shall ye eat" (xi. 3).

"Whatsoever have fins and scales in the waters in the seas and in the rivers, them shall ye eat" (xi. 9).

"Yet these may ye eat of every flying creeping thing that goeth upon all four which have legs above their feet to leap withal upon the earth" (xi. 21).

"Even these of them ye may eat: the locust, beetle, and grasshopper, but all other flying creeping things which have four feet shall be an abomination unto you" (xi. 22).

"And these are they which ye shall have in abomination among the fowls; they shall not be eaten: eagle, ossifrage, osprey, vulture, kite, raven, owl, night-hawk, cuckoo, hawk, cormorant, swan, pelican, stork, heron, lapwing, and bat" (xi. 13).

It is interesting to note what the Koran says in this connection, viz.: "Ye are forbidden to eat that which dieth of itself, and the blood, and swine's flesh, and that which has been slaughtered or killed by a blow or by a fall or by the horns of another beast, and that which has been eaten by a wild beast."

The Jews eat nothing that has been shot or trapped; in fact none but domestic animals, and only those that are properly slaughtered. This brings us to the most important part of our subject, except perhaps the prescription of pork, namely, the method of slaughter.

A Russian by the name of Denbo has investigated this question, in its relation to cattle more particularly, and I shall quote quite extensively from him. Before taking up Dr. Dembo's work I will quote from Prof. Dr. W. Preyer, of the University of Berlin: "As I have declared in a report based on observations and experiments in the laboratory and in the slaughter house, the method of *shechita* which is practised by the Jews with remarkable success is superior to all other methods of killing, because it is the safest and most expeditious, because the animals killed by it are subjected to the least amount of pain, and by it the removal of the blood is effected in the most complete manner."

I am too little acquainted with the history of the Jews and with the Jewish ritual law to understand why they have for centuries adhered to the latter with astonishing pertinacity; but that this consistency is well justified from the standpoint of physiology, that it much better answers the humane purpose of the protection of animals than the uncertain methods of the Christian butchers, and that it is better calculated to further the well-being of the nation than the other, is proved and established.

Dr. Dembo claims that the Jewish method of slaughter is more humane, more hygienic, and more economical than any other method, and he proceeds to prove his claim in a lengthy monograph. The matter of determining which of the methods of slaughter is most humane is of great importance and is gone into at considerable length by Dr. Dembo, and as a result of many personal observations in the slaughterhouses of England, France, Germany, Switzerland, and Italy, he concludes that the Jewish method is most humane, because consciousness on the average is lost sooner than by any of the other methods, as, for instance, transfixion, stunning with a mallet, with a poleaxe, Bruneau's mask, shooting, or the neck stab; consciousness is lost in from three to five seconds by the first-named method.

Approaching the subject from a hygienic standpoint, I shall first give a butcher's reasons for using the Jewish method:

"Because it combines the most humane treatment of the animal with the greatest safety in killing it. The *shechita* cut is indisputably the most rapid and safe mode of slaughtering. The fact that the cut is made with a sharp knife, which occasions no swelling of the arteries and allows a great outflow of blood to take place in a few seconds, shows this to be the most rapid and at the same time least painful mode of slaughtering, for the sharper the instrument the less painful the cut. Stunning is attended with much more danger and too often with much more pain to the animal.

"It often, when the hand that carries it out is not a thoroughly practical one, results in torture to the animal. The slightest movement of the head by the animal at the moment of striking will cause the blow to fall wrong, the most skilful slaughterman being unable to prevent this, and no matter whether the ill-falling blow cause the animal pain or whether it be only frightened and excited to movement by it, the result in any case is that the killing is protracted and made more difficult.

"Viewed from the standpoint of economy the stunning methods are unquestionably more advantageous to the butcher, for every stunned animal yields a greater weight of meat; this is because the blood remains stagnant in the veins as the result of the blows,

and when the arteries are afterward cut the blood flows out very slowly, the total loss of blood being always less than in the case of throat cutting direct, and the weight of meat consequently greater. But the consideration of the few pounds of meat less by the Jewish method is many times outweighed by its hygienic advantages.

"Every animal stunned and then cut must afterward be washed, especially in the cavity of the chest, with pure water. But it is well known that water has the worst possible effect on meat, especially during the hot summer months, when a great deal of meat spoils through this washing.

"The meat of animals killed in any way with blows is also much darker and always softer than that of cut animals, the flesh of which is in every case light in color, free from blood, and firm. Every animal killed by the cutting method is clean in the cavity of the chest, and there is no need to touch the flesh there or elsewhere with water. The flesh of cut animals is as firm in two hours as that of stunned or felled animals in ten, and the latter indeed never attains the firmness of the former."

Now the main reason for the better bleeding by the *shechita* method is that during the whole time of bleeding the nerve centres regulating the flow of blood in the vessels are not interfered with. Whereas, in the case of stunning and particularly in the case of the neck stab with injury to the spinal cord, as in all other methods depending for their effect on injury of the brain, the case is altogether different, since, as Koch, Witkowsky, and others have proved scientifically, destruction of the brain causes paralysis of the vaso-motor centres, and this paralysis in its turn would entail a stoppage of blood within the blood-vessels. The reason for the quicker rigor mortis, greater firmness, and hence more pronounced keeping qualities in cut meat is that a great and rapid loss of blood promotes the formation of lactic acid in the meat and decreased alkalinity in what blood remains; or, to quote again from Dembo: "Keeping in mind that the blood forms an excellent nutrient medium for the lowest forms of vegetable life, that germs that have accidentally found their way into it multiply with an extraordinary rapidity, that these micro-organisms cannot grow in acid tissue as well as they do in alkaline, and further remembering that in the Jewish method not only is less blood retained in the meat, but also the alkalinity of the blood retained lessened by more than half by the violent convulsions, and finally that the same convulsions as well as rapid bleeding considerably advance and promote the formation of lactic acid; considering these facts it will be evident that no doubt whatever can be entertained as to the fact that the growth of micro-organisms will proceed (all other conditions being equal) much more slowly in the meat of animals killed in the manner of the *shechita* than in meat of those killed by any other method."

From an economical standpoint the stunning methods are more advantageous to the butchers and less so to the consumer, and on the contrary the Jewish method is more advantageous to the consumer and less so to the butcher.

Osteomalacia.—Dr. Guillaume (*Therapeutische Monatshefte*, 1895) suggests phosphorus in doses of from one-sixty-fourth to one-sixteenth of a grain. If this does not prove beneficial, then castration is to be considered. The results that have been obtained from the use of bone marrow in certain blood diseases suggest from the standpoint of changes in the blood and in the bones that it might be a useful remedy in this disease also.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 13, 1896.

MEDICAL CHARITY AND "THE CHURCHMAN."

OUR esteemed contemporary, *The Churchman*, takes us to task for "a rather impracticable article on the subject of free hospitals and dispensaries." With every desire to discuss the question with becoming calmness and impartiality, we are always inclined to listen to opposite opinions. We are willing to assert, however, at the outset that we entirely disagree with the position taken by *The Churchman* in the article named. It is fair to assume that, being practically acquainted with hospital and dispensary work for over a quarter of a century, during which time we have been brought in direct and daily contact with this class of charity patients, we may have some views on this subject which are founded on fact and experience and which should have some weight when balanced against mere suppositions and loose and unfounded assertions.

"We are inclined to think," says our amiable critic, "from our experience of an American population, that very few people accept free assistance in the case of sickness, excepting those who cannot afford to pay for the services of a competent physician or specialist."

We congratulate our good brother on his anomalous experience and would respectfully ask him to compare it with that of any dispensary or hospital physician or surgeon within his reach. This refreshing confidence in human nature must have been fostered by an exceptionally agreeable contact with a totally different class of people from that with which the charitable doctor has to do.

The medical profession can never be accused of want of charity for the really poor. Its freely volunteered services are as much at command as are those of the clergy, with perhaps a trifle more of tangible and practical application. The sick lamb in the deep pit has as much faith in the efficacy of the only hand that lifts him out as in the encouragement of the exhorters who sound the alarm from the safer distance above. We have no intention of discussing the relative merits of practical charity as applied to the respective professions, but merely wish to remark in passing that the clerical profession, with a full knowledge of what the doctor does for the sick poor, should be the last to cast a slur on his laudable intentions or in any way to impugn the motives of his purely charitable mission.

It is hardly fair to imply that the doctors look upon

the abuse of charity wholly from a selfish and pecuniary standpoint. The profession of this and other cities gives yearly hundreds of thousands of dollars in services to the poor, and is only too glad to do it when it can be done properly. It is equally jealous, however, of free services to those who can pay. It does not follow that because "a dispensary is free it offers aid to all who will take it," whether rich or poor. The man who can pay and does not, always takes advantage of the man who cannot. The great cry of all charitable institutions is poverty of funds. No hospital nor dispensary is rich enough to supply all who may apply. All are ostensibly for the poor alone. The money is contributed by the unsuspecting donors for a specific purpose, and any diversion of the gift by the laxity of managers or the pretension of unworthy recipients is open to the charge of very un-Christian-like and purely worldly motives. Every such institution is cheated whenever an unfit applicant is served, and every well-to-do man, "free citizen" or not, who accepts such services gratuitously is a sneak and a fraud, *The Churchman* to the contrary notwithstanding. Obviously, also, such a patient cheats the doctor, who must live as well as others. Even the clerical profession, so often proudly styled by itself the greatest of all, sets the example of caring for its own household in money matters. It is against all law and gospel that a rich man should occupy a free pew, or that the good clergyman should not be regularly paid for the work that he does. The clergy is noted for its appeals in support of the Church and its missions, and the prosperity of both is very apt to react favorably upon the advancement of the earnest and business-like pastor. Contrariwise, we seldom if ever hear of a minister who feels that he is called in the line of his duty to any position with a reduced salary. Whatever he does for rich or poor, he is, quite differently from the doctor, guaranteed an ordinary living. That "the laborer is worthy of his hire" applies very forcibly to the doctor when accused of "bad temper" in complaining against such of the well-to-do as openly and constantly defraud him of his just dues. The poor doctor is no worse than the poor clergyman when he asks for his own. Both owe a duty to the poor and both owe a duty to themselves. There never was a question concerning relative rights in these matters until it was raised by our innocent, well-meaning, and usually justice-loving neighbor. Naturally, but quite erroneously our good friend ventures to "suppose that there are not too many hospitals and dispensaries in New York City, with its thousands of poor and suffering inhabitants." And he would have them free to all who might choose to apply for treatment. With hospitals already so much in excess of actual needs, and with a still greater abuse of charity, what would be the fate of the doctor, and what could the hospitals do without him?

THE SUMMER HEALTH RESORTS.

THE present number of the MEDICAL RECORD will doubtless carry with it a certain suggestiveness of preparation for that much-needed recreation which all our readers have fairly earned. There is a something

about professional work of every kind which, at the end of certain periods, calls for that absolute rest which means alike the healthful renewal of wasted energies and the helpful relaxation of strained and anxious thought. An annual vacation is becoming so much of a necessity that few in any walk of life are willing to run the risk of omitting it. The American people above all others have earned the reputation of being a nation of travellers. This disposition to change place and scene is becoming more and more manifest every year, so that during the summer months more particularly, and to an increasing extent also in the winter season, few of the wealthier classes remain long at home. It is with a view of ministering to the needs of such pleasure seekers and health hunters, and of adding to the resources of the physician, who is so often appealed to for advice in the matter, that we have undertaken to collect as many facts as possible pertaining to the summer health resorts and such of their peculiarities of climate, surroundings, and comforts as may appeal to the largest variety of tastes and the widest range of necessities. No pains have been spared to obtain accurate descriptions of different localities, and every effort has been made to give the reader a perfectly trustworthy and absolutely impartial account of the leading features of each of the many and widely scattered summer health resorts. By so doing we are satisfied that all idea of special advertising can be eliminated and the information really needed by the reader can be easily and satisfactorily obtained upon the reliable basis of unbiassed judgment. Although it is obviously impossible to go into much detail, enough, we trust, is stated to enable the reader to make such selection as may suit his purpose. The publishers of the RECORD, in the interests of such as wish to avail themselves of opportunities, have consented to supply, on application, any additional information desired, as to routes, rates of fare, and other matters of necessary expense. In order to make this number more especially interesting to vacation seekers we have endeavored to group such articles as may bear in a suggestive way upon matters connected with the care of the general health and the influence of climate and environment on preventable diseases.

UNNECESSARY NOISES.

WE are much pleased to see that several of the influential dailies, notably the *New York Tribune* and *New York Sun*, have seconded our endeavors to abate the noise nuisances at present so prevalent in this city. With such powerful aids in calling popular attention to the subject, some reform may be possible. *The Tribune* in its earnest protest calls attention to some additional sources of nervous irritation occasioned by other noises than those already mentioned.

"In most American towns the pavements seem to be constructed with a view to making as much noise as possible. The recent adoption of rubber tires for carriages has shown what can be done in eliminating the noise of vehicles; but nearly all trucks are needlessly noisy. They are so loosely put together that

they rattle through the streets like a moving boiler shop. The same thing is true in a large measure of street cars, and there are few railway trains that are not run with a great deal more noise than is at all necessary. The New York Central Railroad has set a good example in this matter by ordering for its yard in this city a noiseless switch engine. But the strange thing is that public opinion has not long ago forced every railway company to do the same thing. In our patient endurance of evils that could easily be avoided we are a long-suffering people. We allow trucks to carry loads of loudly clanking iron rails through our streets, when we might, just as well as not, insist on their being packed so as to be noiseless. And we permit thousands of milk wagons to disturb our morning rest by noisy tintinnabulations that could easily be avoided by a little care.

"It is taken for granted that a city must be noisy. Doubtless some noises are unavoidable; but many even of such noises could be modified, and a vast number of other noises that we now endure without protest are wholly unnecessary. Of the many municipal problems that are to-day pressing for solution the elimination of unnecessary noises is by no means the least, though it has received little attention from municipal reformers."

The Sun very properly stigmatizes the "ol' clo'" men as the worst offenders in the more exclusively aristocratic quarter.

THE WASTE OF LIFE IN CUBA.

To whichever side of the present deplorable contest in Cuba one's sympathies may incline, no one can contemplate the terrible sacrifice of human life in the island without a feeling of horror and of the deepest commiseration for the poor victims and those who mourn for them in the mother country. Although the rainy season has but just begun, the loss of life in the army of occupation is already appalling. According to the reports received by the Marine Hospital Service in Washington from the sanitary inspector in Havana and by the State Department from the United States Consuls in Cuba, both yellow fever and small-pox are epidemic in nearly all the seacoast cities and in many of the interior parts of the island. The number of deaths due to them during the past few weeks has been very large, and not less than seven per cent. of the Spanish troops were sufferers from them in the first three weeks of the month of May. Of three thousand eight hundred and seventy-seven deaths in the Spanish army in the island since the beginning of March, no fewer than three thousand one hundred and ninety, it is said, were caused by the vomits.

In consequence of the insanitary conditions which necessarily exist in the army, the soldiers are even more liable to suffer from yellow fever than are the unacclimated civilians, and few of the latter escape during an epidemic. General Vicuna died May 18th of yellow fever, and many officers of lesser rank have fallen victims to the disease. General Weyler left Havana recently to take the field in person against

the insurgents, but returned the next day, having been so frightened, according to general report, by the accounts which were brought to him of contagious disease in the army, that he abandoned his project. In addition to yellow fever and small-pox, which chiefly attack the soldiers in garrison towns, although those in the field do not escape entirely, the soldiers in the country, those forming the trocha across the island, are suffering severely from pernicious malarial fever, and many deaths from that disease occur every week. In addition to the crowding and to the exposure, another powerful predisposing cause of disease exists in the despondency which reigns among the Spanish soldiers. Many of them are young men, hardly more than boys, who are out of their native villages perhaps for the first time in their lives, and they are suffering from nostalgia, depressed by the almost certainty that they themselves will soon fall victims to one of the scourges whose ravages they see all about them, and overworked in a hot climate, now drenched with a tropical downpour and then scorched by the vertical rays of a tropical sun. And the worst part of the long rainy season has yet to come.

The god of pestilence is fighting harder than he of war for the independence of Cuba, and that he will come off victor in the end can scarcely be doubted. The question of right or wrong of the Cuban revolution aside, for the sake of Spain herself, for the sake of her noble sons, who are spending their strength and giving up their lives—not on the field of battle, but in the barrack hospitals—we can but long for the day when this slaughter shall cease.

THE BLESSINGS OF "UNSEASONABLE" WEATHER.

WHENEVER the temperature during any of the winter months rises to an endurable height and it is possible for one to go out-of-doors without acute suffering, we always hear prognostications of sickness and death which are sure to result from a green Christmas and an open winter. But the truth is, it is the "good old-fashioned winter," the "seasonable temperature," that kills. The incorrectness of the popular idea is well shown by the vital statistics for the first quarters of 1895 and 1896 in England and Wales, which we find summarized in the *British Medical Journal* of May 16th. These two periods of time "formed a great contrast in so far as the general temperature of the air was concerned. In the former year the mean temperature of the three months was 35.2° F., which was 3.7° F. below the average, while in February it was no less than 9.9° F. below the mean of that month. In 1896 the temperature of the three months was 42.3° F., or 3.4° F., above the average. The public health fully reflected these noteworthy differences in temperature. In 1895 the deaths in the first quarter amounted to 170,501, and the death rate was 22.8 or 1.1 above the average. In 1896 the deaths in the corresponding period numbered 136,809, and were in the proportion of 17.9 deaths annually per 1,000 persons living, which rate was 3.9 below the average.

The increased mortality in 1895 was chiefly among persons aged sixty years and upward, of whom 60,454 died, giving a death rate among such persons of 10.90, or 15.4 in excess of the mean. In 1896, 39,208 persons aged sixty and upward died in January, February and March, and the death rate was 69.2, no less than 26.2 below the average."

These statistics furnish fresh evidence of the killing power of frost and of the beneficent influence of a mild temperature. But popular beliefs are not to be overthrown by statistics, and if we are blessed next winter by a mild atmosphere and absence of snow, there will be plenty of physicians whose surprise will be equalled only by their disappointment that there is not more for them to do.

News of the Week.

Cholera has appeared among the Turkish troops in Bitlis, on the shores of Lake Van, in Turkey in Asia.

Dr. C. J. MacGuire has been appointed consulting physician to the City Hospital, to represent the University Medical College division, upon the recommendation of the faculty of that institution.

The Montana Medical Law requires, as a preliminary to practice in that State, both the registration of a diploma and an examination before the State board. The examinations are held on the first Tuesday of April and October and at such other times as the board may determine. The president of the board is Dr. W. C. Riddell, of Helena, and the secretary Dr. W. M. Bullard, of Wickes.

The Plague in China.—According to the reports of passengers by the steamer *Pera*, which arrived in San Francisco on June 5th, the plague is gaining alarming proportions in the Orient. The disease is spreading in all quarters, and communication with many places is entirely cut off. The Japanese officials are doing all in their power to keep the disease out of that country, and so far seem to have met with success. In Hong-Kong, during the week ending May 19th, there were seventy new cases of the disease reported and ninety-two deaths.

Dr. Emma Ward Edwards, of Newark, N. J., who died of dysentery at Clear Water, Fla., on March 28th, in the fifty-first year of her age, was graduated in 1870 from the Woman's Medical College of the New York Infirmary. In 1872 Dr. Edwards, then Dr. Ward, was married to Dr. Arthur Mead Edwards, when she gave up active practice. In 1876 she removed with her husband and two children to Berkeley, Cal., where her husband began practice. Two years later the family returned to Newark, and Dr. Edwards resumed her professional work, which she continued to within a few weeks before her death. A very large and successful general practice, the esteem and admiration of her medical associates, and the affection of a wide circle of friends and patients, bore testimony to her ability and her integrity, as well as to the sweetness and charm of her character. Dr. Edwards was

one of the attending physicians of the Newark City Dispensary, visiting physician to the Home for Incurables and the Home for Aged Women, and examining physician for the Working Girls' Club. She was also one of the managers of the Society for the Prevention of Cruelty to Children.

Sir George Johnson, M.D., F.R.S., F.R.C.P., died in London on June 3d, at the age of seventy-eight years. He was born in Kent and studied medicine at King's College, receiving the M.D. London in 1844. His entire medical life was identified with King's College. Soon after receiving his degree he was appointed the first medical tutor of that institution, and in time became professor of materia medica and of the principles and practice of medicine. In 1876 he was made professor of clinical medicine, and in 1886 he was elected emeritus professor of clinical medicine and consulting physician to the hospital. From 1884 to 1886 he was president of the Royal Medical and Chirurgical Society. In 1889 he was appointed physician extraordinary to the Queen, and in 1892 he received knighthood. He was a recognized authority on diseases of the kidneys, on which subject he wrote two treatises and many journal articles. He was also the author of a work on the laryngoscope and of several essays on laryngological subjects, and was honorary consulting physician to the Royal College of Music.

New State Hospital Buildings.—A dispatch to the *Evening Post* from Albany says that State Architect Perry has completed plans for a large addition on Ward's Island to the Manhattan State Hospital. The building will contain one hundred and fifty beds. Another building to be connected with the hospital with accommodations for one hundred patients is to be erected at Central Islip, L. I. Plans for additional cottages at this place for the institution are being prepared. The cost of all these improvements will be about \$600,000. A site has been chosen at King's Park by the State architect for a group of three cottages which are to surround a commodious dining-hall. They will be connected with the Long Island State Hospital and will accommodate seven hundred beds. These improvements will cost \$380,000.

Small-pox in Havana.—It is reported that small-pox has broken out among the prisoners confined in Morro Castle, sixteen patients having been removed from there to the small-pox hospital on May 24th.

The Cholera in Egypt.—The disease in Cairo and Alexandria is increasing in spite of the feeble efforts of the authorities to stay its spread. As usual, the physicians have to contend against the ignorance and prejudice of the natives, not only those of the lower classes but also some among the officials. The local press refuses to acknowledge the existence of cholera and is stirring the people up to resistance against the efforts of the doctors to keep the disease in check. It was even asserted in the council of ministers that the medical men were in the habit of throwing a yellow handkerchief over the face of a suspected cholera patient, of rendering him insensible, and of thus conveying him to the hospital. A consequence

of such statements as this was that in Alexandria an ambulance was overthrown by the mob and the patient, who was ill with cholera, was taken away and concealed. In Cairo serious disturbances have taken place at the Moslem University Mosque. Some sanitary officers attempted to visit the school, where a case of cholera had been reported, but the students opposed their entry and stoned the police and the governor, wounding the latter. The police fired on the students, killing one and fatally wounding three others.

Mr. William Reynold Salmon, of Pennlynn Court, Glamorganshire, England, the medical centenarian, the celebration of whose one hundred and sixth birthday was noticed a few weeks ago in these columns, died the middle of May. He was born in Suffolk on March 16, 1790, and was admitted to membership in the Royal College of Surgeons the year of Mr. Gladstone's birth, and was therefore the oldest member of that body, as well as the oldest medical man and the oldest freemason in England, having been one of the original members of the Jerusalem Lodge of London. In early life he was an army surgeon and was on the field of Waterloo soon after the battle was concluded. When but twenty-six years old he married an heiress and thereafter spent most of his active years in travel, retiring to his estate in Glamorganshire at the age of seventy. He took up smoking when ninety years old, but did not like it very well, and gave it up a year or so later. He always took wine with his dinner.

An Honorable Rival.—The French Academy of Medicine has divided the Prix St. Paul of \$5,000 between Dr. Roux, of the Pasteur Institute, and Dr. Behring, of Berlin, for their discovery of the antidiaphtheritic vaccine. The *Figaro* says that a large number of German and English savants have accused Dr. Roux of having wished to take to himself all the credit of this discovery. The truth is that Dr. Roux has constantly refused every prize or reward, unless a part thereof shall have been granted to Dr. Behring.—*Journal of the American Medical Association*.

The Twenty-Fifth Congress of German Surgeons was held on May 27th–29th.

Dr. Amos Howe Johnson, of Salem, Mass., died at his home in that city on May 12th, after a long illness. He was born in Boston and was graduated from the Andover Theological Seminary in 1857. At the end of five years he was forced to retire from the ministry on account of a throat trouble. He then entered the Harvard Medical School and was graduated in medicine in 1865. He immediately began practice in Salem, in which town he resided for the rest of his life.

The Same Old Story.—A writer in the *Medical Times and Hospital Gazette* recently made a tour of inspection of the West End hospitals in London, and found that at a few an attempt was made to exclude persons who are not fit objects of charity, but at some no attempt whatever was made to prevent impostors from receiving the benefits intended for the poor. At one hospital the secretary said: "We welcome everybody who chooses to apply, without asking questions

as to their ability to pay for medical and surgical advice." The consequence is that the physicians and surgeons are kept for several hours daily ministering to the necessities of patients many of whom are well able to pay half-a-crown fees. He gathered in the course of his investigations that some doctors prefer to see well-dressed persons as patients, as, with a keen eye to business, they are able to make private patients of some of them.

Defective Sanitation in the Transvaal.—A Johannesburg correspondent writes to the *Medical Press* that the last annual report of Dr. Visser, health officer, on the general health and sanitation of the town, just issued, gives the percentage of deaths from typhoid as very great, due chiefly to bad water; the deaths from typhoid during 1895 are given as upward of one thousand. Pneumonia, also, was very prevalent during the winter months. A repetition of this can be obviated only by the sufficient and effectual watering of the streets so as to completely lay the dust, which is the chief cause of the annual epidemic. The sanitation of Johannesburg is altogether in the most primitive state, the disposal of its sewage being at the present time but little in advance of that which obtains in semi-barbarous states.

Photographing the Viscera.—The General Electrical Society of Berlin announces that an improvement has been made in the Roentgen process, by which one may see the brain or study the action of the lungs, the larynx, and the heart, in the picture thrown out on a fluorescent screen.

Pennsylvania State Medical Examinations.—The next examinations of the Pennsylvania State Board of Medical Examiners will be held at Harrisburg on June 16th.

The Medical Society of the State of Pennsylvania held its forty-sixth annual session at Harrisburg on May 19, 20, and 21, 1896, under the presidency of Dr. W. S. Foster, of Pittsburg. After prayer addresses of welcome were delivered by Governor Hastings, by City Solicitor Seitz on behalf of Mayor Patterson, and by Dr. W. T. Bishop, chairman of the committee of arrangements and credentials. A committee, consisting of Drs. H. S. McConnell, G. B. Sweeney, and John J. Buchanan, was appointed to take measures to prevent the passage of a bill before Congress providing for the abolition of vivisection in the District of Columbia. The usual addresses and a large number of papers were read and discussed. Among the social events of the meeting was a reception held at the Pennsylvania State Lunatic Asylum by the superintendent, Dr. H. L. Orth, and the trustees; another by the governor at the executive mansion; a dinner by the Dauphin County Medical Society; and an excursion to the vaccine farm at Marietta. The following officers were elected for the ensuing year: *President*, Dr. E. E. Montgomery, of Philadelphia; *First Vice-President*, Dr. C. S. Shaw, of Alleghany; *Second Vice-President*, Dr. B. F. Ball, of Clinton; *Third Vice-President*, Dr. F. M. Livingston, of Lancaster; *Fourth Vice-President*, Dr. A. C. Wentz, of York; *Secretary*, Dr. W. B.

Atkinson, of Philadelphia; *Assistant Secretary*, Dr. Adolph Koenig, of Alleghany; *Treasurer*, Dr. G. B. Dunmire, of Philadelphia. The next meeting will be held in Pittsburg in September, 1897.

Obituary Notes.—DR. P. B. BREINIG died at Bethlehem, Pa., on June 21st, at the age of sixty-eight years. He was graduated from the New York University in 1856 and began the practice of medicine in Hellertown, moving to Bethlehem in 1873. He was the founder of the Lehigh Valley Medical Association and was a member of the American Medical Association—and one of its vice-presidents—and of the Medical Society of the State of Pennsylvania.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the U. S. Navy for the week ending June 6, 1896: June 2d.—Surgeon L. L. von Wedekind ordered to the Naval Academy. June 3d.—Surgeon C. A. Siegfried detached from the *Columbia* and ordered to the *Massachusetts*. June 3d.—Surgeon E. Z. Derr detached from the *Raleigh* and ordered to the *Columbia*. June 3.—Surgeon H. G. Beyer detached from the Naval Academy, June 5th, and ordered to the *Raleigh*, June 6th. June 4th.—Passed Assistant Surgeon M. S. Guest detached from the *Constellation*, June 8th, and ordered to the *Massachusetts*, June 10th.

Health Board Examination.—On June 15th the New York City civil service boards will hold an examination at 10 A.M. for the position of assistant resident physician, board of health. Citizens of the United States holding the degree of M.D. are eligible to this examination, and may obtain application blank by addressing S. William Briscoe, secretary, new criminal court building, New York City.

Headquarters of the American Medical Association.—According to a resolution adopted at the Atlanta meeting of the American Medical Association, the members are to determine by vote where the permanent home of the association shall be located. The ballots have now been distributed to the members, who have until July 31st to cast their votes. As soon as the count is completed the result will be announced in the *Journal*. Members may vote for any place they desire, but it is probable that the choice will be practically limited to either Washington or Chicago. Certainly the former would seem to be the appropriate home for a national organization. The other representative association of the practitioners of America, the Congress of American Physicians and Surgeons, has always held its triennial reunions in Washington, and this society would be wise to follow suit.

Dr. Gerard Rohlfs died at Godesberg, Prussia, June 3d, at the age of sixty-two years. He had received a medical education, but did not practise, his life having been spent in travel and exploration.

The Duchess of Marlborough was present at a dinner given at the Hôtel Métropole, London, on May 14th, in aid of the funds of the National Orthopædic Hospital. The Duke of Marlborough is president of the hospital board.

Summer Health Resorts.

(Specially Prepared for MEDICAL RECORD.)

AT this time when so many families throughout the land are struggling with the annual and often perplexing question of where and how the hot summer months shall be spent, the same question is being put by patients to busy physicians all over the country, and these latter are often sorely tried in their attempts to find a location suitable alike to the character, inclinations, and means of the individual patient.

It is with the hope of rendering some practical aid in the solution of this problem of where patients shall be sent for the summer that this article has been prepared.

In approaching such an extensive subject as the summer health resorts of this country, it is manifestly impossible, in an article such as this, to discuss, or even mention, all of the myriad of attractive, health-giving summer places with which the continent abounds.

We can, at best, only take up in turn the different regions; giving, in a general way, the salient features of each, and then, in a more or less sketchy way describe some of the more desirable places in each region.

Such famous resorts as are well known to all our readers will be omitted, or only very briefly touched upon, in order to make room for those less widely known.

A "change" is, in almost every case, the object sought for by the physician. In one case it is a change of air; in another a change of scene and occupation; in a third a change of elevation and temperature, etc. Very frequently it must be a change in all these particulars—a "complete change," in other words.

To obtain the best result, then, the patient must be studied as an individual with individual peculiarities and whims rather than as a member of some particular morbid family. All consumptives do not do best in the dry, piney air of the Adirondacks, any more than do all convalescents from acute illnesses or from surgical operations flourish in the strong, moist breezes of the seashore, although, in general, this may be said to be true. Moreover, the inclinations of the patient as regards exercise and diversions will necessarily have weight in deciding the matter of his summer home. In one set of cases difficulty of access and inadequate telegraphic and rail communication will be sufficient to exclude a place from the list of eligible ones. In another set these very features may be the *sine qua non* of the whole situation. The overworked professional man, the nervous, exhausted banker or merchant will often want to go where the sound of the telegraph key and the sight of the daily paper with its columns of stock quotations cannot possibly reach him to disturb and interrupt his period of recuperation and rest.

In many instances the matter of expense is often a determining factor in the selection of a summer resort. The patient of moderate means living in the middle West, for example, who is in need of the strong, moist air of the seashore, may often find it inconvenient or impossible to take the long and expensive journey to the better-known resorts of the seaboard. Are there not less expensive places nearer home where the same end may be attained and the same good be accomplished?

To answer, if possible, some of these perplexing questions; to put briefly before medical men throughout the country the resources of the different regions, are the objects hoped for in these pages.

In the following account it has seemed desirable to take up in turn the different classes of health resorts,

and before going on to speak of the individual places to devote a few lines to the general character of the class of resorts in point and to the character of the patients usually most benefited thereby.

In following, then, this somewhat arbitrary plan, we shall consider in turn seashore resorts, mountain resorts, mineral springs, the region of the great lakes, and inland resorts of miscellaneous character.

Seashore Resorts.—The climate of the seashore in summer approaches, in a general way, closely to that of the ocean itself. As compared with the interior the temperature is apt to be lower and is much less liable to sudden variations; the air is dense, in consequence of the low level, and it therefore contains more oxygen. The air, moreover, is heavily charged with moisture and the quantity of ozone is greater than that contained in other air. As regards the salt in seashore air it may be well to say that it has been demonstrated that salt exists as an ingredient of the air only in the immediate neighborhood of the water, where the wind catches up the finely divided spray of the breakers and carries it a short distance up the shore. It is questionable, then, if the salt in the air plays an important or even appreciable part in producing the therapeutic effects of seashore life. The dense air, the large proportion of moisture, the freedom from dust particles, and the equable temperature are probably the essential factors. To these, however, must be added the wonderfully stimulating effects of salt water and, more especially, of surf bathing, and the vigorous, healthy out-of-door sports of sailing, boating, etc.

A seashore resort, therefore, is indicated where a strong, stimulating, moist, and equable climate is desired. It is to be recommended in many cases of anæmia and chlorosis, of scrofula, of convalescence from acute diseases, such as typhoid fever, and from surgical operations. Many victims of neurasthenia thrive there as nowhere else. The same is true of a certain number of cases of chronic pulmonary tuberculosis of mild degree and of many cases of hay fever, of spasmodic asthma, and of emphysema and chronic bronchitis. Diseases of the heart and blood-vessels and of the kidneys do better, in general, at the seashore than in the mountains.

St. Andrews, N. B.—St. Andrews, a charming old resort situated in the southwest corner of New Brunswick upon Passamaquoddy Bay, has been a quiet but favorite summer retreat for generations. During the past few years its charms have become more widely recognized, and now it ranks among the most popular places of the northeast coast. The hotel accommodations are excellent. The visitor has before him a beautiful panorama of mountain, bay, and island. The fine roads invite cycling, and the picturesque bay offers every facility for yachting and fishing. The immunity from hay fever is said to be complete.

Grand Menan.—South of Passamaquoddy Bay at the entrance to the Bay of Fundy and lying a few miles off the coast is the island of Grand Menan. This is about twenty miles long, presenting on its western side a rugged shore line of high cliffs, but on its eastern side a series of little harbors and coves, in which are nestled quaint fisher villages. The island has long been, from its wildness and splendor of scenery, a favorite resort of artists, and of late years has, very properly, gained greater prominence as a wild and secluded seashore resort for tired brain-workers. Tramping, riding, sailing, and sea fishing are the chief diversions. As yet there are no large settlements upon the island and no swarm of summer tourists. The hotel accommodations are accordingly modest and primitive. The atmosphere is wonderfully soft and moist, much resembling that of Scot-

land, but without its sudden changes. Fog is less common than at Mount Desert, but is occasionally troublesome.

Eastport, Me.—A few miles across the frontier, in the southeast corner of Maine, and lying on the western shore of Passamaquoddy Bay, is the pretty town of Eastport—a place of some four thousand people, and a favorite among the many delightful resorts of the Maine coast. The place has many of the natural features of St. Andrews, but with them the advantages and disadvantages of a town residence.

Mount Desert Island.—The fame of Mount Desert as a place of summer residence is now so wide that a detailed description of the place seems almost unnecessary. The island is fourteen miles long and eight miles wide, and has an area of about one hundred square miles. It lies in Frenchman's Bay, one hundred and ten miles east of Portland, and its northern coast approaches so closely to the mainland as to be connected to the latter at one point by a bridge. It is made up of a mass of mountains, some of them rising abruptly from the sea, which terminate in a series of thirteen peaks; the highest, Green Mountain, reaching an altitude of fifteen hundred and twenty-seven feet. On the west the mountains rise in a gentle slope from the water, but on the east they form a range of towering cliffs rising perpendicularly from the sea. The mountain slopes are heavily timbered, and hidden away high up among these are many beautiful mountain lakes, whose wonderfully clear waters reveal the presence of the wary trout far below the placid surface. The superb picture of ocean, mountain, forest, and lake lends a charm to the place which is irresistible. As one writer says of it: "Certainly only in the tropics can the scene be excelled—only in the gorgeous islands of the Indian and Pacific oceans. On the coast of America it has no rival except, perhaps, on the Bay of Rio Janeiro."

The air of Mount Desert is strikingly fine and exhilarating. It combines with the strong air of the sea the purity and crispness of that of the mountains. Equability is the feature of the temperature. Extremes of heat and cold are almost unknown. Government records show the average during the summer months for the warm hours of the day to be 70° F., and that for the night to be 64° F. The fact that during the summer it is not uncommon to have fog during the morning and evening hours may, with certain patients, prove an objection to the place.

As for diversions, they are simply numberless. The many indentations of the coast and the number of cozy harbors, together with the grandeur of the scenery, make it an especially attractive place for yachtsmen. There is besides every facility for boating, canoeing, sailing, fishing, and, for those who do not mind the somewhat chilly water, salt-water bathing. Among the land sports may be mentioned climbing, walking, riding, driving, tennis, etc.

Mount Desert may be recommended for cases of overwork, anæmia, and debility, for neurasthenia, hay fever, spasmodic asthma, etc. Many bronchial and pulmonary sufferers do remarkably well there for the summer. For those cases of chronic valvular disease in which Oertel's treatment of carefully graduated hill climbing seems desirable, the island would seem to be especially suitable.

Bar Harbor. Bar Harbor, on the eastern shore of the island, is the most widely known and most fashionable of the resorts. Here one will find magnificently appointed hotels and every luxury that can be desired. Northeast Harbor, Southwest Harbor, Seal Harbor, Sorrento, Winter Harbor, and Sullivan Harbor, though smaller and less widely known than Bar Harbor, are all attractive, high-class resorts.

Penobscot Bay.—A few miles to the westward from

Mount Desert lies the beautiful Penobscot Bay, and upon its shores are to be found a number of quiet, charming retreats—among them Castine, a pretty and wealthy village, situated on a narrow peninsula projecting into the bay; Northport, Fort Point, and Blue Hill.

Islesboro.—Islesboro, at the entrance of Penobscot Bay, is a narrow, well-wooded island, thirteen miles long, with charmingly picturesque scenery and much about it that is interesting in history and tradition. There are good hotel accommodations.

Camden.—Camden, lying eight miles north of Rockland, combines the charm of mountain and sea, and is steadily growing in favor among the Maine coast resorts.

Popham Beach.—At the mouth of the Kennebec River is situated Popham Beach—a semi-fashionable resort, with a fine, hard, white beach, and interesting fort ruins. There is every opportunity for aquatic sports. The hotels are comfortable and commodious.

Portland.—The commercial metropolis of Maine and "one of the most beautiful cities in the country," is also the centre of a group of delightful seaside places. Situated on a peninsula at the southwestern extremity of Casco Bay, its summer climate is made delightful by the cool, fresh sea breeze which blows with great constancy.

Casco Bay.—The great bay is dotted with hundreds of small islands, some of which present scenes of wild beauty. Many of them are occupied by attractive summer hotels and cottages. There are many excellent bathing-beaches, as well as good sea fishing, sailing, boating, etc. Cushing's Island, the largest of the islands, lies three miles off from Portland and is reached by steam ferries. It furnishes excellent hotel accommodations. Cape Elizabeth, at the southern side of the bay, is another attractive place.

Scarboro Beach.—A few miles south of Portland lie Scarboro Beach and Pine Point, two popular seaside places, offering excellent bathing, boating, fishing, and shooting. They possess a number of comfortable hotels and boarding-houses and are especially patronized by Canadians.

Old Orchard Beach.—The next point of importance in following down the coast is one whose name has been for many years a familiar one throughout the land. Old Orchard has perhaps the most magnificent beach to be found along the whole length of the Atlantic seaboard. It extends in the form of a crescent for a distance of ten miles, slopes very gradually to the water, and is composed of dazzlingly white, compact sand, upon the smooth hard surface of which the fine surf dashes unceasingly. The gradual slope of the beach makes it an especially safe one for bathing. There are, besides, good fishing and shooting in the vicinity. Many hotels, large and small, boarding-houses, and cottages make up the settlement. A camp-meeting ground, where meetings are held each summer, is also near at hand.

Kennebunkport.—About midway between Portland and Portsmouth lies the pleasant old village of Kennebunkport, once famous for its ship-building. It is situated about one mile from the mouth of the Kennebunk River, and has of late found much favor as a place of quiet summer residence.

Wells Beach.—Wells Beach, reached by a stage ride of six miles from the station of Wells, is very popular with sportsmen by reason of the good fishing and shooting to be had there. The beach supplies many snipe and curlew and the adjacent woods partridge and woodcock. A large trout stream is also in the immediate vicinity.

York.—A few miles farther south and nine miles north of Portsmouth, N. H., is the village of York, with its neighboring York Beach and York Harbor.

These are attractive resorts, with good hotels and good bathing, boating, canoeing, and fishing.

Portsmouth.—Portsmouth, the seaport of New Hampshire, is a charmingly old-fashioned town of ten thousand people, with wide, finely shaded streets, large gardens, and comfortable old residences, and with much of historic interest about it. The town lies two miles from the mouth of the Piscataqua River and is almost entirely surrounded by water. There are several good hotels.

Isles of Shoals.—Portsmouth is the starting-point for steamers which run daily to the famous Isles of Shoals, which lie some nine miles off the coast at this point. These islands, so widely known through the writings of Lowell, Celia Thaxter, and others, consist of eight small rocky ledges, bleak and barren in aspect, and with ugly jagged reefs extending from them in all directions under the water. There is, however, much that is attractive about them for those who love their severe, rugged beauty. Several of the islands possess good hotels and pleasant cottages, and they are much frequented during the summer.

New Castle.—Two miles from Portsmouth at the mouth of the harbor and on an island of the same name is the historic old village of New Castle. The island affords fine land and water views, and there are excellent bathing, boating, fishing, and driving. There is near the village a large, finely appointed hotel.

Rye Beach.—Rye Beach, the most fashionable, perhaps, of the many New England seashore resorts, is situated seven miles south of Portsmouth. The beach itself is a beautiful one and the surf bathing unexcelled. The place contains several high-class hotels and many charming cottages.

Hampton Beach.—Only a few miles to the south of Rye is another attractive though less widely known resort. Hampton Beach offers capital surf bathing, fishing, driving, etc., and good hotel accommodations.

Newburyport.—Built upon the steep Massachusetts shore of the Merrimac River, three miles above its mouth, is the historic old town of Newburyport, now a place of some fourteen thousand inhabitants. There is much that is quaint and interesting in the old place, and steamers ply constantly between it and the two neighboring ocean resorts, Plum Island and Salisbury Beach.

Cape Ann.—Cape Ann, with its peaceful fishing-village, has long been used as a place of summer residence by the many who prefer to enjoy their seaside life in restful quiet and seclusion rather than amid the excitement and conventionalities of the fashionable summer hotel.

Plymouth.—Still farther south lies ancient Plymouth, the "Mecca of the New World," with its wealth of historic interest and charm. It possesses, moreover, many attractive natural features. The diversions of a watering-place are all there, and there are besides many charming excursions and drives in the surrounding country.

Cape Cod.—Cape Cod, with its hundreds of miles of coast line, its barren sand wastes, its constant association with storm and shipwreck, its famous sea fisheries, and its quaint, interesting fisher-folk, stands unique among seashore resorts. The absence of hills and rocks and woods over a great part of the cape offers to some a serious objection to the place, but, on the other hand, there are many who affirm that for those who really love the sea Cape Cod has an indescribable charm not to be found at any point along the coast. The places along the shore of Buzzard's Bay are perhaps the most attractive. Sea fishing of every variety, surf and still-water bathing, sailing and boating are all to be had in perfection on the cape. Near Bourne on Buzzard's Bay are "Gray Gables," the summer home of President Cleveland, and "Crow's

Nest," Mr. Joseph Jefferson's charming place. Wareham, Bourne, Monument Beach, Cataumet, Sandwich, Barnstable, Hyannis, Yarmouth, Dennis, Harwich, Chatham, and Provincetown, are the chief centres for summer visitors.

Wood's Holl.—Wood's Holl, at the southeastern extremity of Buzzard's Bay, is an attractive resort and the headquarters of the United States fish commission.

Martha's Vineyard.—Lying some ten miles south of the Massachusetts coast and separated from it by Vineyard Sound is Martha's Vineyard, an island twenty miles long and six miles wide. This has long been a popular summer retreat, and of late has become known as the place of the great Methodist camp-meeting ground, where twenty thousand to thirty thousand people gather every August. The island furnishes delightful still-water bathing and good fishing, sailing, driving, and wheeling. There are good hotels and many attractive cottages. Cottage City, pleasantly situated on the north shore, is the chief town. Oak Bluffs and Edgartown are popular places.

Nantucket.—Some thirty miles eastward of Martha's Vineyard, and far out in the Atlantic, lies Nantucket, once the headquarters of the whaling industry in this country and now recognized as one of the most charming of the quiet watering-places along the coast. The island lies so far out that the strong, moist air is exactly that of the ocean itself. The proximity of the Gulf Stream tempers the water so as to make the bathing especially pleasant. The island is almost treeless, but the low hills are covered to a great extent with heather, and one is constantly reminded both by climate and landscape of the lovely Scottish moors. The quaint old town of Nantucket, lying on the western side of the island, furnishes excellent sailing, fishing, and boating. At Siasconset, a queer but charming old fishing-village on the eastern shore, fine surf bathing is to be had. The island contains a number of first-class hotels, but is chiefly occupied by cottagers. Martha's Vineyard and Nantucket are reached from New Bedford, by steamers running twice daily during the summer months and touching at Wood's Holl.

Newport.—This queen of watering-places is too well known to need detailed description. The place abounds in luxurious hotels and palatial "cottages." There are to be had fine surf bathing, good sailing, and land sports of every variety.

Narraganset Pier.—Narraganset is another fashionable and famous watering-place. It lies on the west shore of Narraganset Bay at its mouth, has a superb bathing-beach and many first-class hotels.

Watch Hill.—Situated on a bold promontory at the extreme southwestern point of Rhode Island is Watch Hill, another delightful shore resort. The scenery is bold and beautiful, the bathing and fishing are good and the hotels metropolitan in point of excellence.

Block Island.—Lying ten miles south of Rhode Island and at the eastern entrance to Long Island Sound is Block Island, reached by steamer from New London and Stonington. The island is seven miles long and along its southern shore is bordered by high bluffs. The northern shore furnishes good bathing-beaches and a fine surf. The island is patronized by a high class of visitors and offers many attractions both on land and water.

The Connecticut Shore.—The northern shore of Long Island Sound is lined with pleasant summer resorts where still-water bathing, sailing, fishing, and boating are to be had in perfection. The air lacks some of the freshness and coolness of the more northern resorts, but the nights are always cool and breezy. Lack of space forbids more than a mere mention of

the more important places. These are Stonington, New London, Saybrook, Guilford Point, Branford Point, Milford, Black Rock, Fairfield, Westport, Norwalk, Stamford, Greenwich, and Rye.

Long Island.—Long Island, by reason of its accessibility and its natural attraction, is so completely occupied during the summer by multitudes in search of relief from the heat of the cities and of rest and health among the innumerable watering-places, that it may be considered as one vast seashore resort. Both the northern and southern shores of the island afford a whole series of attractive places, although the latter has by far the greater number.

North Shore.—The north shore, washed by the sound, has many little bays and inlets and furnishes all the usual seashore diversions and many charming drives.

South Shore.—The south shore, although flatter and more monotonous in landscape, is fanned by the cool, strong breezes of the Atlantic, and is perhaps the more attractive. The shore is separated from the ocean by a line of dunes, extending for seventy miles, which form two long, narrow landlocked bays—Great South Bay and Shinnecock Bay—admirably suited for safe sailing and bathing and for fishing. Beyond the dunes excellent surf bathing is to be had. Riding, driving, wheeling, and tennis are all indulged in extensively. At certain points along both shores mosquitoes are sometimes troublesome.

Along the north shore from west to east the chief places are Glen Cove, Oyster Bay, Cold Stream Harbor, Northport, Port Jefferson, and Greenport. Shelter Island and Gardiner's Island are two popular island resorts reached by steamer from Greenport.

Along the south shore in the same direction are found Rockaway Beach, Amityville, Babylon, Bay Shore, Islip, Bayport, Patchogue, Bellport, the Moriches, West Hampton, Quogue, South Hampton, East Hampton, and Montauk Point.

New Jersey Resorts.¹—The coast of New Jersey presents a chain of flourishing watering-places, the most famous of which is, of course, Long Branch. These resorts are especially popular because of their ready accessibility from the large cities of the East and of the fine surf bathing to be had at most of them. The summer climate is, of course, not so cool and exhilarating as that along the coast farther north, but the weather is tempered most of the time by the fresh balmy ocean breeze, and the nights are always comfortable and refreshing. On Shrewsbury River and Barnegat Bay good sailing and boating may be had. The country abounds in fine roads, and driving and wheeling are popular diversions. Fine beaches and high surf exist all along the coast. Resorts of every character are to be found here, from fashionable and dissipated Long Branch to the great Methodist settlement of Ocean Grove.

From north to south the principal resorts are as follows: Highlands, Seabright, Monmouth Beach, Long Branch, Elberon, Asbury Park, Ocean Grove, Ocean Beach, Spring Lake, Sea Girt, and Manasquan. Along the shores of Barnegat Bay are Point Pleasant, Tom's River, Bayville, Barnegat, Manahawkin, Tuckerton, Beach Haven, Barnegat City, Seaside Park, and Bay Head.

Mountain Resorts.—The climate of high elevations differs, in general, from that of the lowlands in the following respects: The air is rarefied, as shown by the lessened barometric pressure; it contains a relatively small proportion of moisture and is therefore dry; as a result of this latter feature the air is cool, although the sunshine may be quite hot, because the

heat absorbed by the air from the sun's rays depends upon the amount of aqueous vapor in the air. There is, moreover, great freedom from both organic and inorganic impurities. Bacteria and kindred micro-organisms exist in very small numbers, probably because of the low humidity, the cold nights, the greater electrical activity, and the increased amount of light, all of which conditions are inimical to the growth and development of these germs. As a result of the above-mentioned peculiarities of mountain climate the activity of the skin is increased, the frequency of the heart beats is augmented, and the individual beats are strengthened; the respirations are usually somewhat quickened and each inspiration is deepened; the respiratory muscles are strengthened, the quantity of blood in the lungs is greater, and the elimination of water and carbonic acid is increased. Besides this, the appetite is usually improved and the assimilation of nourishment increased.

It has been found from experience that the elevated and dry climate of the mountains is particularly beneficial in the following classes of ailments: Exhaustion from overwork with anæmia, loss of appetite, insomnia, etc.; most cases of pulmonary phthisis, especially those in which the process is not acute and severe and in which hectic symptoms are not marked; cases with only an hereditary tendency toward phthisis; chronic catarrh of nose and throat, hay fever, spasmodic asthma not dependent upon emphysema or organic heart disease; many cases of functional liver disorders and chronic dyspepsia; some, but by no means all, cases of neurasthenia. The classes of diseases usually not favorably influenced by mountain life are arterio-sclerosis and senile conditions generally; organic disease of the heart, aneurism of the aorta, severe emphysema with chronic bronchitis, epilepsy, and, in general, rheumatic and gouty affections.

The White Mountains.—The White Mountains, the grandest and most picturesque of the mountain groups in the eastern half of the United States, rise from a plateau sixteen hundred feet above sea level, near the centre of New Hampshire. They cover an area about forty-five miles long and thirty miles wide, and are made up of about twenty separate peaks ranging in height from three thousand to sixty-three hundred feet. These are divided by deep, narrow valleys into two groups—the eastern the White Mountains proper, the western the Franconia group.

These mountains are extremely popular as places of summer resort, not only on account of the health-giving properties of their climate, but also because of their matchless scenery, which has won for them the title of the "Switzerland of America." The region is well supplied with large and finely appointed hotels, both on the mountains themselves and in the charming villages occupying the neighboring valleys and plateaus. There are also many small hotels, boarding-places, and cottages to be found.

The mountains are approached from the northeast through the village of Gorham, from the southeast through North Conway, from the south through Plymouth, and from the west through Wells River.

Bethlehem.—Bethlehem, "the highest village east of the Rocky Mountains," lies on the western side of the mountains. It is a famous place of summer resort and the meeting-place of the American Hay Fever Association.

Jefferson, Lancaster, Bartlett, and Jackson are some of the better known mountain villages.

Green Mountains.—Extending north and south through the western part of Vermont is the Green Mountain range. These mountains are for the most part only high, wooded hills. The country is beautiful and healthful, but the scenery much less rugged and the climate less truly mountainous than in the

¹Atlantic City, Cape May, and the seaside resorts of the southern coast will be considered in an article on winter resorts to appear in the autumn.

neighboring White Mountains. Mount Mansfield, forty-three hundred and forty-eight feet, is the highest peak of the range. Rutland, Waterbury, and Stowe are delightful places of summer residence and the centres of resort in this district.

The Adirondacks.—This great tract of mountain land, now so well known as the summer retreat of many thousands of healthy people from all over the country, is also famous for the multitude of consumptive patients who seek there, successfully, renewed health and prolonged and useful life.

These mountains, up to a few years ago a wild and savage wilderness unknown but to the hunters, trappers, and lumbermen of that region, lie in the north-eastern part of New York, between Lake Champlain on the east and the St. Lawrence River on the north-west. They rise from a great plateau, of some two thousand feet elevation, covering a region of one hundred and fifty miles long and one hundred miles wide, and are composed of several hundred peaks ranging in height from twenty-five hundred to fifty-three hundred feet. The mountains are everywhere covered with dense forests composed of trees of many varieties and afford shelter for all sorts of wild game. In the valleys among the mountains are found a vast number of beautiful lakes and ponds, and these are connected with one another by an intricate network of rivers and brooks which offer to the angler all sorts of delightful possibilities. The mean elevation of these lakes is about fifteen hundred feet and many have a much greater altitude.

The effect of the forests is to modify the climate of this region as compared with that of other mountain districts, in that the air contains more moisture because of the slow evaporation and the temperature is more equable because of the protection afforded against cold winds. Considering the wildness of the region, comfortable hotel accommodation is singularly abundant. At almost all the larger lakes are well-appointed hotels and good boarding-places, and no difficulty is experienced in securing camps, reliable guides, and camping-outfits. It will be quite impossible to mention in detail the many delightful resorts in these mountains; only the larger and better known can be spoken of, but it must be remembered that this whole region teems with wonderfully beautiful places far away from crowds and civilization, where the invalid, in canoe or hammock, with rod or gun, can dream away the long, cool summer days, inhaling with each breath of fragrant, resinous air new life and fresh vigor.

Scroon, Blue Mountain, Long, and Raquette Lakes in the southern part, Elizabethtown and Keene Valley in the east, Chateaugay and Loon Lakes in the north, Tupper Lake in the west, and Lake Placid and the Saranac Lakes in the central part of the mountains, are the favorite regions of resort.

The Catskill Mountains.—In the southern eastern section of New York and lying a few miles west of the Hudson River is this small group of mountains, whose easy accessibility and bold and striking beauty have made them a favorite summer retreat for many generations. They cover an area some thirty miles square and range in height from two thousand to four thousand feet. The region is replete with curious and picturesque scenes, and from the mountain summits views are to be had which for vast extent, grandeur, and beauty can hardly be surpassed by any east of the Rockies. The air of this region is characterized by its dryness, its purity, and its tonic qualities. A few of the highest and most beautiful situations are occupied by large and famous hotels. In the villages mentioned below are to be found many quiet, comfortable hotels and boarding-places and many charming colonies of summer cottagers.

Among the more prominent places of resort are Shandaken (1,060 feet), Pine Hill (1,650 feet), Prattsville, Stamford (1,800 feet), Hunter (2,000 feet), Tannersville, Onteora Park, Haines' Corners (2,300 feet), Kaaterskill, Pine Orchard (2,500 feet), Lexington, and Palenville.

The Shawangunk Mountains.—The Shawangunk Mountains form a small spur lying to the south of the Catskills and possess much the same climate and natural features of these latter mountains.

Lakes Mohonk and Minnewaska.—Situated near the summit of these mountains are two small lakes, Mohonk and Minnewaska, with an elevation respectively of twelve hundred and fifty and eighteen hundred feet. These little sheets of water lie in the midst of bold and picturesque scenery, and afford wide and beautiful views over the surrounding valleys. The region is supplied with good hotel accommodation.

The Delaware Mountains.—To the southwest of the Catskills and forming a link between them and the Alleghany Mountains in Pennsylvania are the Delaware Mountains, a group of hills lying chiefly in Sullivan County, N. Y., and ranging in height from twelve hundred to twenty-five hundred feet. The hills are covered with forests and enclose many beautiful lakes and streams, so that Sullivan County has long been a most popular locality with sportsmen, and especially with fishermen, who find there trout fishing of the most exciting kind. The climate is that of a high plateau, dry, cool, and bracing. The region has gained some repute not only by reason of its charming scenery and excellent sport, but also as possessing a climate eminently suited for consumptives. The summer resorts of this region are essentially quiet and modest in character, and are especially adapted for people of moderate means who wish to avoid the expense incident to life at the large and fashionable hotels. The district furnishes an immense number of small, quiet hotels and comfortable farmhouses, where summer visitors are well cared for at very moderate expense.

Liberty and Monticello are the two chief village resorts of this region, and these furnish excellent hotel accommodations. Four miles from the former place are the White Sulphur Springs, where hot and cold sulphur baths, etc., are to be had.

The following list includes the better known places of resort: Mountain Dale (1,000 feet), Kiamasha Lake (1,600 feet), Woodbourne (1,400 feet), Never-sink (1,450 feet), Monticello (1,500 feet), Loch Sheldrake (1,300 feet), Liberty (1,580 feet), White Lake (1,500 feet), Parkville (1,600 feet), and Livingston Manor (1,430 feet).

The Alleghany Mountains.—The great Alleghany system of mountains, of which the White Mountains and the Adirondacks are really outlying portions, extends in several parallel ranges southwestward through Pennsylvania, Maryland, Virginia into North and South Carolina and Tennessee. These mountains naturally furnish a vast number of health resorts of every character, of which only those of the more northern portion can be mentioned in this paper. The most eastern range, the Blue Ridge—known in Pennsylvania and Maryland as the South Mountains—furnishes perhaps the most attractive summer resorts.

The Delaware Water Gap.—On the boundary between eastern Pennsylvania and New Jersey, in the midst of wild and beautiful mountain scenery, is the Delaware Water Gap, a deep narrow gorge, at the bottom of which the Delaware River flows in passing through the Blue Ridge Mountains. The walls of the gorge rise almost perpendicularly to a height of sixteen hundred feet and are topped by the two frowning mountains, Minsi and Tammany. This place has

long been a well-known and popular mountain resort. The neighborhood is rich in picturesque tramps and drives and the summer climate is cool and bracing. The forests shelter small game and the mountain streams furnish excellent trout fishing.

Mauch Chunk.—In the heart of the Pennsylvania coal region and in the midst of the most rugged and beautiful mountain scenery of the East, lies the town of Mauch Chunk. The Lehigh River flows at its foot and the narrow gorge-like valley is surrounded on every side by high mountains. Here is the famous switchback railroad, now used only as a pleasure road. The immediate neighborhood of Mauch Chunk is much frequented as a place of summer retreat, and abounds in comfortable hotels and manifold diversions.

Glen Summit.—Thirty miles from Mauch Chunk is Glen Summit, another well-known mountain resort. It lies at the very crest of the great ridge, two thousand feet high, and offers a series of magnificent mountain views and many charming walks and drives. The place has a large hotel and many attractive cottages and is much patronized in summer.

Wilkesbarre.—The prosperous city of Wilkesbarre occupies the central part of the picturesque Wyoming Valley, lying on the bank of the Susquehanna River. The town itself has an altitude of only five hundred feet, but the neighboring mountains afford many attractive places for summer retreat. Shawanese Lake, a lovely sheet of water high up in the mountains, is growing rapidly into prominence as a popular resort. Lake Ganoga, also in the vicinity of Wilkesbarre, has an altitude of twenty-three hundred feet and lies in the midst of a great forest with wonderful mountain views all about it. Lake Carey, a few miles beyond, has an altitude of one thousand feet and abounds with black bass and pickerel. It has comfortable hotels and is very popular with sportsmen.

Cresson Springs.—A few miles west of Altoona on the very summit of the Alleghany range and three thousand and twenty feet above sea level is Cresson Springs, one of the largest and most visited mountain resorts in Pennsylvania. The high altitude insures for it in summer dry, pure air and low temperature. Aside from the delightful climate there are in the neighborhood entrancing mountain views.

Deer Park.—The last of the Alleghany resorts to be mentioned here is Deer Park. This is situated in the extreme southwestern corner of Maryland, in the very heart of the Alleghanies, at an altitude of twenty-four hundred feet. The scenery in this region is of surpassing beauty and the summer climate delightful in its freshness and coolness. There are many attractive walks and drives and good boating and fishing. The region affords excellent hotel accommodations and contains many charming cottages.

The Rocky Mountains.—The Rocky Mountains by their enormous area and high altitudes afford, of course, a multitude of health resorts, suitable especially for patients with pulmonary disease. Only a few of the more important regions can be mentioned here.

Denver.—The capital and chief city of Colorado lies at an altitude of fifty-three hundred feet and shares with all the other resorts of the eastern slopes of the Rockies a singularly dry, pure atmosphere. The value of its climate in pulmonary complaints has been attested by the thousands of invalids who have there regained completely their health or have at least won comparative freedom from the distressing symptoms of the disease.

Colorado Springs.—This famous and fashionable resort lies seventy-five miles south of Denver in the neighborhood of Pike's Peak and has an altitude of six thousand feet. It is used both as a summer and

winter resort. The town is pleasantly laid out and contains many handsome residences, large hotels, and good boarding-places. The region supplies many pleasant rides and drives and all sorts of outdoor amusements.

Manitou Springs.—Six miles west of Colorado Springs at the foot of Pike's Peak is the village of Manitou Springs, famous not only for its mountain climate, but as well for the mineral springs to be found here. These are six in number: two supply muriated alkaline water, two acidulous alkaline, one chalybeate alkaline, and one aperient. The climate has been found especially suitable for patients with asthmatic as well as tuberculous trouble, and the springs are useful in liver and kidney disorders and for their tonic effects. The region about Manitou supplies some of the most wonderful bits of mountain scenery on this continent. Pike's Peak, Glen Eyrie, the Garden of the Gods, and Monument Park are reached by short excursions.

San Luis Park.—San Luis Park, by far the largest of the four great natural parks of Colorado, lies in the southern part of the State, at a height of between six thousand and seven thousand feet. This enormous valley, covering an area of eighteen thousand square miles, is surrounded on all sides by high mountains, and this sheltered position and its southern location give it a climate wonderfully mild, genial, and equable. Near the centre of the park is San Luis Lake, a beautiful sheet of water, into which most of the many streams of this region flow. The country is, of course, wild and unpopulated and abounds in excellent hunting and fishing.

South Park.—In the central part of Colorado and some distance north of San Luis Park is South Park, the most accessible and most beautiful of the Colorado parks. Its average elevation is nine thousand feet. It lies surrounded on all sides by gigantic snow-covered mountains, and offers a delightfully mild, balmy summer climate and scenery of the utmost grandeur.

Middle Park.—Middle Park, situated directly north of South Park is separated from the latter by a branch of the Park range. It lies at a height of seventy-five hundred feet and comprises an area of some three thousand square miles. This vast district teems with every variety of big game and the streams are filled with fish. The climate, though less warm than that of the two above-mentioned parks, is still mild and dry and in every way suitable for invalids who can stand the fatigues of the journey thither. Hot Sulphur Springs is usually the objective point of visitors to this region. The sulphur baths here are recommended especially for chronic rheumatism, neuralgias, and chronic skin diseases. The hotel accommodations are fairly comfortable.

North Park.—In the extreme northern part of Colorado, at an elevation of nine thousand feet, is North Park, the wildest and least accessible of the four. The climate is cold, but the air dry and exhilarating and the region is one of the best hunting-grounds of the continent.

Yellowstone Park.—The great National Park is now perhaps the most popular inland summer resort of tourists and invalids in the West. Its grand mountains, wonderful geysers, beautiful lakes and streams, exhilarating climate, and easy approach conspire to make it one of the most attractive and interesting regions on the continent. It comprises an area of some thirty-five hundred square miles, lying at an altitude of from six thousand to seven thousand feet. Camping is much resorted to in the park, and reliable guides and complete outfits are readily obtainable. The park abounds with all sorts of big game and the lakes and streams with fish. Fishing with line and hook is permitted, but the use of firearms is prohib-

ited. Capital hunting, however, is to be had across the borders of the park. The climate is cool, dry, and invigorating.

Banff Springs.—Farther north in the Rockies in eastern British Columbia lies the Canadian National Park, and in this is situated Banff Springs, a mountain resort of much beauty, but best known by reason of the hot sulphur springs here. The spot lies in the midst of wild mountain scenery and possesses a dry, cool summer climate. Only a few miles away are the famous Lakes in the Clouds, three mountain lakes of surpassing loveliness. The climate at Banff is suitable for pulmonary diseases and the sulphur baths are useful especially in rheumatic affections. Hotel accommodations are excellent.

Mineral Springs.—The benefit derived from a visit to a spa is by no means altogether, or even chiefly, to be attributed to the mineral ingredients of the water there imbibed. The change of climate and scene, the freedom from care, the regular habit of life, the simple regimen, and the regular out-of-door exercise, all play an important part in producing the very satisfactory results so often seen from such a pilgrimage. And it may be said in general that just in proportion as these important features of the treatment are carefully and faithfully complied with can a satisfactory result be expected.

Mineral springs are classified in various ways and most of these classifications are open to objections of one sort or another. A simple and fairly satisfactory arrangement is the following one: alkaline, saline, chalybeate, sulphuretted, carbonated, and thermal springs.

Alkaline Springs.—That class of springs in which the chief mineral ingredients are the alkaline carbonates is called alkaline. The carbonates are those of sodium and potassium, and upon these the chief therapeutic action depends. These waters are often also strongly impregnated with carbonic-acid gas.

When taken before meals the physiological action is chiefly to stimulate gastric secretion. • During and after meals the water tends in the stomach to neutralize free acids and the products of fermentation. When absorbed into the blood the alkalinity of the blood is increased, the excretion of urea made greater, and the functions of the various mucous membranes stimulated. These waters are useful especially in acid and atonic dyspepsias, in catarrhal conditions of the different mucous membranes, particularly those of the respiratory tract, bladder, and biliary passages.

Sheldon Springs, Vt.—Ten miles from St. Albans in the northwestern part of Vermont are the Sheldon Springs lying in an attractive country, with views of several of the Green Mountain peaks. There are a comfortable hotel and good bathing facilities.

Middletown Springs.—In Rutland County, of the same State, are the Middletown Springs—four alkaline springs located on the north bank of the Poultney River. The village lies at the foot of the mountains and affords fine views. There are comfortable accommodations for three hundred and fifty guests.

Orkney Springs, Va.—The Orkney Springs lie near Mount Jackson, in Shenandoah County, Va., at an elevation of twenty-one hundred feet. There are several hotels and numerous cottages and the place is well known as an attractive summer resort.

Jordan Alum Springs.—In the Mill Mountains in Western Virginia are the Jordan Alum Springs. The water is alkaline and astringent, and is useful in chronic diarrhœas as well as in the list of ailments given above.

Perry Springs in Pike County and Versailles Springs in Brown County, Ill., are valuable alkaline waters, as yet not widely known.

Waukesha, Wis.—Waukesha is one of the popular

summer resorts of the West and lies in a valley famous for its lovely scenery. The village is in summer a gay and lively one. There are first-class hotels and many cottages. The Bethesda Spring is well known and much patronized.

Manitou Springs, Col., with its alkaline water, has been mentioned under mountain resorts.

Saline Springs.—These may be subdivided into two groups: First, the saline springs proper, or those in which sodium chloride is the chief ingredient, and second, the sulphated or bitter springs, which depend for their active properties upon the presence of sodium and magnesium sulphate.

Mount Clemens Springs, Mich.—One of the strongest saline springs of this country is that of Mount Clemens, Mich. The town lies on the Clinton River, a short distance above its entrance into Lake St. Clair. The region is admirably suited for a place of summer resort. The climate is cool and invigorating, the place affords pleasant drives, and the neighboring waters are filled with fish. Mount Clemens has, within a few years, grown to be a large and very popular health resort. The water, besides containing a very large amount of sodium chloride, is also impregnated with sulphuretted hydrogen gas and is used extensively both internally and in the form of baths. The best results have been obtained in rheumatism, gout, chronic skin diseases, and chronic catarrhal conditions of the gastro-intestinal tract.

The Sodium Chloride Waters.—The physiological effect of these waters is to stimulate the functions of all the mucous membranes, but especially those of the gastro-intestinal tract. In the stomach and intestines they dissolve mucus, stimulate the digestive juices, and hasten osmosis and absorption. Peristalsis is increased. These springs are useful in catarrhal processes of stomach, intestines, and bile ducts, in chronic congestion of the pelvic viscera, in obesity, and in syphilis.

Saratoga Springs.—Under this class come most of the springs at Saratoga. These contain large quantities of saline ingredients and have a distinctly purgative action. The following analysis is that of the Congress Spring, which may be taken as a type of these waters. One gallon contains:

Bicarbonate of lithium.....	4.761 grains.
Bicarbonate of sodium.....	10.775 "
Bicarbonate of magnesium.....	121.757 "
Bicarbonate of calcium.....	143.399 "
Bicarbonate of strontium.....	trace.
Bicarbonate of barium.....	0.928 grain.
Bicarbonate of iron.....	0.340 "
Chloride of sodium.....	400.444 grains.
Chloride of potassium.....	8.049 "
Sulphate of potassium.....	0.889 grain.
Phosphate of sodium.....	0.016 "
Biborate of sodium.....	trace.
Bromide of sodium.....	8.559 grains.
Iodide of sodium.....	0.138 grain.
Fluoride of calcium.....	trace.
Alumina.....	"
Silica.....	0.840 grain.

Total..... 700.895 grains.
Gas, carbonic-acid..... 392.289 cubic inches.

As regards Saratoga itself little need be said. It is the most famous spa of this continent. Its enormous hotels are filled each summer by a fashionable throng gathered there from all parts of the country. The climate is delightful and the surrounding country beautiful.

Ballston Spa.—Seven miles from Saratoga lies Ballston, another famous resort. This place, although much more quiet than Saratoga, is visited by a delightful class of people and contains excellent hotels and many beautiful summer residences. The springs resemble closely in character those of Saratoga.

Blue Lick Springs, Ky.—Blue Lick Springs is one of the popular summer resorts of the Southwest. It lies in Nicholas County, Ky., on the banks of the Licking River. The waters are sulphuretted and saline. There are good hotel accommodations.

Michigan Congress Springs.—At Lansing, the capital of Michigan, are the Michigan Congress Springs, whose water resembles that of the Saratoga Springs. Lansing is a town of fifteen thousand inhabitants, with comfortable hotels.

Borland Well and Kanawha Spring in West Virginia, and Sheboygan Well in Wisconsin, are springs of this type.

Sulphated or Bitter Springs.—These names are used to designate waters characterized by the presence of large amounts of the sulphates of sodium and magnesium (epsom and Glauber's salts). These waters produce profuse, watery discharges from the bowels, and are useful in obesity, congestions of the pelvic organs, hemorrhoids, etc. Their action in obesity depends partly upon the fact that food is hastened through the intestines and absorption is thus rendered incomplete.

Bedford Springs, Pa.—The Bedford Springs lie at an elevation of one thousand and eighty feet on the eastern slope of the Alleghanies and possess in addition to the curative water the features of picturesque mountain scenery, pure air, and a salubrious climate. The place has long been a favorite summer resort and affords commodious hotel accommodations. The analysis of the "Mineral," one of the five springs here, is appended. One gallon contains:

Carbonate of calcium.....	8.471 grains.
Carbonate of magnesium.....	0.591 grain.
Carbonate of iron.....	0.046 "
Carbonate of manganese.....	trace.
Sulphate of strontium.....	0.007 grain.
Sulphate of calcium.....	90.455 grains.
Sulphate of magnesium.....	38.683 "
Sulphate of sodium.....	0.608 grain.
Sulphate of potassium.....	0.295 "
Chloride of lithium.....	trace.
Chloride of sodium.....	0.534 grain.
Phosphate of calcium.....	0.022 "
Sulphide of hydrogen.....	0.005 "
Silicic acid.....	0.160 "
Carbonic acid (free).....	1.273 grains.
Total.....	140.505 grains.

Crab Orchard Springs in Lincoln County, Ky., and Estill Springs in Estill County of the same State are well-known examples of this type of spring and are popular summer resorts.

Chalybeate Springs.—This name is given to those mineral springs which contain salts of iron in quantities sufficient to be of some therapeutic value. These salts are usually the carbonate and the sulphate. Alum is often present in conjunction with the iron salts. Waters containing the carbonate of iron are odorless, clear, of only slightly inky taste, and are usually highly charged with carbonic-acid gas. The sulphate waters, on the other hand, have a pronounced astringent taste, which often renders them unpalatable. This class of springs is used in anæmia, chlorosis, hysteria, neurasthenia, dysmenorrhœa, amenorrhœa, etc.

The following list includes most of the better known chalybeate springs suitable as places of summer resort: Columbia Springs, Richfield Springs, Sharon Springs, and Oak Orchard Springs in New York State; Cresson Springs in Pennsylvania; Bedford Alum Springs, Jordan Alum Springs, Orkney Springs, Rawley Springs, Rockbridge Alum Springs, and Sweet Chalybeate Springs in Virginia; Greencastle Spring in Indiana; and Schuyler County Spring in Illinois.

Sulphuretted Springs.—The characteristic which distinguishes these springs depends upon the presence

in them of sulphuretted hydrogen gas. They also usually contain alkaline and earthy sulphides and often considerable quantities of the salts of iron. Many of these springs are of high temperature and are useful especially as baths. The physiological action of these sulphur waters is not well understood. They probably act chiefly upon the intestinal tract, increasing the glandular secretions and producing mild catharsis. These waters are used internally in plethora, in hepatic and splenic engorgements, in chronic congestion of the pelvic organs, in hemorrhoids, and in chronic metallic poisoning. As baths they are used extensively in chronic rheumatism, gout, and in various chronic skin diseases.

Sharon Springs, N. Y.—One of the best-known examples of this type of springs is the Sharon Springs, which lie in the central part of New York, about sixty miles west of Albany. They are situated in a narrow valley at an elevation of eleven hundred feet and are surrounded by high hills which furnish charming drives and many beautiful views. Sharon is famous especially for its baths. The bathhouses are spacious and elaborate and have facilities for every possible variety of baths. The place is very largely patronized in summer, and possesses excellent hotels and attractions of many sorts. The following analysis is that of the White Sulphur spring at this place. One gallon contains:

<i>Solids.</i>	
Sulphate of magnesium.....	34.000 grains.
Sulphate of calcium.....	85.400 "
Bicarbonate of magnesium.....	24.000 "
Chloride of sodium, {.....	2.700 "
Chloride of magnesium, {.....	3.000 "
Sulphurets of calcium and magnesium.....	
Total.....	149.100 grains.
<i>Gases.</i>	
Sulphuretted hydrogen.....	20.50 cubic inches.

Richfield Springs, an account of which is given under sulphated springs, are also famous sulphur waters.

Avon Springs.—Avon Springs are located in Livingston County, N. Y., eighty-five miles east of Buffalo. These are strong sulphur waters, and by reason of the presence of large quantities of sulphates of sodium and magnesium are actively purgative as well. There are adequate bathing facilities, and the village contains several good hotels.

Clifton Springs.—Clifton Springs is a popular health resort situated on Seneca Lake, eleven miles west of Geneva. It lies in a pleasant pastoral country and has a temperate, equable summer climate. The place has all the requirements of a first-class spa and is much patronized.

Columbia Springs, lying four miles from the town of Hudson, possess saline-sulphur waters and good accommodations for bathing.

White Sulphur Springs, W. Va.—The most famous of the many Virginia springs are the White Sulphur Springs, situated in Greenbrier County, W. Va. They lie in the midst of charming mountain scenery and have long been the favorite summer resort of wealthy and fashionable Southerners.

Estill Springs and Blue Lick Springs in Kentucky both possess useful sulphur waters and are popular resorts.

French Lick and West Baden Springs, Ind.—In the southern part of Indiana, in Orange County, are situated two springs, French Lick and West Baden, which are yearly gaining in popularity and repute.

They lie in a picturesque hill country, one mile apart, and possess saline-sulphur waters of similar character. There is a large and comfortable hotel at each place.

An analysis of the Pluto Spring at French Lick is given below. One pint contains:

Carbonate of magnesium	0.198 grain.
Carbonate of iron and aluminum	trace.
Carbonate of calcium	0.868 grain.
Chloride of sodium	17.567 grains.
Chloride of calcium	0.668 grain.
Sulphate of sodium	2.796 grains.
Sulphate of magnesium	2.264 "
Sulphate of calcium	7.573 "
Total	31.934 grains.

Gases.

Carbonic acid	1.87 cubic inches.
Sulphuretted hydrogen	3.18 "

Carbonated Springs.—These waters are characterized by the presence in them of a large amount of carbonic-acid gas and of comparatively little mineral matter. This gas is present in many mineral springs, but in most of them its effect is quite secondary to that of the mineral salts. In these waters, however, it is the chief therapeutic agent. The physiological action consists in a mildly stimulant effect upon the mucous membrane of the stomach, which increases peristalsis and hastens digestion. The urine is increased in quantity. The waters are useful internally in nervous dyspepsia, in neurasthenia, to increase appetite, etc. As baths they are used for their general tonic effects.

Old Sweet Springs, W. Va.—In Monroe County, W. Va., only a few miles distant from the White Sulphur Springs, are the Old Sweet Springs, a quiet, charming old resort lying in the midst of the Alleghanies and possessing many attractions besides the springs and the delightful swimming-baths which are the feature of the place. The hotel, of brick, is large and comfortable.

The Clysmic Spring at Waukesha, Wis., and the Blue Lick Springs in Kentucky have both carbonated waters.

Thermal Springs.—The therapeutic effects of these springs are due to the high temperature of the water. They are used chiefly as baths and are recommended especially in chronic rheumatism and gout, in syphilis, in neuralgias, and in chronic skin diseases.

Almost all the examples of this class of springs lying east of the Rocky Mountains are situated in the South, and are used rather as winter than as summer resorts.

The Region of the Great Lakes.—For those patients living far inland, who need a moist, cool, and equable climate and with whom the long and expensive journey to the seacoast is not to be considered, there is fortunately, in this country, a happy alternative. The vast bodies of fresh water constituting our "Great Lakes" supply these close at hand with a seashore climate and seashore life, the importance of which can hardly be overestimated. Although differing in some particulars, it may be said that the climate of the Great Lakes in summer resembles closely that of the seashore. There is the same high proportion of moisture in the air, the same coolness, the same increase in ozone, and the same comparative freedom from dust particles and from bacteria. The chief difference lies in the somewhat lessened equability, since, although the Great Lakes are much less subject to sudden and extreme changes of temperature than are inland regions, they still possess hardly so equable and even a climate as does the seacoast. They supply, moreover, all the water sports and diversions that make seashore life in summer so attractive.

The thousands of miles of coast line of these lakes are thronged with summer resorts of all sorts, big and little, fashionable and primitive. We can only attempt in these pages to mention some of the better-known ones, but one of the great advantages of this

region is that it abounds in quiet, unpretentious but comfortable resorts where, at very moderate expense, patients can obtain a summer outing and lay by a store of strength and vitality by living the unconventional, healthful, out-of-door life of the lakeshore.

Lake Ontario.—Lake Ontario, the smallest of the great lakes, has a length of one hundred and ninety miles and an elevation of two hundred and thirty-four feet above sea level. On the Canadian shore the places of chief interest are Toronto, the capital of Ontario, an attractive city of one hundred and eighty thousand inhabitants; Hamilton, at the western end of the lake; and Kingston, a flourishing place of fifteen thousand people, located at the foot of the lake and at the entrance of the St. Lawrence River. On the American side, at the eastern end of the lake are Sacket's Harbor and Henderson Harbor, two pleasant summer places, with good fishing, boating, sailing, etc. Oswego, an attractive and prosperous city, lies at the southeast corner of the lake and is much used as a place of summer residence because of its cool climate and attractive location.

Charlotte, the seaport of Rochester, is a pleasant and picturesque village lying at the mouth of the Genesee River. Just below Charlotte is Ontario Beach, a large and very popular lakeshore resort, and much patronized by Rochester people. It possesses an excellent hotel and every variety of entertainment. Farther westward are Lakeside and Olcott, two pleasant summer places.

Niagara Falls is too well known to need more than simple mention.

Niagara-on-the-Lake lies at the mouth of Niagara River, fourteen miles below the falls, and is much patronized in summer.

Lake Erie.—Lake Erie lies at an altitude of five hundred and sixty-four feet and is the least attractive, scenically, of the five great lakes.

Buffalo, Erie, Cleveland, and Sandusky and Toledo all lie on its southern shore, and each of these cities has in its vicinity attractive shore resorts which are much frequented in summer.

Put-in Bay Island.—At the western end of Lake Erie, sixteen miles from Sandusky and sixty miles from Detroit, lies a charming group of some fifteen islands known as the Put-in-Bay group. These islands, on account of their easy accessibility, their delightful climate, fine scenery, and excellent fishing, bathing, and boating, have of late years become very popular as summer resorts.

Detroit, on the river of the same name, lies in the midst of some of the most charming river scenery of this country. Below it, twenty miles, is Grosse Isle, a beautiful island near the mouth of the river and a popular summer resort. Above it lies Lake St. Clair, a famous fishing-ground and resort of water fowl. From Detroit, in summer, daily steamers go to these and the various other popular water resorts, and many delightful water excursions may be made.

Lake Huron.—The western coast of Lake Huron is dotted with many places of summer retreat. The northern part in particular, in the vicinity of Cheboygan and Macinac Island, has recently gained wide repute as a cool and delightful place of residence.

Along the western shore are Port Huron, Sand Beach, Port Austin, Bay City, Au Sable, Alpena, and Cheboygan.

Macinac Island.—In the strait of Macinac between Lake Michigan and Lake Huron is the small island of Macinac, lying almost midway between Detroit and Chicago. Macinac resembles, both in climate and natural features, the rugged, beautiful islands of the Maine coast. The scenery is wild and bold, the air wonderfully strong and exhilarating, and the waters are clear as crystal and full of gamy fish. The place is

patronized by an attractive class of summer visitors, and has large and comfortable hotels.

Lake Michigan.—Lake Michigan has on its north-eastern shore two beautiful bays, known as Grand and Little Traverse Bays. Upon Little Traverse Bay is Petosky, a quiet but very attractive shore resort. As is the case with all the resorts of this region, this place is famous for the quality of the air, which is tonic and stimulating to a high degree. The waters abound with fish, there are attractive drives, fine beaches, and good boating. Harbor Springs and Bayview are situated quite near Petosky on the same bay. Charlevoix, a few miles farther south, is another very popular summer place.

Still farther south lies Great Traverse Bay, and upon it Traverse City and several other very pleasant resorts. Continuing down the coast one reaches in turn Frankfort, Manistee, Muskegon, Grand Haven, Ottawa Beach, South Haven, and Benton Harbor.

On the west coast above Chicago are Waukegan, Kenosha, Racine, Milwaukee, Sheboygan, Manitowoc, Two Rivers, and Kewaunee.

Upon Green Bay are several pleasant resorts, and the region is especially famous for its fishing.

Lake Superior.—Lake Superior, the largest of the great lakes, is also by far the wildest and most picturesque. The north side of the lake is dotted with numerous islands, many of which rise precipitously from the water to a great height. Almost the entire coast of the lake is rugged and rockbound, and affords views which in point of picturesqueness and grandeur can hardly be surpassed. This is especially true of the northern coast of the lake, where the mountainous, precipitous shore presents a series of the most awe-inspiring pictures. This whole region is a paradise to the fisherman, for the multitude of little streams entering the lake fairly teem with trout and other varieties of fish. The climate of Lake Superior in summer is exceedingly cool and bracing.

The chief centres for sportsmen and tourists along the southern coast are Munising (near the famous "Painted Rocks"), Marquette, The Apostle Islands (a beautiful group of twenty-seven islands), Bayfield, and Duluth. Along the northern shore are Fort William, Port Arthur, Nipigon Bay, Isle Royal, Saint Ignace, and Michipicoten Island.

In concluding with the region of the great lakes, a word must be said concerning one phase of summer life upon them which deserves a wider recognition. Passenger steamer travel has of late years increased to such an extent that steamer lines now run in every direction, which furnish comfortable and even luxurious accommodations. The longest trip is that between Buffalo and Duluth. This veritable inland ocean voyage occupies from five to six days, and offers, in addition to the features of an ordinary sea voyage, a series of the most beautiful and entertaining views. The steamers rival the trans-Atlantic ones in point of size and luxury.

Inland Resorts of Miscellaneous Character.—Under this head must be included regions and climates of such variety and dissimilarity that general statements cannot be made to apply.

Inland resorts present every variation in climate and character: it may be said only that, in general, the air is less moist, the temperature less equable, and the winds less constant in direction and force than those of the seashore.

The Forest and Lake Region of the Northeast.—This vast region includes most of Maine, New Brunswick, and Quebec. Almost the whole of this country is one great primeval forest, broken only by the myriads of lakes which dot the entire region. These lakes, many of them of surpassing beauty and wildness, are arranged for the most part in chains and

systems with connecting streams, so that one may, with a portable canoe, travel vast distances, going from place to place and from lake to lake as fancy dictates. While this region is pre-eminently one for the sportsman, it is by no means an uninhabited wilderness, devoid of all comforts and difficult of communication with the outside world. Railroads pierce it now in various directions and many invalids and families spend their summers here in comfortable camps or small hotels, breathing the fragrant, healthful forest air and enjoying the wholesome, open-air life, to whom shooting and fishing are by no means the chief end of man.

The Rangeley Lakes.—Of the Maine resorts perhaps the most popular and best known is the Rangeley Lake region. Here is a series of several charming lakes, all joined by a chain of narrows and streams so as to form a continuous waterway nearly fifty miles long. They lie in the northwest corner of Maine, at an altitude of over one thousand feet, in the midst of dense forests, and furnish exceptionally fine trout fishing. The forests abound with large and small game. Rangeley, a village at the head of Rangeley Lake, affords comfortable hotel accommodations. Small steamers ply during the summer season on the different lakes, and the region is by no means inaccessible.

A short distance to the northeast of the Rangeley Lakes is the Dead River region, another famous resort of sportsmen, and some distance to the north, across the frontier, in Quebec, lie Lake Megantic and Spider Lake, the site of the immense clubhouse of the Megantic Fish and Game Association.

Moosehead Lake.—North of the centre of Maine, at a height of one thousand feet, is Moosehead Lake, the largest of the Maine lakes. It is about forty miles long and from two to eighteen miles wide. Mount Kineo (two thousand feet) overhangs the water at one point, making a sheer precipice of eight hundred feet. Greenville, on the southern shore, is a small village with several good hotels. The lake affords excellent fishing, boating, canoeing, etc.

The Schoodic Lakes, just across the boundary of New Brunswick, form the source of the beautiful St. Croix River and lie in the centre of a famous fishing and shooting district.

Both New Brunswick and Nova Scotia, as well as the other maritime provinces, abound with lakes, streams, and forests, where fishing, shooting, and all the charms of camp life may be had in perfection.

St. Lawrence River.—The lower part of the St. Lawrence River, that below the city of Quebec, widens steadily until it becomes some twenty or thirty miles in width. The water is salt, but deep and clear. The shores are high and rugged, and the scenery imposing and beautiful. The region is very popular with sportsmen, but is also much frequented for its cool climate, stimulating air, and picturesque scenery. The better known places of resort are the Saguenay River, Trois Pistoles, Cacouna, Rivière du Loup, Murray Bay, and St. Paul's Bay.

Between Montreal and Quebec are many small summer resorts, but none of special note.

Thousand Islands.—The most popular section of the St. Lawrence is that of the Thousand Islands. These wonderful islands begin at the head of the river and extend from Lake Ontario downward a distance of forty miles. They are of every size and appearance, some of them mere bare rocks, others large, thickly wooded, and covered in summer with most brilliant foliage. Alexandria Bay, on the American shore, is the largest and most fashionable resort of this region. There are many other charming places, however, with good hotels and handsome summer cottages and where splendid fishing and boating are to be had.

Lake Champlain.—Lake Champlain is too well

known as a delightful place of summer residence to require detailed description. It lies in the valley between the Green Mountains on the east and the Adirondacks on the west, surrounded by magnificent scenery, and lined with pleasant villages and attractive watering-places. The lake is one hundred and twenty-six miles long and is navigated by commodious steamers and all sorts of pleasure craft. Pickerel, bass, muscalonge, and other fish abound. The lake has upon its shores several famous and luxurious hotels. The following list includes the chief towns and centres of summer travel: Ticonderoga, Shoreham, Port Henry, Westport, Essex, Burlington, Port Kent, Plattsburg, and St. Albans.

Lake George.—Lying just south of Lake Champlain, and emptying into it, is Lake George, equally famous as a summer resort and rich in lovely scenery. The shores are less rugged and the mountain views less extensive, but the lake is surrounded by high wooded hills and dotted with a multitude of small islands, and well deserves its long-established popularity as a watering-place. Caldwell, Crosbyside, Bolton, and Hague are the chief places of resort on the lake.

New York State contains, besides those already mentioned, a number of beautiful lakes which afford many attractive summer places. The more prominent of these are Oneida Lake, Skaneateles Lake, Cayuga Lake, Seneca Lake, and Canandaigua Lake.

Watkins Glen.—At the head of Seneca Lake near the village of Watkins Glen, a spot long known for its wonderful gorge and picturesque scenery and now much frequented as a health resort and place of summer residence. The climate is cool and invigorating, the scenery is exceptionally fine, and the region abounds in delightful drives and walks. There are several first-class hotels in this neighborhood.

The Berkshire Hills.—The lovely Berkshire Hills, the continuation southward of the Green Mountains, occupy the western part of Massachusetts and cover an area fifty miles long and twenty wide. This region has for many generations been the favorite summer home of old and aristocratic New England and New York families, and is by far the most famous hill country of this continent. Nowhere is the air quite so pure and fine, the foliage quite so rich and deep, the hills so soft in outline, and the old villages so peaceful as in the Berkshires. The climate is dry and bracing, and many cases of pulmonary trouble do admirably here. The region is especially famed for its drives, and driving and wheeling tours through the Hills have become very popular. Great Barrington, Stockbridge, Lee, Lenox, Pittsfield, North Adams, and Williamstown are all charming old towns, containing the handsome summer homes of the wealthy classes of New York and the New England cities.

Wisconsin and Minnesota.—Among regions of medium elevation suitable for summer health resorts must be mentioned the many pleasant villages and pretty lakes of Wisconsin and Minnesota. The general elevation of this country is high, often over one thousand feet above sea level, the air is dry and pure, and the summers cool. Both States possess an immense number of small lakes and afford many charming resorts admirably suited for many cases of pulmonary phthisis, bronchitis, hay fever, etc. In Wisconsin among the better known places of this sort are Madison and Oshkosh.

In Minnesota, within easy distance of St. Paul, are White Bear Lake and Lake Minnetonka, with their two large and popular summer lake resorts, Fontenac and Winona. Farther north is Brainerd, situated in the midst of pine forests.

Litchfield, Detroit, Park Rapids, and Osakis lie in the so-called "lake and park region," a district thickly studded with beautiful lakes, where capital boating,

fishing, and shooting are to be had. These places are all much frequented as summer resorts.

Manitoba.—To the northwest of Minnesota lies the province of Manitoba, a vast, level country with an elevation of about eight hundred feet, in which are several large and beautiful lakes. The chief of these are Lakes Winnipeg, Winnipegosis, and Manitoba, and the Lake of the Woods. Manitoba possesses a climate of especial dryness, which has proved beneficial in many cases of tuberculous disease. The region has especial attractions for sportsmen, for the lakes teem with many varieties of fish and the forests with both large and small game.

Winnipeg, the capital, is an attractive town of twenty-six thousand people, with comfortable hotels and within easy distance of the lakes.

Society Reports.

ANNUAL MEETING OF THE AMERICAN SURGICAL ASSOCIATION.

Held at Detroit, Mich., May 26, 27, and 28, 1896.

LOUIS McL. TIFFANY, M.D., OF BALTIMORE, MD.,
PRESIDENT.

First Day—May 26th.

The Operative Treatment of Trifacial Neuralgia.

—The president of the association, DR. LOUIS McLANE TIFFANY, of Baltimore, called the meeting to order and read an address with this title.

DR. S. J. MIXTER, of Boston, read a short paper in discussion of the subject, which was then thrown open for general discussion.

DR. W. W. KEEN, of Philadelphia, said he was very much disappointed to learn that the mortality of operations for the relief of trifacial neuralgia is ten per cent. Dr. Keen stated that he has had two deaths out of nine cases, one of which was due to sepsis and was avoidable. He explained the high mortality as being due in his opinion to the fact that the operations had been done by so many different operators, and he thought that special operations should be reserved for the hands of those who have had some special training. In three of the nine cases mentioned, trouble was experienced with the cornea, but in no case was the eye lost. The following is Dr. Keen's method of dealing with corneal ulcer: sew the lids together at the margin so as to prevent the opening of the eye, take a circular piece of rubber plaster, cut a circular hole in the centre a little smaller than a watch glass, insert a watch glass in the hole thus made, and place this shield over the eye, the non-adhesive surface being next to the patient's eye. Although the rubber plaster does not absolutely occlude the whole space, yet the inside of the watch glass is always moist.

DR. J. EWING MEARS, of Philadelphia, said he would like to ask whether the president was clear in his own mind that the lesion exists in the Gasserian ganglion. If his experience with the operation upon the Gasserian ganglion demonstrates that the relief from pain is permanent, Dr. Mears considered it right to feel that the real lesion has been discovered.

DR. GEORGE RYERSON FOWLER, of Brooklyn, stated that in one of his cases there was a recurrence of pain, even although he was absolutely certain that he had removed the ganglion. Post-mortem showed the existence of a neuroma upon the stump in that portion which occupied the foramen rotundum. Dr. Fowler fully agreed with Dr. Keen as to the necessity for keeping the eye protected, and mentioned an illustrative case. Concerning the sclerotic changes in the

vessels, it may be that these are at the root of the pathology of these cases. Dr. Fowler referred to a case operated upon by Dr. Morton, of Philadelphia, in which Meckel's ganglion was positively removed, and yet the pain returned with all its former violence in less than two years, when ligation of the common carotid gave the man permanent relief. The author mentioned other cases in which ligation of the carotid had produced excellent results, and in one of which there was a deviation of the tongue toward the side operated upon. In this case the patient was unable to straighten the tongue. Dr. Fowler referred to one patient who died during an epidemic of sepsis, and stated that he saw no reason why there should not be epidemics of sepsis as well as of small-pox and scarlet fever.

DR. PARMENTER mentioned the case of an elderly woman who had had facial neuralgia, and also a small aneurism of the external carotid, in whom ligation of the common carotid had afforded complete recovery. He also mentioned a case in which he had operated successfully on a man who had been subjected to three previous operations.

DR. H. S. WEEKS said he doubted if a surgeon is justified in resorting to intracranial operations before an extracranial had been done, in view of the large mortality. The speaker's plan of operating is to trephine through the ramus of the jaw, seize the inferior dental nerve, and pull it away, as he considers this method much better than cutting.

DR. N. P. DANDRIDGE, of Cincinnati, mentioned a case in which he had operated two and a half years ago, since which time the man had been relieved from pain, but there is marked deformity of the face on account of atrophy of the muscles. There is also a small sinus leading down to dead bone.

DR. CHRISTIAN FENGER said he prefers the extracranial operation, as he considers it less dangerous. He called attention to the fact that the mortality from ligation of the common carotid is eighteen per cent.

DR. JOSEPH RANSOHOFF said he does not think ten per cent. a very high mortality under all circumstances, and that if all the cases are included it will be nearer fifty per cent. In Dr. Ransohoff's opinion the lesion is not located in the Gasserian ganglion, but is a central affection.

DR. ROBERT ABBÉ said the members should not be daunted by a mortality of ten per cent., as in the next hundred cases it would be much less. In his opinion preference should be given to an anterior operation in the first place. Now that we know what to steer clear of, with the improvement of sepsis and the avoidance of operating on old people, the mortality should be considerably lessened.

DR. W. W. KEEN said he had omitted to mention two methods of medical treatment which have been of great service, one recently suggested by Dr. Dana, of New York, that of giving massive doses of strychnine, and the other suggested by Esmerich, who has spoken of the value of purgatives.

DR. MAURICE H. RICHARDSON said he thought that the operations could be taken up in order, and that attacking the ganglion should be done as a last resort, especially in old people and those who are unable to stand so formidable an operation as intra-cranial neurotomy. In many cases a simple operation will give considerable relief.

DR. FOWLER explained that the mortality of eighteen per cent. in ligations of the carotids included cases of aneurisms, gunshot wounds, etc. In fifty-two cases in which the vessels were not affected by disease nor complicated by carcinomatous tumors, the mortality was less than five per cent.

DR. P. S. CONNOR, of Cincinnati, said he considered that the two most important points are the cause of the

neuralgia and the results of operative interference. In a certain proportional number of cases the exemption from pain ranges from three months to three years, while in another proportion the exemption is scarcely worth mentioning, as the pain returns immediately after the operation. In some cases the loss of blood during the operation and the shock following it are important factors. In either event a man would rather take forty-nine chances out of fifty to get relief.

DR. T. A. MCGRAW was of the opinion that sufficient investigation has not been made of the possibility of the neuralgic conditions being due as well to motor as to sensory nerves, and stated that he is not at all sure that a division of some of the motor nerves may not be a great benefit.

DR. RICHARDSON stated that this operation had been performed and had resulted in considerable facial deformity, but no relief of the neuralgia.

DR. S. J. MIXTER mentioned two cases in which merely a reopening of the old intracranial wound had afforded some relief.

DR. TIFFANY closed the discussion, and stated that forty-five operators had participated in the hundred cases reported, of which number twenty-four had operated upon only one case each. He also mentioned that there is diminished sensation in these cases and lessened lacrymation. He considers the curving of the tongue due to atrophy of the muscles, but does not understand why the perception of heat and cold should be interfered with.

As to tying the carotids, Dr. Tiffany stated that Dr. Park, of Buffalo, had successfully done this in two cases.

Tuberculosis of the Female Genital Organs (including tuberculosis of the kidney). — DR. ALBERT VANDER VEER, of Albany, read a paper with this title. He stated that this subject had been neglected until recent years, and that the modern ideas and progress depend upon careful histological and bacteriological examinations. Tuberculosis of the female pelvic viscera is not limited to any age, the extreme limits being ten weeks and eighty-three years. External genital lesions may be confounded with tuberculosis. Heredity is important as suggesting tuberculous possibilities. Tuberculosis is extremely rare in the external genitals, but by no means infrequent in the uterus. Tuberculosis of the uterus can be demonstrated by microscopical examination of the discharges and by curetting. Gonorrhoeal infection is often grafted upon tuberculosis. Sometimes infection takes place through the fingers or the instrument or the semen. Tuberculosis originates in the tubes and infects the uterus and cervix. The uterus can be infected from without or within and the infection is aided by a lacerated cervix, pelvic peritonitis, trauma, etc. The symptoms are local irritation, a pea-sized wart near the vaginal outlet, a discharge from the uterus, etc. The differentiation between the ulcers of syphilis and epitheliomas depends on age, history, local appearances, etc. Tuberculosis of the cervix can be mistaken for cancer. Many vaginal cases are infected from the tubes, and tuberculous peritonitis may infect the vagina and the tubes. The author mentioned several cases illustrative of the points referred to.

With regard to tuberculosis of the kidney, there may be two forms, (1) miliary tuberculosis and (2) caseous or true tuberculosis. The author gave the details of one or two cases and referred at some length to Kelly's nephro-ureterectomy.

Tuberculous Peritonitis. — DR. ROBERT ABBÉ, of New York, thought it would give a fairer understanding of the multiform appearances of the disease if we view it from the standpoint of the bacillus, rather than, as others have done, from the gross appearance, which has led to the division into the ascitic, the dry, and the case-

ating form. A sudden tuberculous irruption into the peritoneal cavity may be as acute in symptoms and duration as acute peritonitis from other causes. A slower outbreak may result in ascitic distention in three or four weeks, and a less virulent bacillus action may occupy months in inducing ascites and wasting. In other cases, possibly due to the route of invasion (penetration through lymphatics, communicating mucous and peritoneal serous coats, or by follicular ulcers—allowing tuberculous milk to be the medium of infection) a dry or adhesive form follows in which hectic and rapid wasting result. Again the bacillus produces an outpouring of thick lymph and flocculent serum which rapidly become purulent, producing unsymmetrical cakes of thickened omentum, matted coils, and encapsulated purulent collections. The bacillus products rapidly caseate and ulcerating fistulae may result. All phases of the disease may be regarded as representing the life history of the bacillus and its products. Tuberculous peritonitis may be, and in the early stages often is, the only site of tubercle deposit in the patient; hence, if overcome there, a practical cure often follows. Even when other phases of infection (pleural, intestinal, bronchial) are seen, an operative cure of the peritonitis has often been followed by general recovery. The mode of entrance of the bacillus is directly through the intestinal wall or through ulcerating appendicitis or tubal or ovarian tuberculosis, or through the blood. The claim of a few recent authors to having cured tuberculous peritonitis by medical treatment were reviewed and credited.

The unquestioned cure of true tuberculous peritonitis by laparotomy is proved by two classes of patients, those who have long survived operation, and those who, having come to autopsy long afterward, have been found free from tubercles that studded the peritoneum at the time of operation. Experimental proof in animals corroborates also operation by simple laparotomy and evacuation of the ascites; closing the dry abdomen is credited with a large number of cures. Irrigation with warm salt solution is advocated by preference. Camphor-naphthol application, as used by Rendu, is advised for bad cases.

Dr. Abbé reviewed many interesting and illustrative cases in speaking of direct medication. The many theories advanced to account for the surprising cures were carefully considered, and it was said in conclusion that the theory that is sustained by most facts is that based on the life history of the bacillus and the capacity of the animal economy not only to suppress the activity of the organism by encapsulating it, but to remove it by absorption. The proper opportunity for conquests is not afforded in the presence of ascitic fluid, which acts as a veritable culture bouillon and by its fluidity aids dissemination. When, however, the peritoneum has been aroused by congestion, which follows evacuation, and a reactionary inflammation is set up, engendering cell hyperplasia, the intruder is walled in and retrograde degeneration sets in.

Intrathoracic Tuberculosis.—DR. GEORGE RYERSON FOWLER, of Brooklyn, went into the historical part of the disease at great length, and devoted considerable attention to the surgical treatment of pleuritis and empyema. Of all the organs in the human body, the lungs are most frequently the seat of these affections. Inasmuch as there is no lung affection that cannot be complicated by tuberculosis, it follows that pleural affections are most frequently tuberculous in character. Few patients who have suffered from pleurisy escape tuberculosis, and this fact increases the importance of the surgery of pleuritic affections in their relation to tuberculosis. The author gave a brief discussion of the effects of the presence of the pleuritic effusion upon the progress of tuberculous disease

of the pulmonary structure. The view formerly held that the activity of the circulation in the lung tissue constitutes a trustworthy means of protection against the occurrence of tuberculous infection of the respiratory organs was combated, and reference was made to the observations of Laennec, who in the early history stated that stasis was incompatible with the progress of pulmonary tuberculous affections, and Bier's observations, supported by those of Miller, in the treatment of tuberculous joint disease by means of a constricting bandage were held to confirm the views of Laennec in this particular. Note was taken of the fact that in any pleuritic affection, even when due without doubt to tuberculous infection, if the effusion is found to be serum, the inference follows that the effusion possesses some resisting influence over the development of the tubercle bacillus, while it undoubtedly forms a favorable culture medium for other organisms. The application and technique of exploratory puncture or thoracentesis, incision and drainage, and Koenig's operation, the resection of a portion of rib, were gone into by the speaker quite extensively. This was followed by a consideration of the operation of thoracoplasty and its indication. Schede's operation for extensive resection of the chest wall, including with the bony resection removal of the attached soft parts, namely, the intercostal muscles and thickened pleural membrane, was described. It was recommended that the edges of the incision be closed tightly about the drainage tube and the dressing be applied in such a manner that the tube passes through these. The drainage tube is then attached to a tube sufficiently long to extend over the side of the bed and touch the surface of a sublimate solution. When the patient can sit up, the tube is fastened to a bottle at the waist, as suggested by Lulau, of Hamburg. By this method and drainage the patient is saved from the discomfort produced by soiled dressings. The question of the complications occurring in connection with thoracoplastic operations upon the chest wall, namely, pulmonary thrombosis, cerebral embolism, and the resulting paralysis, was alluded to.

The consensus of opinion at the present day seems to discountenance thoracotomy in tuberculous patients, preference being given to repeated puncturing or at the most to the method of permanent siphonage.

The question of the direct treatment of tuberculous cavities was entered into quite extensively, and it was stated that some difficulty must necessarily be experienced in the selection of proper cases. In cases in which the disease has come to a standstill any interference would be unjustifiable, for the reason that it is these cases that undergo cure by natural processes. In addition to limiting operations on tuberculous cases to those that are circumscribed, the operation may be applied to certain cases of a doubtful nature which form at the expense of both pleura and lung, namely, pulmonary abscesses secondary to tuberculous caries of the ribs. Three examples of these are quoted.

The operation of resection of the lung was discussed at some length, and attention was called to the fact that the pulmonary structure differs from all other structures of the body in its susceptibility to infection and its anatomical peculiarities.

The experiments of Gluck, of Berlin, and Hans Schmidt upon the lower animals for resection of the lung were gone into in detail, and also those of Virondi, who produced localized tuberculosis in the lower animals.

Tuberculosis of the Superficial Glands.—DR. DE FOREST WILLARD, of Philadelphia, first detailed the method of tuberculous infection of the lymph nodes. The route of entrance is usually by very slight abrasions or injury. Slight wounds are more liable to admit bacilli, as they arouse local resistance to a less

degree than more severe injuries. The face and neck are especially common routes of entrance. The lymph glands act as filtration stations and often prove effective in overpowering the invading foe. They are likely to be successful in proportion to their amount of resistive force. An individual resistive force may be lessened by hereditary impairments of cells, or by the temporary conditions of the tissues.

Local karyokinetic action may be successful, or if partially successful, caseation and absorption may occur with less resistive power, or if staphylococcus infection results suppuration follows.

When once the glands have become infected they are a perpetual menace to the general system and should be removed. Suppuration will sometimes effectually destroy all the invading bacilli; yet this is a slow and dangerous process subjecting the individual to constant risks. Infected glands should be removed if possible during the stage of induration.

The removal of tuberculous glands from the neck is frequently a most serious operation, provided connective infiltration is present and especially if the chain of glands has dipped deep beneath the cortical vessels and nerves or has extended below the clavicle. These deep glands can be safely removed only by following the line of cleavage between the gland and the protection wall, which has been partially thrown about it, each gland being cautiously shelled out.

The jugular veins, the branches of the carotid, and the pneumogastric and phrenic nerves should be carefully avoided. When a vein is injured immediate pressure with subsequent ligation or lateral suturing should be performed. If the phrenic or pneumogastric are injured they should be at once sutured with fine silk.

Great care should be exercised to prevent the discharge of pus and caseating material upon the fresh wound. If such accident occurs, the area should be thoroughly cleansed and disinfected.

Temporary drainage is advisable when infection has occurred from such discharge; but in healthy operations with clean enucleation primary union without drainage can be secured. In infection in the axilla, the glands should be enucleated with the same care that is employed in the removal of the carcinomatous nodule. The same rule holds good in regard to glands situated in other portions of the arm.

In the groin many difficulties may be encountered, especially if the indurated glands extend deep about the femoral or saphenous veins. Secondary operations are advisable if necessary. In cases that absolutely refuse operation, local and constitutional measures must be employed, including tuberculin and orrhoterapy.

The author has more confidence in the local effects of iodine upon tuberculous granulations than in iodoform. He has also had beneficial results from stimulation of cell growth by a mixture of aristol with nuclein or protonuclein applied locally. His conclusions are that tuberculous infiltration glands should not be allowed to remain and contaminate the general system.

Second Day May 27th.

Castration in Hypertrophy of Prostate Gland.—DR. ALBERT CABOT, of Boston, dwelt at great length upon the operations of castration and prostatectomy, and gave many statistics from various sources bearing upon this subject. After considering the relative merit of each operation, he closed his paper with the following conclusions:

1st. In the matter of mortality the operation of prostatectomy has a slight advantage over castration. It seems probable that with later statistics, reflecting the

last improvements in the technique of prostatectomy, this advantage will be further increased.

2d. Prostatectomy has the further advantage that it allows of a thorough examination of the bladder and of the discovery and correction of other conditions not before suspected. Stones are frequently removed in this way without adding to the gravity of the operation. In several reported cases of castration the absence of improvement has led to the subsequent discovery of stones, which have required other operations for their removal.

3d. Prostatectomy has, on the other hand, the disadvantages that it confines the patient for a longer time and that it is sometimes followed by a fistula. This occurred in one of the forty-two cases referred to in this paper.

4th. It is too early to determine whether any permanent loss of vigor follows castration when done on old men. The nervous effects which sometimes immediately follow the operation suggest a suspicion that with the testes the system may lose some tonic effect exerted by those organs.

5th. The functional results of the two operations seem at present to be as nearly equal as possible, and the tendency to relapse shows itself in about the same proportion of cases after either operation.

6th. The reduction in the size of prostate after castration is largely due to a diminution of congestion. Later a degeneration and absorption of considerable portions of the gland may occur. The glandular elements are particularly affected by this atrophy.

7th. Castration would seem to be especially efficacious in cases of large tense prostates when the obstruction is due to pressure of the lateral lobes upon the urethra.

8th. Castration is of but little use in myomatous and fibrous prostates.

9th. Prostatectomy has its especial field in the treatment of obstructing projections which act in a valvular way to close the urethra. There is, however, no form of prostatic obstruction which a skilful operator may not correct by prostatectomy.

10th. Prostatectomy is, then, applicable to more cases than castration, and is especially to be selected when an inflamed condition of the bladder makes drainage desirable.

The Ambulatory Treatment of Fractures of the Lower Extremities.—DR. LOUIS S. PILCHER, of Brooklyn, read a paper on this subject. He mentioned a large number of cases of fracture in which the ambulatory treatment had been employed, and illustrated his paper with diagrams of the apparatus employed. He described in detail the manner of applying the plaster bandage so as to form a sufficiently rigid and protecting case and also explained the splints used in this method of treatment. He stated that the number of cases of fracture of the leg treated by himself up to the present time with the ambulatory dressing was twenty, and the results that have followed this treatment in these cases have been very satisfactory. The time after the injury when it may be proper to apply the ambulatory dressing depends upon the nature and extent of the damage to the soft parts and the amount of local reaction following the injury.

The Treatment of Traumatic Lesions of the Kidney.—DR. W. W. KEEN, of Philadelphia, read a paper with this title. After reading a tabulated list of one hundred and sixty-three published cases of renal traumatism since 1878, the author stated that the traumatic lesions have, as a rule, two advantages over the lesions of disease: first, being apt to be unilateral, the other kidney is not injured, and second, the injured kidney is apt to be healthy or fairly so. Gunshot wounds, on the contrary, have two disadvantages: first, that the treatment of the kidney alone in many cases cannot be

solely considered, and second, if the renal substance is only moderately injured, no one would be willing to do primary nephrectomy.

As to the treatment of gunshot wounds, they may be divided into, first, those involving only the renal substance; second, those involving the pelvis; third, those involving the vessels; and fourth, those involving the ureter. The incision in most cases should be abdominal, either median or at the outer border of the rectus, and, if the vessels are badly torn, so that there has not only been a great deal of hemorrhage but the integrity of the organ is threatened, nephrectomy should be performed.

In treating the extravasated blood in case the kidney is not removed, if the bleeding is into the peritoneal cavity the blood must be removed by abdominal section, but if the blood accumulates in the perinephritic tissues alone, it may be left undisturbed.

Referring to wounds of the kidney other than gunshot, first, only one kidney is usually involved; second, the other kidney is usually healthy; third, no foreign bodies are apt to be carried in as they are in gunshot wounds; and fourth, other organs are usually not involved.

In treating the kidney, if the wound is sufficiently large for it to prolapse, it should be sutured and replaced if its condition is suitable, and the same procedure may be carried out if the pelvis of the kidney is opened. A partial nephrectomy would be advisable if a portion of the kidney is so far severed that its future integrity is threatened, the fragment being removed.

Although in most cases of rupture of the kidney but one kidney is affected, occasionally the other kidney ceases to act and anuria results, usually being fatal, while it is on record that patients have necessarily died after nephrectomy. Rupture is usually transverse to the curved long axis of the kidney, and only very rarely longitudinal. If the capsule is not torn, the hemorrhage is not apt to be very great; but whether or not the peritoneum is torn is a much more important question, since if it is, both blood and urine will escape into the peritoneal cavity.

As the dangers of rupture of the kidney are primary and secondary, the treatment may be conveniently so divided. Usually it must be decided if a nephrectomy shall be done within the first few days or even hours, but it may occasionally be postponed and become a secondary operation, when the lumbar route will be best.

Of one hundred and sixteen cases of rupture of the kidney reported, sixty-six recovered. Secondary nephrectomy is nearly twice as fatal as primary.

Susceptibility and Immunity, with Special Reference to Surgical Cases.—DR. ROSWELL PARK, of Buffalo, presented a communication with this title. He divided this subject into three classes: (*a*) local and general; (*b*) congenital or acquired, and (*c*) absolute and relative. Man seems to be immune from numerous infections which are common to many of the domestic animals, for instance, hog cholera, symptomatic anthrax, and chicken cholera, while he is in common with them susceptible to the infection of anthrax, glanders, tuberculosis, and actinomycosis. Then, too, men differ among themselves in susceptibility to the same disease, and, of course, we explain this, so far as mere words can, by saying that at the time of exposure their bodies were not receptive or were resistant. The consideration of susceptibility seems to be inseparable from a study of the causes favoring infection, which should be considered in the following order: (1) the virulence of the infecting organisms and the amount introduced; (2) association; (3) hereditary influences; (4) local predisposition; (5) vestiges and disappearing organs and tissues; (6) pre-existing disease; (7) personal habits and environment, and (8) foetal infection.

Immunity may also be (*a*) local or constitutional and (*b*) congenital or acquired, and acquired immunity may be natural or artificial. Immunity is, in some sense, a racial characteristic; as for example, in the case of the Japanese, who it is said never have scarlet fever, but are more susceptible to beri-beri than are Europeans, while the negroes escape yellow fever and are less liable to malaria and dysentery than are Europeans. Acquired immunity is not necessarily a matter of juggling with bacteria of the disease in question, but may be produced by the employment of other agencies.

In a general way it may be said that the conditions which afford protection, in so far as they are controllable by the surgeon, are those which tend to increase what, for lack of better knowledge, we must call vital resistance and to decrease vulnerability. In closing the author said:

"The conclusions of surgical importance which may be legitimately reached from the study of the conditions dealt with in this paper are essentially these: that the surgeon in emergency cases has to do the best he can, not merely with the means at hand, but with the tissues at hand; and here, so long as he can control what may happen outside of the body, he has done his full moral and legal duty. On the other hand, in any case where patients deliberately come under observation, and where time may be afforded, it is the surgeon's bounden duty, bearing in mind a summary of the conditions which notoriously conspire, upon the one hand to lower vulnerability, upon the other hand to afford protection, to so order the habits, the diet, the surroundings, and the preparation of his patient as to restore his tissues and vital fluids, so far as possible, to their normal condition, before he interferes with their functions by an operation.

"A distinct and as yet an unworked field lies before him who will study carefully and for sufficient length of time the effect of anæsthetics in increasing susceptibility and infection. This is a problem which must be worked out upon human patients rather than upon animals, since the conditions are so exceedingly different, most of the animals used for experiment being too relatively susceptible, dogs notoriously so. I have for years cherished the opinion that anæsthetics affect all people to a greater or less degree in this direction; yet am not able to present to you any definite statistics or statements. Loss of blood is certainly a factor lowering vitality, and in the complex condition of shock it must assuredly be that natural immunity is at least temporarily lowered. Equally important in my estimation are the auto-intoxications and toxæmias, of which two particularly call for attention here. The effect of sugar in the urine, or rather the effects of the condition which leads to its presence, is everywhere recognized, but I am more and more convinced that in the body condition which is most easily recognized by hyperacidity of urine and which is so often a complication of uricacidæmia, oxaluria, etc., we have a grave and sometimes insuperable obstacle to ideal success after operating. The other condition to which I particularly allude is that which I usually speak of as intestinal toxæmia, and relates to auto-intoxication produced by absorption from the contents of the alimentary canal of substances which ought not to be therein retained, nor allowed to so accumulate and undergo chemical changes which shall permit such absorption. This condition is in a large measure represented by chronic constipation; and yet it certainly does occur in patients who have a regular daily habit of alvine evacuation. It is to be recognized by the hue of the skin, by the appearance of the tongue, often by the presence of indol or indican and ethereal sulphates in the urine, and quite often by the diminished elimination of the fluid and mineral elements of the urine. It should be combated, if possible, by a careful course

of hot air or Turkish baths, copious draughts of fluid, the administration of saline laxatives, and of intestinal antiseptics, among which, in my estimation, the very best is a solution of mercury and arsenic in hydrochloric acid (given in the shape of mercuric chloride, dissolved in dilute muriatic or nitromuriatic acid, with the addition of liquor arseniosi chloridi). I have tried a great variety of the vaunted intestinal antiseptics, but have settled upon the conviction that some such mixture as this gives results far superior to any which can be obtained from salol, naphthalin, etc. If, in conjunction with these measures, we resort to exercise, when it can be taken, to sunlight, which is always available, and perhaps to massage, by which circulation is quickened and equalized, excretion hastened and waste material dislodged and taken out of the system, we have done what we can to prevent infection.

"And I have, furthermore, for years contended that since the inauguration of the so-called antiseptic era and in our enthusiasm for combating infection from without, we have lost sight of a most important truth which we cannot afford to disregard, viz., that in our enthusiasm for combating infection from without we have almost neglected the measures for, first, the recognition, and, second, the successful prevention of infection from within. Certain it is that in the majority of instances the latter (*i.e.*, infection from within) is much the more liable to ensue, and particularly in a class of cases in which one is tempted, for one reason or another, to be less careful than he ought to be. I would give then this most important practical conclusion to my remarks, that only he who weighs judiciously the possibility or the eminent probability of one or the other of these forms of infection is really capable of guarding against both of them, and that the best surgeon is he who will always take time, when it can be afforded, for the preparation of his patient for operation. In other words, I would remind you of Sir James Paget's too often neglected statement, that we ought to examine patients for operation with fully as much care as we do for life insurance; and add to it that if this examination be so conducted we shall often find that which will make us hesitate and prepare them before subjecting them to the enhanced risk of what may, in other respects, seem for their good."

AMERICAN PEDIATRIC SOCIETY.

*Eighth Annual Meeting, Held at Montreal, Canada,
May 25, 26, and 27, 1896.*

JOSEPH O'DWYER, M.D., PRESIDENT.

DR. JAMES C. WILSON, of Philadelphia, presided, owing to the unavoidable absence of the president. The first session was opened by the reading of the president's address, entitled the "Evolution of Intubation." This was prepared at the request of the council and was a paper of the greatest interest, as it described the labors which Dr. O'Dwyer pursued with untiring devotion to a great idea through five long years. A bivalve tube was first used, but after three years of continuous effort it was abandoned and experiments were begun with the solid tube. The paper described the various experiments made with alternating failure and success, until at last obstacle after obstacle was overcome, and imperfection after imperfection was removed. As a result of this patient toil, perfected instruments were given to the profession, a very rare thing in the history of medicine. The various steps taken in accomplishing this great result were narrated with the simplicity and modesty which has always characterized the work of Dr. O'Dwyer.

A complete set of instruments showing the evolution of intubation from the first bivalve tube to the present perfected model proved of the utmost interest.

DR. GEORGE N. ACHER, of Washington, read the first paper, entitled "Gangrene of the Lung Following Typhoid Fever."

DR. J. H. FRUITNIGHT, of New York, read a paper on "Malignant Endocarditis," and presented a specimen. As the bacteriological examination showed the condition to be due to the presence of streptococci, the author advocated the use of streptococcus antitoxin serum in such cases.

At the second session, DR. A. H. WENTWORTH, of Boston, read a most exhaustive paper on "Lumbar Puncture," and reported twenty-nine cases. He affirmed that while normal cerebro-spinal fluid contains neither fibrin nor cells and is always clear, it is always cloudy in case of meningitis, though the cloudiness is sometimes very slight. This is caused by cells, the character of the cells differing with the variety of meningitis. The operation, the author believes, offers a valuable means of differential diagnosis. For such purpose, however, the microscope is essential and inoculation experiments are also of value.

This was followed by a paper on "Tapping the Vertebral Canal," with remarks on local treatment for tuberculous meningitis, by DR. AUGUSTUS CAILLÉ, of New York. He reported twenty-one cases and said that he believed that a study of the cases reported up to the present time will certainly convince the most sceptical that Quincke's puncture is of positive value as a method of diagnosis. It is simple and usually easy of performance. In two cases Dr. Caillé injected antiseptics into the subarachnoid space, but without material results. He proposes in some future case to lay bare the dura by removing a button of bone and irrigating from a lumbar puncture upward through an opening in the dura.

DR. C. C. JENNINGS, of Detroit, also read a valuable paper on "Lumbar Puncture," and reported practical experience. DR. FLOYD M. CRANDALL, of New York, read a paper on the "Occurrence of Influenza in Children," and reported local epidemics. DR. SAMUEL S. ADAMS, of Washington, reported an extremely interesting case of "Temporary Insanity Following Typhoid Fever." DR. FREDERICK A. PACKARD, of Philadelphia, reported a case of "Endothelioma of the Brain with Atrophy of the Paralyzed Members."

DR. HENRY JACKSON, of Boston, read a paper on "Nasal Feeding in Diphtheria," in which he advocated feeding by means of a soft tube passed through the nose into the œsophagus in certain cases of diphtheria. As this can be done with ease, it does much in preventing exhaustion of the child's strength.

DR. WILLIAM OSLER, of Baltimore, read a paper on the "Classification of Tics or Habit Movements." He made the following classification: 1. Simple tic or habit spasm. 2. Tics with superadded psychical phenomena; *maladie de la tic convulsif*, or *Gilles de la Tourette's disease*. 3. Complete co-ordinate tics. 4. Tic psychique. An imperative idea is the psychical equivalent of and has an origin similar to the motor tics. Each of these subdivisions was elaborated and illustrated by practical examples.

The third session was devoted to the "Antitoxin Treatment of Diphtheria." The report of the collective investigation committee of the society upon the results of the "Antitoxin Treatment in Private Practice" was read. Over five thousand cases were reported, the results being, on the whole, far more favorable than those of any extended reports that have thus far appeared. A detailed report will soon be published in full.

DR. F. A. PACKARD reported favorable results of the antitoxin treatment, and DR. S. S. ADAMS read a paper

on the "Comparative Results of the Treatment of Diphtheria with and without Antitoxin in the District of Columbia." It appears that the death rate from diphtheria in the District of Columbia since the introduction of antitoxin has materially diminished.

DR. A. SEIBERT, of New York, read a paper on "Sudden Death after Antitoxin Injections." He reported a series of striking experiments which showed that the injection into animals of carbolic acid even in very weak solution was constantly followed by most characteristic spasmodic movements. Another series of experiments was made to determine the effects of subcutaneous injections of air. The results seemed to show that antitoxin can contain but infinitesimal quantities of carbolic acid. They also rendered the proposition reasonable that the few sudden deaths reported after the use of antitoxin might be due to the injection of air at the same time.

The general discussion elicited by these papers was extremely interesting and showed a unanimous and very strong sentiment in favor of antitoxin.

At the fourth session, DR. ROWLAND G. FREEMAN, of New York, read a paper on "Low Temperature Pasteurization of Milk at about 67° C." He proved that this temperature was sufficient to kill numerous pathogenic bacteria and various atmospheric bacteria, and referred to the importance of avoiding unnecessary heat in the preparation of milk for infants' use. He presented a new apparatus of simple construction, designed to Pasteurize milk at 67° C.

DR. CHARLES W. TOWNSEND, of Boston, reported several cases of "Thigh Friction in Infants." DR. WILLIAM P. NORTHRUP, of New York, reported a most interesting case of "Apparently Relapsing Cerebro-Spinal Meningitis Followed by Death and Autopsy," which elicited a warm discussion on the pathology and diagnosis of meningitis. DR. HENRY LAFLEUR, of Montreal, reported a case of "Insolation in an Infant of Thirteen Months." DR. A. D. BLACKADER, of Montreal, reported a case of "Enlargement of the Liver" in a young child, with symptoms closely resembling those of typhoid fever.

Papers were read by title by DRs. B. K. RACHFORD, of Cincinnati; F. FORCHHEIMER, of Cincinnati; IRVING M. SNOW, of Buffalo; and HENRY D. CHAPIN, of New York.

The last session was devoted to the presentation of pathological specimens, specimens being presented by DRs. ROTCH, HOLT, CAILLÉ, ADAMS, PACKARD, ACKER, FREEMAN, and TOWNSEND.

The following officers were elected for the coming year: *President*, Dr. Samuel S. Adams, Washington, D. C.; *First Vice-President*, Dr. W. S. Christopher, Chicago; *Second Vice-President*, Dr. Charles P. Putnam, Boston; *Secretary*, Dr. Frederick A. Packard, Philadelphia; *Treasurer*, Dr. Charles W. Townsend, Boston; *Recorder and Editor*, Dr. Floyd M. Crandall, New York; *Member of Council*, Dr. William Osler, Baltimore; *Chairman of Council*, Dr. William P. Northrup, New York.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, May 18, 1896.

JOSEPH E. JANVKIN, M.D., PRESIDENT, IN THE CHAIR.

Disturbance of Arm Circulation Simulating Neuritis.—DR. L. F. BISHOP presented a girl, about fourteen years of age, who had come to the clinic with the history that the day before she had felt pain in the elbow and wrist. He found complete anæsthesia from

the wrist down, but subjective pain in the finger tips, and here pressure caused some increase of pain. Tactile sensation was quite absent. At first glance he thought of neuritis, perhaps due to trauma, but found absence of radial pulse and of all pulsation until he reached the upper third of the arm. There had since been gradual return of sensation and of collateral circulation, but there was slight dry gangrene of the tip of the index and ring fingers, less of the thumb. He supposed there had been sudden plugging of the brachial artery, followed by gradual development of collateral circulation. The radial pulse was still absent.

Experience with Pilocarpine in the Treatment of Uræmia of Bright's Disease.—DR. CHARLES J. PROBEN in the first part of this paper briefly considered the physiological action of pilocarpine and pointed out the antagonism between it and atropine. The inconvenience in the use of other measures to excite the skin and kidneys to action in uræmia and eclampsia, and the slowness of their action, he said, have led to a trial of pilocarpine by Barker, Saenger, and many others, in spite of the dangers from depressing effects. Barker considers the use of pilocarpine in eclampsia contraindicated; Saenger reports three cases with one recovery; Loomis thinks the drug can be tried cautiously in uræmia of Bright's disease under certain conditions. Briefly stated, the author thinks it is not safe when there is fatty degeneration of the heart, dilatation, senile change of arteries, cardiac inefficiency; in fact, probably its only indication in uræmia is when there is simple hypertrophy of the heart with strong action. Here its beneficial effects are said to be striking. Moreover, the modern way of directly attacking the blood is a far more efficient method of treating uræmia. By some, this is carried out by withdrawing a portion of the venous blood, even to the extent of a thousand grams, and replacing it with saline solution. The proportion of poisonous elements withdrawn from the circulation in this manner is far greater than it would be in withdrawing an equal amount of sweat or urine. Dr. Proben thinks it is seldom necessary to make venesection, it being sufficient to use rectal injections or venous transfusion of saline solution. He outlined the histories of three or more cases illustrating adverse results from the use of pilocarpine in his early experience. Each of the three patients had uræmic toxæmia from chronic Bright's disease, and as other measures had failed, he tried injection of one-fifth of a grain of pilocarpine, and in all the same result was soon noticed. The drug exerted all of its influence upon the heart muscle, producing tumultuous action, venous stagnation, collapse, œdema, clammy sweat. Death soon followed. In one instance atropine was used to neutralize the effect of the pilocarpine, but without avail. He also recalled that, when interne in a city hospital, pilocarpine was sometimes used and caused cardiac failure. It is established that pilocarpine is a marked cardiac depressant, dangerous to use in uræmia, and its use should be restricted to other conditions than Bright's disease.

The author related a case of eclampsia before and after delivery, with almost complete suppression of urine with one hundred per cent. albumin. He injected two quarts of saline solution into the vein of the arm, with the result that in twenty-four hours the woman passed one hundred and nine ounces of urine. There is no means more effectual for stimulating kidney secretion.

Pilocarpine in Scarlatinal Nephritis.—DR. J. LEWIS SMITH opened the discussion. His attention was first called to pilocarpine many years ago by the remark of a gentleman distinguished in the profession

that he would never use it again because it was likely to produce fatal bronchorrhœa. Soon after this, Dr. Smith was called to see a child in consultation by a physician who had given it one dose of pilocarpine for transudation of serum following scarlatina. The child was breathing with the utmost dyspnœa, the chest was full of very coarse râles, a condition which might be called bronchorrhœa, evidently due to the pilocarpine. The child died.

Although pilocarpine is efficacious beyond all other remedies in producing urination and perspiration, yet Dr. Smith has not used it in hospital pauper adults, with anæmia attending their dropsical accumulations in Bright's disease, lest its depressing effects should prove fatal. His record books, however, contain the histories of two children with dropsical accumulations depending on scarlatinal Bright's disease in which pilocarpine given internally in doses of one-thirty-second of a grain has been efficacious in saving life, and this experience inspired the hope that a way may be found of using it, say in small doses or guarded by some other drug, by which its beneficial effects can be secured without its dangerously depressing effects.

DR. J. BLAKE WHITE said his experience with pilocarpine has been more favorable than Dr. Proben's. He employs it in smaller doses, and usually in connection with some cardiac stimulant, as strychnine or digitalis. To a child he gives not more than one-thirty-second of a grain, to an adult one-twelfth to one-sixth of a grain by the stomach, never more than one-sixth hypodermatically. He doubts whether the pulmonary and cerebral œdema in the cases of Barker and Saenger were due to the pilocarpine, as they are apt to occur in the usual course of the disease. Children are especially tolerant of pilocarpine. Careful examination should be made of the circulatory system in order to exclude heart disease, etc.

In some closing remarks DR. PROBEN said that while œdema is a frequent cause of death in Bright's disease, yet as it comes on so rapidly after administering the pilocarpine, he must attribute it to the action of this drug. Authorities are agreed that it is best to administer the pilocarpine hypodermatically. The crystallized form alone is reliable. Jabborandi contains other alkaloids which are more or less antagonistic.

Diagnosis of Paralysis of Peripheral Origin, and the Value of Electricity as an Essential Element in Differential Diagnosis, Prognosis, and Treatment.

—DR. WILLIAM M. LESZYNSKY read the second paper of the evening. It was based on a study of nearly four hundred cases of peripheral paralysis which have come under the writer's observation during the last ten years. For want of time, his remarks were confined chiefly to facial paralysis and paralysis involving the brachial plexus, these being the more common forms seen by the practitioner. It is not uncommon for paralysis of peripheral origin to be mistaken for disease of the brain or cord, and naturally there is chagrin when spontaneous recovery takes place in a few weeks or months after giving an unfavorable prognosis.

The most common cause of peripheral paralysis is trauma, direct or by pressure during sleep; then come refrigeration, lead poisonings, and constitutional diseases—syphilis, gout, etc. Paralysis affecting a number of muscles in the same extremity, when due to a lesion of the trunk of the nerve or nerves, is always of flaccid type, affecting muscles in the distribution of those nerves; frequently there is loss of sensibility and of irritability in greater or less degree, lesion of the anterior horn of the cord as in poliomyelitis, weakened or paralyzed muscular groups which are functionally associated; the paralysis is of flaccid type, but is

rapidly followed by atrophy, while, as a rule, sensory symptoms are absent. The changes in electrical reaction are similar in these two conditions, the reaction of degeneration, while in monoplegia or hemiplegia of central origin the electrical reaction is normal or increased. After speaking of pain in neuritis, together with trophic changes, the author said it may be difficult in some cases to decide whether the lesion producing the paralysis is in the nerve trunk, cord, or brain, but a definite decision can almost invariably be reached by a critical electrical examination.

When a person awakes with paralysis of one side of the face, the friends speak of it as a stroke, meaning a cerebral apoplexy, but clinical experience shows that isolated facial paralysis of cranial origin is exceedingly rare. Not so when there is also hemiplegia. In simple facial paralysis of central origin, the upper branches of the facial nerve are rarely paralyzed, only the lower face showing palsy. The nerves continue to react to faradism, usually quantitative increase being present. In peripheral facial paralysis all branches are affected, the patient is unable to close the eye or raise the forehead, and the faradic irritability is either diminished or lost within two weeks. It is not necessary to confuse the practitioner by speaking of change in polar reaction, for in general it is sufficient to compare the electrical irritability to the faradic current on the two sides; if it is diminished or absent on the paralyzed side it indicates reaction of degeneration. If the galvanic reaction be tested, the normal condition should give greater response on cathodal closure than on anodal closure, and greater response on cathodal closure than on cathodal opening. A reverse of this indicates reaction of degeneration (R. D.). Reaction of degeneration is conclusive proof of a lesion of some severity at the nucleus or in the course of the nerve trunk. This test is also important in prognosis.

One rarely sees atrophy of the muscles in paralysis of the facial nerve, whereas in peripheral paralysis of the extremities atrophy is not at all uncommon. Pain is an obtrusive symptom in the latter when there is degenerative neuritis. Cases of paralysis of the peripheral nerves without a wound can be classed in three categories—slight, medium, and severe. The first form usually gets well in about fourteen days; the second, with partial reaction of degeneration, in about two months; the severe form, with complete reaction of degeneration, in from three to nine months. Dr. Leszynsky thinks this period can be shortened in the two latter classes by electrical treatment begun two or three weeks after the onset. Patients usually think the benefit is in proportion to the strength of the current and its duration, but this is a mistake. In palsy due to division of a nerve, suture is called for at the earliest moment. Electricity, to be of diagnostic value, must here be used early, since after two or three weeks one cannot say whether the reaction is due to division or to neuritis.

The paper was discussed by DR. H. W. BERG and DR. L. F. BISHOP, both of whom have been unable to arrive at a conclusion as to the therapeutic value of electricity in cases of peripheral paralysis. Dr. Leszynsky, however, has no doubt on this point. In dispensaries it is most used in anterior poliomyelitis of infants, where its beneficial results are less apparent than in paralysis of peripheral origin.

DR. THOMAS H. MANLEY presented a woman and a sarcomatous tumor weighing a pound and a half, which he removed from her lower jaw at a second operation. He also showed a portion of gangrenous intestine which he removed by resection some days after his subject was kicked in the lumbar region by a horse.

Therapeutic Hints.

Myxœdema.—The first case of this disease which was treated by thyroid, beginning in April, 1891, and continuing till the present time, is to-day free from swellings, the skin is soft and moist, the hair has grown in again, and the woman leads an active life, taking, however, each week three or four grams of thyroid extract.—GEORGE MURRAY (*British Medical Journal*).

Ozæna.—

R Pure glycerin..... 70
 Borax..... 20
 Distilled water..... 30
 S. Used as a nasal spray two or three times a day.

—*Nouveaux Remèdes*.

Diabetes.—

R Arseniate of soda.....mgm. .002
 Carbonate of lithium.....cgm. .15
 Codeine......02
 Powder of theriac......25
 Dry and powdered extract of quinquina " .40
 For one powder. Make thirty. One before the first breakfast and the dinner.

—A. ROBIN.

Spasmodic Asthma.—

R Tinct. lobeliae æthereæ..... ℥ xv.
 Spirit. ætheris..... ℥ xx.
 Tinct. chlorof. comp..... ℥ v.
 Aquæ camphoræ..... ad ℥ i.
 To be taken when breathing is difficult.

—*The Practitioner*.

High Arterial Pressure when nitroglycerin is contraindicated:

R Chloral,
 Bromide of sodium.....āā ℥ ij.
 Syrup of lactucarium..... i
 Water.....q.s. ad ℥ iij.
 M. S. Teaspoonful every four hours.

—*Therapeutic Gazette*.

Ergot.—One or two five-grain powders before bedtime often give satisfactory results in night sweats.—GOLDENDACH.

Dentifrice.—

R Pulv. pot. chl..... gm. 12.
 Pulv. borac.,
 Pulv. mag. calcin.,
 Precip. calc. carb..... āā gm. 28.
 Ess. menth. pip..... gtt. 10.
 Mix and make a powder.

—*Gazette Hebdomad.*

Thyroid is applicable in psoriasis to those cases alone which have received no benefit from all other known means of treatment, and in which the patient is desirous of making trial of a new remedy even to be disappointed.—THIBIERGE.

Atropine hypodermatically in paroxysm of asthma.

Aconitine, one-two-hundredth grain every two hours, relieved a most obstinate facial neuralgia on the second day.—HAUSEBERGER.

Nitroglycerin, one-one-hundredth grain every hour, in puerperal eclampsia.

Pyoktanin (yellow) is sometimes successfully used for excoriations about the corners of the mouth.

Vinegar placed on a cloth over the face of a patient who has had chloroform administered will prevent the sickness which so often follows.—LEWIN.

[If it will prevent the deaths which are of such frequent occurrence across the water, we most heartily commend it to our English cousins.—ED.]

Ethyl-Chloride spray stopped hemorrhage from an extracted-tooth socket.—HIND.

Silver Nitrate, two-per-cent. solution, applied to throat of infant with soft brush for "cold."

Ether Collapse.—Hypodermic injection of camphor in large (half-grain) doses.—SCHILLING.

Sciatica.—In obstinate cases nitroglycerin, beginning with one-one-hundredth grain and gradually increasing up to one-twentieth three times daily.—LAWRENCE.

Guaiacol applied to the skin penetrates the system and is excreted in the urine. It is therefore possible to saturate a patient without recourse to the stomach or hypodermic syringe.—LISSOIS and LAMOIS.

Alopecia Areata in Children.—Feulard gives (*Rev. Intern. de Méd. et de Chir. Pract.*, September, 1895) the following treatment:

R Salicylic acid..... gr. xv.
 Precipitated sulphur..... gr. xlv.
 Lard,
 Vaseline.....āā ℥ ss.
 M. Apply at night.

In the morning wash with salicylic soap and apply the following lotion:

R Corrosive sublimate..... gr. ss.
 Alcohol,
 Tincture of rosemary.....āā ℥ iijss.

Once a week brush on equal parts of essence of wintergreen and ether.

Chromic Acid Combined with Nitrate of Silver in Syphilis and Other Affections.—Boeck (*Monatsh. f. prakt. Derm.*, 1895) applies a ten-per-cent. solution of chromic acid to the lesion to be treated and immediately afterward the solid stick of silver nitrate. Chromate of silver and free nitric acid are formed; the latter acts vigorously on the tissues, but with less pain than when used alone. It is especially useful in indurated syphilides of the mouth and dry papules of the mucous membrane, but it is also serviceable in chancroid, nævus, lupus erythematosus, and condylomata. The crust formed by the caustic falls off in a few days.

Favus.—Dr. Josif Khrenitchek, a military surgeon of Servia, recommends cleansing the head thoroughly with a solution of potassic soap (sapo kalinis) and shaving; then the application of the following preparation:

R Acidi carbolic..... 10
 Petrolei,
 Glycerini.....āā 100
 Balsami peruviani..... 10

Cough of Measles.—Widerhofer recommends the following:

R Ext. hyoscyami..... gr. ij.
 Syrup..... ℥ iij.
 Distilled water.....ad ℥ ij.
 M. S. A teaspoonful every two hours.

Eczema of Face and Neck.—Dr. Shoemaker finds the following preparation useful:

R Aristol..... ℥ ss.
 Camphor..... ℥ ss.
 Lanolin..... ℥ ss.
 Carbolic acid..... ℥ ss.
 Ointment of oxide of zinc..... ℥ ss.
 M. S. Apply locally.

Vomiting.—

R Bismuthi subcarb..... ℥ ij.
 Aq. laurocerasi..... ℥ iij.
 Syr. simp.....ad ℥ ij.
 Teaspoonful for an adult every three hours.

—SAUER.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ROYALTY AND CHARITIES—JENNER CENTENARY—
INTESTINAL ANASTOMOSIS—WOMEN MEMBERS DE-
CLINED BY THE PATHOLOGICAL SOCIETY—QUEEN'S
BIRTHDAY HONORS—CHELSEA HOSPITAL—LIVERPOOL
LYING-IN HOSPITAL—ADELAIDE HOSPITAL DIFFI-
CULTY—A CENTENARIAN SURGEON—ILLNESS OF SIR
J. MILLAIS.

LONDON, May 22, 1896.

YESTERDAY royalty was again to the fore in aid of our charities. The Princess of Wales (accompanied by her husband, their daughter Maud, and Prince Charles of Denmark) opened a bazaar on behalf of the West London Hospital. The Princess received purses amounting to nearly £500 toward the funds, and afterward inspected some of the wards and spoke to a number of the patients. In declaring the bazaar open the Prince of Wales, on behalf of his wife, referred to the time when, seventeen years ago, he presided at a festival on behalf of the hospital, and expressed satisfaction in taking part in such philanthropic work.

The Duke of York presided at a dinner in aid of the Royal Albert Orphan Asylum. A sum of £2,440 was raised.

One hundred years ago this month, on the fourteenth day of the month, Edward Jenner vaccinated a child of eight years of age. This event, so pregnant with the welfare of the race, produced but little effect at the moment, and, indeed, to the end of his life Jenner never attained the honor of his countrymen to the extent that foreigners accorded it to him. And it is so now—the Jenner centenary is being celebrated in various countries, while in his native land it attracts little attention. Had it not been for the awful example of Gloucester, the "antis" in their folly might have been continuing their denunciations of the great discovery and accumulating their responsibility for preparing further holocausts by their self-conceit and misrepresentations. The *Practitioner* for May was issued as a "vaccination number," and, appearing on the 1st inst., may be said to have opened such celebration of the Jenner centenary as England seems inclined to give. The *British Medical Journal*, not to be outdone by a monthly, devotes this day's issue to a Jenner number. Thus far we have portraits, lives, and articles enough, but all this is merely medical celebration. It would be better for the country if the great newspapers enforced the lessons of the centenary.

Mr. Lewis is issuing a "History of Vaccination," with colored plates, including a reproduction of those of Jenner's "Inquiry" and a facsimile of the first folio edition of his original paper.

We shall not fail, therefore, of a medico-literary celebration of the centenary.

At the last meeting of the Royal Medical and Chirurgical Society, Mr. Walter Edmunds and Mr. C. A. Ballance communicated a paper entitled "Observations and Experiments on Intestinal and Gastro-Intestinal Anastomosis." The object of the experiments was to determine the best method of uniting either bowel to bowel or bowel to stomach. The experiments were made on dogs. All the various methods were tried, and the conclusions arrived at are: (1) For lateral anastomosis Halsted's operation is best. A needle should be threaded at each end of each suture; the needles then had only to be passed in one direction; (2) for end-to-end suturing the most perfect result is obtained by Maunsell's operation, but the conditions will not always allow of its performance; and (3) for certain cases implantation is indicated.

There are three main conditions for which these operations are required—namely, artificial anus from any cause, gangrenous hernia, and malignant disease of intestine. The enterotome appears to have fallen into disuse in the treatment of artificial anus and the extra-peritoneal operation is applicable only to certain cases; the intra-peritoneal operation must, therefore, be used for the majority. This can be performed either by an end-to-end junction, or by implantation, or by lateral openings after inverting and closing the open ends. The last is considered the easiest and safest proceeding, especially if the surgeon has not much experience in intestinal surgery; and of the methods of effecting it, Halsted's operation is preferred to Senn's. For end-to-end anastomosis (which is the ideal operation) Maunsell's operation is preferred to all those in which recourse is had to mechanical aids, whether of decalcified bone or of metal. The treatment of intussusception, gangrenous hernia, and malignant disease of the bowel was discussed; in the last the new growth should, if possible, be excised at the primary operation. Whether or not an attempt at reunion or anastomosis should now be made depends mainly on whether there is any chronic obstruction or not; if there is any to speak of, the reunion should be postponed, because the passage of pent-up feces and the muscular action which this requires are unfavorable to surgical repair. In gastro-enterostomy, say the writers, operations are preferably performed by pure suturing (Halsted's operation) and also by Paul's method with ivory rings. Both these methods are successful. Some interesting physiological observations were added, and the paper was illustrated by numerous drawings.

The President (Dr. Dickinson) observed that he has noticed the extraordinary healing powers of the intestine. In one case, probably of intussusception, a great length of the bowel came away and the patient recovered. When a post-mortem examination was made some years later, it was impossible to see which portion had separated.

Mr. Greig Smith considered that on this subject no more valuable communication has been made to the profession since Senn's work was first published. One important conclusion arrived at by the writers is that it is best to avoid apparatus, and he himself, from a different point of view, has arrived at the same conclusion. He bases his opinion upon recent statistics which on this point are quite convincing. He considers the Halsted suture incomparably the best, as no infolding is necessary and it possesses great healing power. Murphy's button is a marvel of ingenuity. It is said to produce what is euphemistically called pressure atrophy. This latter appears to him to be very closely allied to gangrene.

Mr. Harrison Cripps said that he prefers fingers to bobbins and buttons. He has found end-to-end approximation with Lembert's sutures the best. He has applied them at a little more than one-eighth of an inch from the margin of the bowel, and this, he thinks, prevents infolding.

Mr. Leonard Bidwell mentioned that a temporary fecal fistula had occurred in each of three cases of Maunsell's operation which he had seen, and in two cases of gastro-jejunostomy in which Mayo Robson's bobbin was used there was after-obstruction due to the opposite wall of the jejunum occluding the lumen of the bobbin.

Mr. Bryant remarked on the much greater thickness of the walls of the intestines in dogs. A great deal of the ridge or diaphragm which is found after the Lembert suture is, he thought, due to this. One should, therefore, be very careful in applying these results to the human being. In some cases artificial appliances help the surgeon very much.

Mr. Edmunds, in reply, said it is only because the end-to-end method of suture has proved so unsuccessful that other measures have been invented. The lateral anastomosis by Halsted's method is the best.

Mr. Ballance, in reply, said that they are agreed that the fingers are the best form of apparatus to use. In these cases the stitches are not placed far away from the ends of the bowel, and the same ridge occurs also in human intestine after the Lembert suture.

The Pathological Society has declined to admit medical women to membership.

A number of honors were as usual conferred on the occasion of the Queen's birthday. In these surgeons in the services participated to some extent.

The Chelsea Hospital board has carried its resolutions, with the consent of the staff, who thus become the humble servants of a discredited board which can dismiss them at pleasure.

Honor to the Liverpool profession. The board of the Lying-in Hospital met on Monday to receive applications from gentlemen for positions vacated, as I have mentioned, by the medical staff. Notwithstanding the advertisements, not a single candidate applied.

The difficulty at Adelaide has not displayed the same union among London surgeons, for it appears that already one has accepted the offer to go out and take up a post vacated by one of the staff. The example of Liverpool should have deterred him.

The oldest member of the College of Surgeons, Mr. W. R. Salmon, died last week at the rare old age of one hundred and six. His diploma was dated 1812. He arrived in Paris soon after Waterloo, made his way to Brussels, and looked upon the horrors of unburied bodies on the field of battle and the many wounded in the hospitals. He retired from practice many years ago.

Sir John Millais lately had to submit to tracheotomy, and his illness excites much sympathy in the public. As I write, I learn that his strength and cheerfulness remain unimpaired.

PHYTOLACCA IN DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Permit me to say a few words in reply to Dr. M. L. Davis, of Lancaster, Pa., commenting in your journal of April 25, 1896, upon my treatment of diphtheria as outlined in the MEDICAL RECORD of March 28, 1896.

Readers of the later school of materia medica and therapeutics, such as Rieger, Bartholow, Phillips, Schoemaker, and others, can easily see why practical physicians were led to use aconite and phytolacca in diphtheria, as excellent results had been effected with those drugs in tonsillitis and chronic follicular pharyngitis. Inhalations and gargles of peroxide of hydrogen, carbolic acid, etc., are used in conjunction with internal medication in true diphtheria, because this disease depends upon a local fungus.

As to the climate of Juarez, Mex., and El Paso, Tex., it cannot be excelled for its sanitary qualities. Snows seldom whiten the ground, and lie but a few hours. Damp chilly days and hot sultry nights are unknown. The heat of summer is not oppressive, and sunstroke has never been known. The sky is clear the year round. No entire day has been known when the sun has not been seen. The atmosphere is unsurpassed for its dryness and purity; full of electricity, it is wonderfully exhilarating and is never burdened with malarious or poisonous exhalations. Blankets or cover of some kind are necessary for all our nights which follow the hottest days, because the nights are cool, though not damp. Sleep-

ing with doors and windows open, or in the open air, may be practised with impunity. There is no rank, rich vegetation saturated with moisture and constantly undergoing decomposition. Vegetation dries up, never rots. Meat, stripped and hung in the open air and sun in midsummer, will cure and is preserved without salt; but with all the benefit of this magnificent climate the writer, while formerly using Dr. Davis' remedies in diphtheria generally, lost from one-third to one-half of the little innocents, while with his present treatment he has the satisfaction of curing nearly all such cases. As to one drop of aconite to a four-ounce mixture I stand corrected. I generally use from one-fourth to one drop with each dose, according to the case. The mistake was probably a slip of the pen. There exists a foolish prejudice among a few in the regular profession against aconite and phytolacca; for the reason that the former is much in use among the homœopaths and the latter drug is often recommended by the eclectics.

Aconite has done service in the regular school of medicine before Hahnemann was born, and phytolacca has its place in the United States Dispensatory. Both these remedies will be in use among practical physicians after a hundred and more new-fangled "antitoxins" have been relegated to innocuous desuetude.

Dr. Cordeiro, in his report to the surgeon-general of the United States Army on antitoxin or serum treatment of diphtheria, used these words: "We have not the slightest basis on which to found expectation that fewer children will die in the future of this disease on account of the serum treatment."

E. ALEXANDER, M.D.

JUAREZ, PASO DEL NORTE, MEXICO, May 13, 1896.

"SHALL WE GIVE THE APPENDIX A REST?"

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Only to-day has my attention been directed to the letter from Dr. Greene, of Dubuque, under the caption given above, in your issue for May 23d, and which was written, if I remember, while its author was waiting for a train of thought.

As Dr. Greene is an old friend of mine, and as he takes several names in vain—mine among others—I know that he will like to hear from me. Moreover, he is as keen as a briar, and his challenge deserves the courtesy of a reply.

About two generations ago Dr. Oliver Wendell Holmes made a famous list of questions which, a hundred years hence, his spirit would like to ask, regarding progress in earthly matters. One was, "In fatal disease, is euthanasia as yet a *fait accompli*?" So far as gangrenous, perforative, or acutely suppurative appendicitis is concerned, that question will be answered as soon as the opium treatment shall be regularly adopted.

I wonder if Dr. Greene realizes the probable duration of the discussion into which he so light-heartedly enters? I do not wish to alarm him, but when time shall be no more and when all the prophecies are fulfilled, there will still be found the surgeon laboring patiently and prayerfully with his medical brother regarding appendicitis; and the family practitioner pointing out to the surgeon, gently and with Christian resignation, that two and two equal six.

Indeed, some family practitioners seem cultivating a very pretty talent for mathematics. The figures of Dr. MacArtney,¹ of the physician at a meeting of the American Medical Association, quoted (unnamed) by Dr. Wyeth,² and of Dr. Waldo³ amply prove this. I

¹ MEDICAL RECORD, May 2d.

² *Ibid.*, May 9th.

³ *Ibid.*, May 30th.

never was good at figures myself. Therefore these, with their twenty-four to seventy-five consecutive cases of appendicitis treated medically without a death, fill me with the greater admiration.

The statements of these mathematicians refer to diagnoses in which they evidently believe, and that belief must be treated with respect. But what shall be said of Fitz Hektoen?—he who “finds that thirty-five per cent. of all bodies in the dead-room show traces of appendicitis” (Greene). His assertion is not, like theirs, a matter of opinion. He refers to appendices actually seen at autopsies. Hence there can be no doubt, and our respect for him is proportionately deepened. Here is a rare spirit—a real adept at the gentle art of embroidery.

As Dr. Greene has reason to remember, the writer is so placed as to have had for many years opportunity to know the facts in demonstrating operative surgery.

Observe this quotation from Dr. Senn which Dr. Greene brings in as an argument for his position: “The removal of the appendix should be limited to those cases in which during the first attack symptoms arise which portend danger to life and relapsing appendicitis. Some cases of appendicitis yield to medical treatment, and in a large percentage of such cases the patients remain free from a second attack.”

This seems to me, after a cautious perusal, quite harmless. The first sentence is a trifle loose in its grammar; but as a statement the whole thing is safe for the young and for family reading.

Drs. Fenger and Lamphear fare rather badly at Dr. Greene's hands—the former on the strength of a conversation a year ago, the latter regarding a paper written several years back of this day of grace; and both gentlemen he quotes from memory only. However, they need no defence from me. If they have at any time said anything for which they are now sorry, I am sure they are glad of it.

My own small addition to this controversy is an entirely new idea, and is dedicated to the medical statisticians aforesaid. It is that we should not regard every case of pain in the right side of the abdomen as being appendicitis. There are at least a dozen other sources of pain there.

This novel thought, which must strike them as a bold conception, is offered with diffidence.

To Dr. Greene I would present my compliments and the hope that he will not construe anything I have said as meaning that I cut in every case of appendicitis to which I am called. That would be far from the truth.

ROBERT H. M. DAWBARN, M.D.

105 WEST SEVENTY-FOURTH STREET, NEW YORK.
June 1, 1896.

Asepsis in Country Practice.—Where it is impossible to secure the appliances of a clinical amphitheatre for an operation, the water used in washing the hands, the seat of the operation, etc., should be boiled for an hour. All brushes should be boiled. The surgeon should carry with him antiseptic soap, alcohol, and a solution of sublimate. He should also carry handkerchiefs, aprons, bandages, silks, drainage tubes, etc., in a Mehler's sterilizing apparatus. Just before the operation all instruments, cloths, etc., should be boiled again. When possible the room should be wiped up with a damp cloth two hours before the operation, and all curtains, hangings, etc., removed. The patient should be bathed, and all washing-utensils, tables, and, in fact, everything to be used, should be carefully cleansed and disinfected. With infinite pains the difficulties of a country practice may be overcome and operations may be crowned with success.—*Munch. med. Woch.*, Nos. 49-51, 1895.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 6, 1896:

	Cases.	Deaths.
Tuberculosis.....	111	108
Typhoid fever.....	13	4
Scarlet fever.....	75	2
Cerebro-spinal meningitis.....	1	3
Measles.....	288	23
Diphtheria.....	258	39
Small-pox.....	0	0

Poisonous Fish.—Poisonous fish are found in large numbers and in many places, but more especially in the tropics. They are quite common in the Brazilian and West Indian waters, and also in the East Indian and Australian waters. Three kinds of fish belonging to the mackerel family are poisonous. One is called the jurel, and is found in the West Indies in large numbers. It can be distinguished from the common mackerel, which also abounds in the same waters, by certain peculiarities or marks. Thus, the jurel has no black spot on the gill covers; it has scales on the neck, while the harmless kind has a black spot and no scales on the neck. The poisonous kind grows large and often weighs as much as twenty pounds, but the others seldom run over two pounds. Mackerel weighing over two pounds are not allowed to be sold in the Havana markets. The chicaro is another kind of poisonous mackerel. It is also found in the West Indies, but the natives of those islands do not regard it as dangerous. The meat of the chicaro is not fit nor safe to eat at certain times of the year, especially during the spawning season. Then it becomes highly poisonous, and the people of Guadeloupe sometimes use pieces of this fish, which have been caught, to poison rats. The bonito is a kind of mackerel that is most dangerous at certain times of the year. Usually it is a very pleasant and palatable bit of food, but every once in a while people are taken with colic after eating the bonito. So it is best to let it alone. Two kinds of herring are known to be poisonous. The meletta, or tropical herring, is found all along the Atlantic coast as far north as New York. Within recent years there have been several cases in which people have died after eating this fish. The spawning season seems to be the time when the herring and other tropical fish should be let severely alone. The part which is considered most dangerous is the roe. The meletta which is found in East Indian and Australian waters is always poisonous, and it is the more dangerous because it is not easily distinguished from another kind of herring which is comparatively harmless. The poisonous kind has a black nose and a black spot on the dorsal fin, while the other has not these marks. The poisonous meletta resembles a herring, being five or six inches long, with silvery scales and a bluish-green back. Some fish are poisonous in certain localities and harmless in other places; some are poisonous at certain seasons of the year and at other times wholesome; and finally, as a note of warning, we would say that visitors to tropical countries should take no risk of eating fish which are not known to be safe as well as palatable.

Adenoid Vegetation of the Nose.—Paint with a fifty-per-cent. solution of resorcin. Six to ten applications usually prove sufficient.—MARAGE.

CLINICAL OBSERVATIONS UPON THE USE OF ANTITOXIN IN DIPHTHERIA; AND A REPORT OF A PERSONAL INVESTIGATION OF THIS TREATMENT IN THE PRINCIPAL FEVER HOSPITALS OF EUROPE DURING THE SUMMER OF 1895.*

By JOSEPH E. WINTERS, M.D.,
NEW YORK.

SINCE Behring's treatment for diphtheria was proclaimed to the medical profession by Roux at the Buda-Pest congress in 1894, sufficient time has elapsed to warrant our taking a careful analytical review as to what has transpired with reference to it.

Behring's antitoxin was given to the world as a specific against the toxins of the diphtheria bacillus. It has no action on the bacillus; this is not destroyed by the antitoxin, it is not rendered less virulent, it is in no way influenced by the treatment.

Behring has told us that his remedy has no influence on the poisons of other bacilli. Diphtheria in man scarcely ever occurs from pure infection by the Loeffler bacillus. Almost invariably we find in addition to the specific diphtheria bacillus, streptococci, staphylococci, etc. The poisonous substances of the latter bacilli are in no way influenced by antitoxin. This fact limits very much the application of Behring's treatment to diphtheria in man. The toxin of Loeffler's microbe causes the cardiac paralysis, the albuminuria, and the paralytic phenomena. These were to be prevented by the neutralizing effect of the antitoxin. If antitoxin is an antidote to the toxin of the Loeffler microbe, cardiac depression, death from cardiac paralysis, albuminuria, and post-diphtheritic paralysis should all be prevented by the action of this agent. It was to remedy these manifestations of the disease that Behring gave to the world his antitoxin.

Behring told us his treatment to be effective must be applied early in the disease; to get the maximum effect, toxin and antitoxin must be applied at the same moment and at the same spot.

Armand Ruffer¹ states that if you inject toxin on one side of the body and antitoxin on the other side at the same time, fourteen times as much is required to protect the animal; if there is a delay of one hour, one hundred times as much is required to protect the animal, and if there is a delay of eleven hours five thousand times as much is required to protect the animal.

In diphtheria in man we can never apply the antitoxin at the site of infection, nor at the moment of infection. A period necessarily intervenes from the time of infection until there are sufficient symptoms to call attention to the illness, and, as the result of this, there is a great limitation to the application of Behring's remedy to diphtheria in man.

Another consideration of prime importance is: if we are to attribute the reported decrease of mortality of diphtheria to the action of a specific, this decrease

must be uniform and constant. There must be the same reduction in mortality in all parts of the world where the remedy is applied. For instance, a mortality of eight per cent. in Paris and twenty-eight per cent. in London does not mean that the low mortality in the former city is due to the treatment, but that it is due to a difference in the character of the epidemic, and that when Paris is visited by an epidemic of the same severity as the one that exists in London it will have the same mortality in spite of the treatment. If there is at work but a single factor, viz., antitoxin, in the reduction of mortality, that reduction must be below the lowest mortality recorded in the natural history of the disease in any part of the world, and it must be steadily maintained below this rate in all parts of the world; otherwise, the variations in mortality may be said to be due to the epidemic character of the disease. We find recorded the following divergences in the deaths from diphtheria, owing to differences in the type of the disease:

	Deaths from Diphtheria.
In New York in 1884, ...	1,090
" " " 1887, ...	2,167
Again in 1890, only	1,262
" " 1894, ...	2,359
In Boston in 1891, ...	232
" " " 1894, ...	817
In Philadelphia in 1888, ...	350
" " " 1889, ...	375
" " " 1892, ...	1,425
In London in 1891, ...	1,361
" " " 1893, ...	3,265
In Berlin in 1866 (croup and diphtheria), ...	813
" " " 1867, ...	904
" " " 1868, ...	2,154
Again in 1877, with an increase in population of nearly half a million, only	1091

The same variation in the type of the disease is shown in the mortality returns from hospitals in different years. Thus, we find that in the Children's Hospital in Basel the mortality from diphtheria in 1876 was 34.1 per cent., in 1886 6.2 per cent.²

In the Crown Prince Rudolph Hospital³ (Vienna) we find that the mortality in 1887 was 27.1 per cent., and in 1888 62.8 per cent. These normal variations in the type of the disease must be given due consideration when estimating the value of a mode of treatment.

The rule of uniformity of results applies to reports by individual observers. If one hundred physicians report five thousand cases of diphtheria treated with antitoxin with a mortality of five per cent., and ten physicians report five hundred cases treated with antitoxin with a mortality of fifty per cent., the only logical conclusion is that there was a difference in the character of the cases in the two series, and that when the one hundred physicians meet with a series of cases of the same type as those treated by the ten physicians, they, too, will have a mortality of fifty per cent.

The most misleading part of the antitoxin literature is the constantly quoted percentage of mortality. The mortality from diphtheria in the city of Boston in 1895 was 14.48 per cent.; in 1893 32.49 per cent., and yet there were one hundred and twelve more deaths from diphtheria in the city of Boston in 1895 than there were in 1893 (four hundred and seventy-six in 1893

* Read before the New York Academy of Medicine, May 21, 1896.

and five hundred and eighty-eight in 1895). The percentage mortality in 1895 is less than one-half as much as that of 1893, and yet the actual number of deaths was increased about one-fourth. The percentage reduction of mortality is due to the fact that in 1895 four thousand and ninety-five cases were reported, and there were only one thousand four hundred and sixty-five cases of diphtheria reported in 1893 in the city of Boston. The percentage mortality from diphtheria in the Boston City Hospital in 1893 was 48.44 per cent., and in 1895 13.21 per cent.; and yet we find that there were two hundred and three deaths from diphtheria in the Boston City Hospital in 1893 and two hundred and seven deaths in 1895.

BOSTON CITY HOSPITAL.

Year.	Cases.	Deaths.	Per cent.
1893.....	419.....	203.....	48.44
1894.....	597.....	260.....	44.48
1895.....	1,566.....	207.....	13.21

From the foregoing it is readily seen that percentage mortality is not only misleading, but is absolutely worthless unless accompanied by the actual number of cases reported and the actual number of deaths; and the report must also include a series of years, in order to enable the reader to compare present results with the results in previous years when there was a mild type of the disease. Reports on the antitoxin treatment have ingeniously compared years of highest mortality instead of including all years.

The necessity of taking into consideration the character of the prevailing epidemic in order to have a clear understanding, is shown by the following. At Gratz Escherich⁴ treated:

	Cases.	Deaths.	Per cent.
By injection of serum,	51	5	9.8
By non-injection,	36	3	8.3

Kohts⁵ mortality in tracheotomy cases treated with serum is 29.41 per cent.; without serum, twenty-five per cent. For cases not operated on, with serum, 7.6 per cent.; without serum, 6.9 per cent.

At the beginning of the antitoxin treatment Behring told us all cases treated on the first day of the disease could be saved; of those coming under treatment on the second day, nearly all, and of those brought under treatment on the third day, the larger part of them. Behring's words were: "We have it in our hands to reduce the mortality from diphtheria to one-tenth of its former rate" (three to five per cent.). Let us see how this promise of Behring's has been verified.

At the Willard Parker Hospital⁶ during the first nine months of 1895, the results were as follows:

DAY UPON WHICH TREATMENT WAS BEGUN, 1895.

	Cases.	Mortality, per cent.
First day.....	108.....	10.09
Second day.....	130.....	25.19
Third day.....	116.....	34.19

We will cite a few cases showing actual results when treatment is begun in the earlier part of the disease:

CASE I.—Six years old; admitted to scarlet fever ward February 1, 1896; recovered from scarlet fever and was ready for discharge.

March 19th, at 11:30 A.M., she complained of sore throat. The diagnosis of diphtheria having been made by bacteriological examination, she was injected with 2,000 units of antitoxin, March 21st, at 3:30 A.M., just forty hours after the disease began. In spite of treatment croupy symptoms, which manifested themselves early, increased, and intubation was done at 10 A.M., forty-six and one-half hours after the beginning of her illness. On the evening of the same day, intubation not affording sufficient relief from the stenosis,

tracheotomy was performed at 9:40 P.M. The child died at 9:45.

In this case we have an instance of a child developing diphtheria in the hospital and being put upon the serum treatment as soon as the diagnosis was confirmed. Notwithstanding this, the local process extended, even intubation not affording sufficient relief, the whole course of the illness being a repetition of what has been frequently seen in the Willard Parker Hospital service.

CASE II.—Aged two and one-half years; admitted April 22d; ill one-half day. Throat clear; tonsils red and somewhat swollen; croup, some retraction, no cyanosis. Under the head of clinical notes I find: "Child rather croupy on admission." Antitoxin, 2,000 units, on admission. Patient admitted April 22d, about midday.

April 23d, 8:55 A.M., intubation necessary: 2,000 units of antitoxin.

Temperature on admission, 100.8° F. April 23d, temperature, 103.2° F. April 27th, temperature, 99° F. April 28th, temperature, 105° F. April 30th, temperature, 101.6° F. Afternoon of same day, 105.2° F.

May 10th, the baby died, 2:25 A.M.

This is an extraordinary record. The child had been ill one-half day on admission. Clinical notes state: "Child rather croupy on admission." About the only evidence of disease, then, was croup. In spite of antitoxin, 2,000 units, croup increased during the night; intubation became necessary the following day, about twenty-one hours after admission. Next observe the common temperature range which occurs when the patient shows unusual susceptibility to the influence of antitoxin.

CASE III.—Aged two years; admitted October 22d; one day sick. Marked injection and swelling; dirty white membrane on left tonsil, croup. Prognosis doubtful. Antitoxin, 2,000 units, on admission. Admitted, 9:30 A.M.; intubated, 4:15 P.M.

October 23d, antitoxin, 2,000 units; 9:45 A.M., tube coughed up; 10:05 A.M., intubated. Temperature, 2 P.M., 104.6° F.; hypodermics of brandy and nitroglycerin, hot bath, etc.

October 24th, antitoxin, 1,200 units, 11:45 A.M.; temperature, 104° F.; sponging, etc.

October 27th, temperature, 105° F.; sponge baths nearly every hour.

October 28th, rash.

October 29th, tube removed.

November 1st, temperature went to 105° F.; sponge baths almost hourly.

November 3d, temperature reached 105.8° F.; sponge baths nearly every hour.

November 5th, temperature ranged from 102° to 105° F.

November 6th, temperature, 105.8° F.; sponge baths constantly kept up.

November 7th, temperature ranged from 101.2° to 106.2° F.; sponge baths used almost constantly.

November 8th, temperature, 102° to 106° F.

November 9th, patient died 6:40 P.M.

Here we have a baby two years old, taken sick October 21st, admitted to hospital October 22d at 9:30 A.M., given antitoxin immediately (in all, 5,200 units), and the result is shown by the clinical history. If antitoxin has any possible effect in neutralizing the poison of diphtheria, in relieving or preventing stenosis, or in any way allaying laryngeal symptoms, only a very small part of the clinical history here recorded would have manifested itself.

CASE IV.—Aged two years; admitted February 18th; illness began February 17th. Patient well nourished, pulse good, small amount of membrane on tonsils and uvula; K. L. B.: complication by bronchi-

tis. Prognosis favorable. Temperature on admission, 101.8° F.; temperature ranged between 99° and 102° F. from time of admission until March 5th, when it rose to 103.6° F., the following day to 105.2° F.; temperature fluctuated until March 18th, when patient died. Antitoxin, 20 c.c., 1 to 300, injected on admission; February 2d, antitoxin injected, 20 c.c., 1 to 300.

CASE V.—Aged seventeen months; admitted February 4th; illness began February 3d. Well nourished and in good general condition; no membrane visible; tonsils and uvula normal in color; large, irregular ulcer on face, involving lid of right eye, right side of nose, and right cheek; suppuration and considerable inflammation at periphery; lids of right eye badly swollen. Prognosis favorable. Antitoxin, 21 c.c., 1 to 300, injected on admission. Temperature on admission, 101.8° F.; following day, 102° F.; from that time practically normal until February 13th, when the chart was stopped. February 22d the temperature suddenly rose to 105° F., and fluctuated between 105° and 106.8° F. until March 7th, when the patient died.

CASE VI.—Aged one year; admitted May 23d; illness began May 22d. Throat dull red with slight tumefaction; thin white membrane on both tonsils and base of uvula and soft palate; much anterior and posterior nasal secretion; K. L. B. Prognosis favorable. Antitoxin, 6.5 c.c., 1 to 1,000, injected on admission. Patient died May 31st.

CASE VII.—Aged four years; admitted February 11th; illness began February 10th. Well nourished; pulse good; few thin streaks of membrane on tonsils; tonsils much enlarged; but little discharge from nose; right-sided cervical adenitis fairly well marked; slight swelling also on left side. Prognosis favorable. Antitoxin, 15 c.c., 1 to 600, injected on admission; February 12th, 15 c.c., 1 to 600; February 13th, 15 c.c., 1 to 600. Temperature on admission, 101° F.; slight variation until February 19th, when temperature rose to 103° F., on the 20th to 105° F., fluctuating between 102° and 106.5° F. until February 27th, when patient died.

CASE VIII.—Aged sixteen years; admitted May 20th; illness began May 18th. Well developed and nourished; glands of neck enormously swollen; throat much congested; swelling and implication of left tonsil; right tonsil and right peritonsillar space and whole area back into pharynx covered with a dirty white deposit; nares partially obstructed; K. L. B. Prognosis favorable. Antitoxin, 10 c.c., 1 to 1,000, injected on admission; May 21st, 9 c.c., 1 to 1,000; May 25th, 7 c.c., 1 to 1,500.

May 26th (Sunday), pulse 26 to 30 per minute. Patient died May 26th, 10:30 P.M.

This was a remarkably large, strong, well-developed young lady, who was brought to the hospital as soon as the diagnosis of diphtheria was made. If antitoxin has any specific influence over the toxæmia of diphtheria, this patient should have been saved. As the report of the hospital shows, she died from the effects of the toxins on the heart and nerve centres—the pulse having ranged during the last twenty-four hours of life from 26 to 30 per minute, even with the foot of the bed elevated and with the use of all possible stimulants.

CASE IX.—Aged thirteen months; admitted May 16th; illness began May 14th. Well developed and nourished; no apparent anæmia; marked injection and tumefaction; thin white membrane on left tonsil; K. L. B. Prognosis good. Antitoxin, 5 c.c., 1 to 1,500, injected on admission. Patient died June 12th. June 1st rash appeared, with numerous areas of bronchial breathing and fine crepitant râles.

CASE X.—Aged five years; admitted November

11th; two days sick. Necrotic membrane on left tonsil, extending forward to soft palate; grayish membrane on right tonsil; no nasal discharge. Antitoxin, 1,000 units, on admission.

November 12th, antitoxin, 1,000 units.

December 16th, patient died.

CASE XI.—Aged fourteen months; admitted March 25th; two days sick. Speck of membrane on each tonsil; croup rather marked. Antitoxin, 1,000 units, on admission; later, same day, 2,000 units. Intubated at 12:05 P.M., twelve hours after admission. Afternoon of 25th, 1,500 units of antitoxin. Tube coughed up at 9:35 P.M.; intubated at 1:25 A.M., March 26th; tube coughed up immediately after. Intubated at 2:10 A.M.; very restless. At 12:35 P.M. of 26th, tube removed; at 12:45, intubated. At 1 P.M., temperature 106.2° F.

March 27th, 9:30 A.M., tube removed.

March 28th, temperature, 104.2° F.; pulse, 140, very weak.

April 4th, died.

CASE XII.—Aged two years; admitted February 15th; two days sick. Good-sized patch on each tonsil; croupy, husky breathing, and retraction. Antitoxin, 2,000 units, on admission.

February 16th, antitoxin, 1,000 units; 6:10 P.M., intubated.

Admitted February 15th at 2:30 P.M., not having very marked croup, and yet had to be intubated twenty-eight hours after admission and after having had 3,000 units of antitoxin.

February 17th, 3:20 P.M., tube coughed up; 6:30 P.M., intubated; 10:30 P.M., tube removed; 10:40 P.M., intubated.

February 18th, 1:30 A.M., tube removed; 1:40 A.M., intubated, wide calibre; 1:50 A.M., tube coughed up; 2 A.M., intubated, wide calibre. Note states that "urine is scant." 7:30 P.M., tube removed; 11 P.M., intubated; 11:10 P.M., coughed up tube. Urine still scant.

February 25th, 9 P.M., intubated twice.

February 26th, 2:30 A.M., tube removed; 9:30 P.M., intubated twice.

February 27th, 4:40 P.M., tube coughed up.

February 28th, intubated twice; 11 P.M., tube coughed up.

March 5th. Note is found: "Marked retraction." At 2:40 P.M., intubated; 9:25 P.M., tube coughed up plugged; 10 P.M., intubated.

March 6th, 4:45 A.M., tube coughed up plugged; 5 A.M., intubated; 5:05 A.M., tube coughed up plugged; 5:10 A.M., intubated; 8:50 A.M., tube coughed up.

March 7th, 7:45 A.M., intubated; tube coughed up; 8 A.M., intubated; 11:50 A.M., tube coughed up.

March 8th, 7:25 A.M., intubated.

March 10th, child died at 10:55 A.M.

CASE XIII.—Aged fourteen months; admitted February 20th; two days sick. Membrane on both tonsils, croup. Prognosis doubtful. Antitoxin, 2,000 units, on admission. Admitted at 6:30 A.M.; intubated at 7 A.M.; tube removed at 12:40 P.M.; intubated at 1:30 P.M.

February 21st, antitoxin, 1,000 units, 10:20 A.M.; tube removed at 4:30 P.M.

February 23d, rash appeared; extreme restlessness. Note: "Is very sick this morning; temperature, 105° F."

February 24th: "Very restless and excited all night."

March 5th, temperature, 104° F. Temperature ranged from this point to 105° F. until March 7th. Baby died at 1:45 P.M.

CASE XIV.—Aged four years; admitted December 2d; two days sick. Throat dull red in color, considerable naso-pharyngeal discharge, no membrane, croup.

Prognosis unfavorable. Antitoxin, 3,000 units, on admission; intubation immediately after admission.

December 3d, antitoxin, 3,000 units.

December 6th, tube removed, 3:30 P.M.

December 7th, had a bad night; intubated at 9:35 A.M.

December 8th, tube removed.

December 12th, intubated.

December 13th, tube coughed up at 4:30 A.M.; intubated at 6:30 A.M.

December 15th, tube coughed up at 3 A.M.; intubated at 10 A.M.

December 21st, tube removed at 10:10 A.M.; reintubated at 10:50 A.M.; tube removed at 4:05 P.M.; reintubated at 4:15 P.M.

December 23d, rash appeared.

December 24th, tube coughed up at 2 P.M.; reintubated at 2:10 P.M.

December 28th, tube coughed up at 7:10 P.M.; reintubated at 7:15 P.M.

January 6th, antitoxin, 3,000 units. Then I find notes for strychnine, whiskey, cream-of-tartar water, diuretin.

January 28th, when patient died, uncontrollable diarrhoea.

CASE XV.—Aged two years; admitted December 5th; two days sick. Thick yellowish-white membrane on both tonsils and uvula, croup. Prognosis unfavorable. Antitoxin, 3,000 units, on admission; intubation on admission.

December 6th, antitoxin, 3,000 units; cream-of-tartar water, diuretin, poultice to kidneys, mustard bath, glonoin, whiskey, strychnine, calomel.

December 18th, patient died.

CASE XVI.—Aged two years; admitted December 19th; two days sick. Thin white membrane on both tonsils and uvula, croup. Prognosis unfavorable. Antitoxin, 3,000 units, on admission. Admitted at 12:40 P.M.; intubated at 3:35 P.M.; tube coughed up at 3:45 P.M.; reintubated at 7 P.M.

December 20th, antitoxin, 3,000 units; tube removed at 3:30 A.M.; intubated at 3:35 A.M.

December 20th, 11 A.M., temperature, 106.8° F.; pulse, 162. Sponge baths. At 8:30 P.M., temperature, 106° F.; 11 P.M., 103° F.

December 21st, 2:30 A.M., temperature, 102.6° F. Patient died at 5:45 A.M., from exhaustion and cardiac failure.

CASE XVII.—Aged three years; admitted April 19th; two days sick. No membrane in throat, very mild croup, no stenosis, no retraction, slight croupy cough. Child admitted in good condition. Croupy symptoms increased when disturbed; when quiet, breathing normal. Prognosis good. Antitoxin, 1,000 units, on admission.

April 20th, child had only one dose of antitoxin. Second dose not given, as condition of child was good.

April 23d, temperature, 98° F. in forenoon; 102.4° F. in afternoon.

April 24th, temperature, 98.5° F. in forenoon; 103° F. in afternoon.

April 27th. Under clinical notes I find: "Patient not doing very well this morning. Child pale, temperature high."

April 28th, 1:30 P.M.: "Cause of death, heart failure."

CASE XVIII.—Aged one year; admitted April 22d; two days sick. Minute speck on right tonsil. Antitoxin, 600 units. Clinical note states: "Child admitted in pretty poor condition."

April 23d, forenoon, urine scant.

Temperature on admission, 103.8° F. April 23d, 100.8° F. in forenoon; afternoon of same day, 105° F. April 24th, 99.5° F. in forenoon; 104° F. in afternoon. April 25th, 104.8° F. April 26th, forenoon, 99.8° F.; afternoon, 103.8° F.

April 28th, patient died at 2 A.M., from exhaustion and heart failure.

CASE XIX.—Aged fifteen months; admitted April 27th; two days sick. Considerable amount of membrane on tonsils, uvula, and soft palate; membrane was beginning to exfoliate. Prognosis doubtful. Antitoxin, 1,000 units, on admission. Piece of membrane was very loose and washed away when irrigated for the first time.

April 28th, antitoxin, 1,000 units.

May 3d: "Until to-day the child's condition was very satisfactory; she was bright; temperature, pulse, and respiration were fair. She was apparently on the road to recovery, when suddenly during the night the pulse became very feeble, respiration went up to 78 per minute, and she died two hours later of heart failure."

CASE XX.—Aged fifteen months; admitted October 28th; illness began October 26th. Prognosis doubtful. Throat dull red, slight tumefaction, small patch on right tonsil, larger on left, considerable croup. Antitoxin, 2,000 units, on admission. Patient admitted at 1:30 P.M.

Clinical note states: "In spite of poulticing, intubation became necessary and was performed at 3:20 A.M., October 29th," fourteen hours after antitoxin.

October 29th, antitoxin, 2,000 units.

November 1st, forenoon, tube coughed up.

November 2d, antitoxin, 2,000 units, at 12:30 P.M.; 2 P.M., temperature, 105° F.; pulse, 200; 6 P.M., temperature, 105.2° F.; sponge baths, carbonate of ammonia, caffeine, strychnine, ice pack to head.

November 3d, 6 A.M., temperature, 106° F.; pulse, 190; 9 A.M., temperature, 106° F.

November 4th, 7:45 A.M., patient died, bronchopneumonia.

Another death after seven days of treatment, which was begun on the second day of disease; 6,000 units of antitoxin; child of fifteen months.

CASE XXI.—Aged seventeen months; admitted October 2d; second day of disease. Prognosis doubtful. General swelling and injection of throat; thin necrotic membrane on both tonsils and palate, extending into pharynx; considerable nasal discharge, croup, stenosis, and retraction. Antitoxin, 2,000 units, on admission. Admitted October 2d, 2:30 P.M.; 10:40 P.M., fumigated.

October 3d, 1:15 A.M., it became necessary to intubate; 10:20 A.M., tube removed; 10:50 A.M., intubated; 10:53 A.M., tube coughed up; 11:10 A.M., intubated; 11:35 A.M., antitoxin, 2,000 units; strychnine, caffeine, nitroglycerin, carbonate of ammonia, whiskey, sponge bath, dry cupping. Temperature at 4 A.M., 102° F.; 8 A.M., 107° F.; 11:30 P.M., 108° F.

October 4th, temperature at 12:20 A.M., 107.6° F.; 12:30 A.M., 107.8° F. Died at 12:40 A.M.

Several of the following histories are undoubted instances of the bad effects of antitoxin on nerve centres:

CASE XXII.—Aged fourteen months; admitted November 6th; illness began November 3d. Small patch of membrane on right tonsil; K. L. B.; no complication. Antitoxin, 1,000 units, on admission.

November 9th, slept at intervals quietly, but was very restless when awake.

November 10th, extremely restless most of the night; temperature, 104° F.; sponge bath.

November 12th, pulse very weak.

November 20th, rash appeared.

November 6th, antitoxin, 2,000 units, at 5:30 A.M.; intubated at 1 P.M. Very restless during the day. Respiration, 60 to 70. At 5 P.M., temperature, 105° F.; sponge bath; 8:15 P.M., temperature, 106° F. Child failed to respond to stimulants; temperature became more and more elevated, in spite of sponge bath.

December 7th, died at 12:30 A.M.

According to the record this child had almost no illness on admission. It became very restless after first injection of 1,000 units of antitoxin. Restlessness reappeared in exaggerated form after the injection of antitoxin, 2,000 units, along with high temperature and rapid respiration, until death.

CASE XXIII.—Aged seven months; admitted February 4th; three days sick. Nothing in throat, slight laryngeal symptoms. Clinical note states: "Slight croup, otherwise good condition."

February 5th, antitoxin, 2,000 units.

February 6th, antitoxin, 2,000 units; 4 A.M., temperature, 104.2° F.

February 11th, temperature suddenly rose and erythema appeared in patches over the body. Temperature in evening reached 105.4° F.

February 12th, morning, rash more marked since midnight. "Marked opisthotonos and stiff neck."

February 12th, temperature, 106° F. all night.

February 14th, glands and right side of the neck swollen. Temperature ranged from 104° to 106° F. till March 18th, and patient had convulsions during the night.

March 19th, child died at 9 P.M.

CASE XXIV.—Aged thirteen months; admitted October 13th; three days sick. Marked swelling and injection, no membrane, croup. Intubated on admission.

October 13th, antitoxin, 2,000 units.

October 14th, antitoxin, 2,000 units.

October 14th, tube coughed up at 4:10 A.M.; had to be reinserted at 8:30 A.M.

October 15th, tube coughed up at 10:30 A.M.; intubated at 12:30 P.M.

October 16th, tube coughed up at 7:10 A.M.

October 19th, temperature suddenly rose to 104° F.; temperature remained high but somewhat fluctuating until the 21st, when it reached 105.4° F., and the baby had slight convulsions. In the afternoon respiration became very superficial; patient failed to respond to any stimulants.

October 21st, child died at 5:25 P.M.

CASE XXV.—Aged fourteen months; admitted February 20th; five days sick. Rather thick patch on right tonsil, cry and breathing croupy, no retraction. "Patient admitted in croupy condition, not bad enough to require intubation." Prognosis good. Antitoxin, 2,000 units.

February 21st, antitoxin, 2,000 units, at 10:15 A.M.; intubated at 2:10 P.M.; 5:45 P.M., tube removed.

February 22d, 8:30 A.M., temperature, 104.5° F.; 12 M., 105° F.; pulse, 184; respirations, 84; 11 P.M., temperature, 106.2° F.; opisthotonos. Plunge bath for ten minutes.

February 23d, temperature down, but still opisthotonos and great prostration.

February 29th, opisthotonos; eyes rolled up, with lids half-closed when asleep.

March 3d, opisthotonos and rolled-up eyes.

March 6th, died at 8:15 P.M.

CASE XXVI.—Aged three years; admitted February 17th; four days sick. Much membrane on either tonsil and on pillars of fauces; nose plugged. Prognosis doubtful. Antitoxin, 2,000 units, on admission.

February 18th, antitoxin, 2,000 units.

February 19th, antitoxin, 2,000 units.

February 21st: "Patient seems better to-day. This evening he gave a peculiar cry, heard by the nurse, and was dead on arrival of the physician a moment later. There were no heart sounds, but artificial respiration was kept up for ten minutes and stimulants were also given. Patient gasped several times and died."

CASE XXVII.—Aged twenty-one months; admitted September 28th; illness began September 25th.

Antitoxin, 1,000 units, on admission. Thick white membrane on uvula and both tonsils: slight nasal discharge. Child became cyanosed, apparently from accumulation in the throat; turpeth mineral given, resulting in free vomiting and relief.

September 29th, antitoxin, 1,000 units.

September 29th, became cyanotic from slightest exertion, and was very restless, seeming to indicate a considerable cerebral irritation; considerable retraction and stenosis—so much so that it was thought advisable to see if intubation would give any relief. The result of operation was unsatisfactory and the tube was removed.

September 30th, still more stenosis; restlessness even more marked. Patient almost pulseless.

September 30th, 9:40 P.M., patient died.

This child had no evidence of croup nor of laryngeal complication on admission. According to the record its illness was certainly slight and unimportant. After each injection of antitoxin there were restlessness, weakness, and feeble, imperfect respiration. The bad breathing, for which intubation was tried without relief, was undoubtedly due to the action of the antitoxin on the nerve centres and not due to croup.

CASE XXVIII.—Aged three and one-half years; admitted December 25th; four days sick. Dirty necrotic membrane on both tonsils, palatine arches, and uvula. Prognosis good. Antitoxin, 2,000 units, on admission.

December 26th, antitoxin, 2,000 units.

December 27th, urine scant; cream-of-tartar water, diuretin.

December 30th, strychnine.

January 2d and 3d, thirty per cent. of albumin, granular casts; aromatic spirits of ammonia, tincture of digitalis, whiskey, etc. In spite of active stimulation the child grew weaker and weaker, and died of heart failure and nephritis, at 10:45 A.M., January 3d.

CASE XXIX.—Baby; admitted April 1st, 12:40 A.M. Antitoxin same hour; intubated at 12:50 P.M. Second dose of antitoxin, 2,000 units, in afternoon of same day. Temperature on admission, 99.8° F.

April 2d, temperature, 104° F.; wet pack, etc.

April 3d, 11 A.M., tube removed; 11:25 A.M., reintubated; 1:30 P.M., temperature, 105.2° F.; 6:45 P.M., extubated; tube found plugged; reintubated, 7:15 P.M.

April 4th, tube removed at 1:15 A.M., plugged; reintubated at 1:50 A.M.; tube removed immediately after; intubated again at 1:55 A.M.

April 4th, 10:20 P.M., temperature, 101.6° F.

April 5th, temperature, 106° F. Child died at 8:07 A.M.

This child had been ill, according to the record, but one day when admitted to the hospital. Antitoxin was immediately injected; twelve hours later intubation became necessary. According to the record, a second injection of antitoxin was given at about the time of the intubation. The following day the tube was removed at 11 A.M. Notwithstanding the influence of 4,000 units of antitoxin on a child who had been ill but one day when admitted and who did not have severe croup, the tube had to be reinserted within twenty-five minutes. The rest of the record shows that in every instance after the removal of the tube it had to be reintroduced. In other words, antitoxin did not have the slightest influence on the diphtheritic process in the larynx.

CASE XXX.—Aged four years and five months; admitted February 26th; illness began February 23d. Strong, well nourished; tonsils very red and much enlarged; numerous small patches of dirty membrane on tonsils and uvula; abundant and slightly foul discharge from nose; slight nasal obstruction; K. L. B. Prognosis favorable. Antitoxin, 20 c.c., 1 to 200, in-

jected on admission; February 28th, antitoxin, 20 c.c., 1 to 200, injected. Temperature on admission, 99.5° F.; temperature ranged between 98.5° and 102° F. until March 18th, when it suddenly rose from 99° to 104° F.; on the 19th to 105° F. High but fluctuating temperature continued until March 28th, when patient died.

CASE XXXI.—Aged two years; admitted February 2d; illness began January 31st. Patient well nourished; small irregular patch of thin light grayish membrane on each tonsil; mucous membrane only slightly hyperæmic; tonsils and uvula about normal in size; K. L. B.; very slight dyspnea; cough and cry croupy. Prognosis favorable. Antitoxin, 7 c.c., 1 to 400, injected on admission.

February 3d, condition of case satisfactory.

February 4th, antitoxin, 21 c.c., 1 to 400, injected.

Temperature on admission, 99.8° F.

February 15th, temperature, 99° F.; 16th, 103° F.; 17th, 104° F.; 18th, 106° F. Temperature fluctuated until March 25th, when the child died.

CASE XXXII.—Aged nineteen months; admitted March 13th; illness began March 9th. Patient well nourished; white patch well defined on left tonsil, posterior pillar, and uvula; K. L. B. Prognosis good. Antitoxin, 14 c.c., 1 to 500, injected on admission.

March 14th, antitoxin, 10 c.c., 1 to 500, injected.

March 16th, very little urine passed.

March 22d, patient died.

CASE XXXIII.—Aged two years; admitted April 27th; illness began April 23d. Thin white membrane on each tonsil, which were large and infiltrated; K. L. B. Prognosis good. Antitoxin, 8 c.c., 1 to 1,000, injected on admission. Albuminuria, enteritis, pulmonary symptoms, convulsions.

June 7th, patient died.

This child had almost no illness on admission to hospital, according to hospital record.

CASE XXXIV.—A. F.—, aged seven years; admitted June 4th; illness began June 1st. Well developed and nourished; thick dirty white membrane on both tonsils extending to uvula and soft palate; glands of neck moderately enlarged; slight nasal obstruction, K. L. B. Antitoxin No. 6, 6 c.c., 1 to 1,000, injected on admission.

June 5th, antitoxin, 9 c.c., injected.

June 12th, patient died.

CASE XXXV.—Aged seven months; admitted February 5th; illness began February 2d. General condition only fairly well nourished; no membrane on tonsils and very slight hyperæmia of tonsils and uvula; slightly croupy cough and cry; K. L. B. Prognosis favorable. Antitoxin, 17 c.c., 1 to 300, injected on admission.

February 6th, antitoxin, 10 c.c., injected.

February 20th, patient died.

CASE XXXVI.—Aged one year; admitted January 13th; three days sick. Throat much swollen; membrane on both tonsils and base of uvula; naso-pharyngeal discharge. Prognosis doubtful. Antitoxin, 1,000 units, on admission.

January 16th, temperature suddenly rose to 105° F.; remained high until January 19th, when child died at 12:30 P.M.

This child, one year old, admitted to hospital when three days sick, died after six days' treatment without a complication.

CASE XXXVII.—Aged three years six months; admitted December 13th; one day sick. Small patch of membrane on left tonsil, croup. Antitoxin, 3,000 units, on admission. Admitted at 3 A.M. and antitoxin given immediately; intubated at 3:15 A.M. Antitoxin, 3,000 units, at 6 P.M.

December 16th, tube removed at 4:30 P.M.; intubated at 5:20 P.M.

December 29th, tube removed at 11:47 A.M.; reintubated at 12:10 P.M.

January 4th, tube removed at 1:30 P.M.; had to be reintubated immediately.

January 8th, tube removed at 9:23 A.M.; reintubated immediately.

January 14th, tube removed at 10:10 A.M.; reintubated immediately.

January 17th, tube removed and immediately replaced.

January 24th, tube removed at 10:10 A.M.; replaced immediately.

January 25th, tube coughed up at 3:30 A.M.; reintubated at 3:35 A.M.

January 28th, tube coughed up at 11:15 A.M.; reintubated immediately.

January 28th, tube coughed up at 12:10 P.M.; reintubated immediately.

February 5th, temperature, 104.2° F.; rash over whole body; patient restless.

February 6th, temperature, 102.8° F.; free perspiration.

February 7th, had a restless night. Antitoxin was given, two doses of 3,000 units each.

December 17th, patient was transferred to North Brothers Island, and subsequently died.

CASE XXXVIII.—Aged five years; admitted November 14th; illness began November 13th. Croup. Prognosis unfavorable. Antitoxin, 3,000 units, on admission, poultices to neck, calomel, fumigation, etc.

Admitted at 12:35 P.M.; croup, in spite of treatment, increased. Patient was intubated at 3:30 P.M.

November 15th, antitoxin, 3,000 units; tube removed at 2 A.M.

November 15th, died at 7 P.M. Cause of death, heart failure.

CASE XXXIX.—Aged sixteen months; admitted May 19th; illness began May 18th. Dirty white membrane on each tonsil, general hyperæmia, moderately croupy; K. L. B. Child well developed and nourished. Prognosis doubtful. Antitoxin, 7.5 c.c., 1 to 1,500, injected on admission.

May 20th, 7.5 c.c., 1 to 1,500, injected.

June 12th, child died.

CASE XL.—Aged eleven months; admitted December 16th; two days sick. Dirty white membrane on both tonsils, thin white membrane on uvula, naso-pharyngeal discharge, croup. Prognosis unfavorable. Antitoxin, 2,000 units, on admission.

December 17th, intubated at 1:50 A.M.; 6 A.M. a note states on chart: "No urine since admission."

December 17th, antitoxin, 2,000 units; 5:25 P.M., tube removed; 6:35 P.M., intubated; poultices to kidneys constantly. Cream-tartar water, diuretin, etc.

December 18th, child died at 2:30 A.M.

CASE XLI.—Three years old; admitted June 30th; illness began June 28th. Nasal obstruction, thick dirty white membrane covering both tonsils, uvula, and soft palate, extending back toward pharynx; glandular enlargement. Prognosis good, no complication. Antitoxin, 13.5 c.c., 1 to 1,500, injected on admission.

July 2d, 13 c.c., 1 to 1,500, injected.

These histories are of cases brought under treatment in the early part of the disease—many of them on the first and second day. They had full doses of a supposed specific, and yet we do not find recorded in the clinical history one statement which would indicate that this specific modified in any particular a single manifestation of the disease, either in the laryngeal or non-laryngeal cases. Not one item in the clinical records can be found to indicate that any one of these patients was in any way benefited by the antitoxin. This is particularly noticeable in the laryngeal cases. Patients brought in without evidences of very marked croup and after receiving full doses of

antitoxin had to be intubated twelve and twenty-four hours after hypodermic use of this so-called specific. The clinical records of these cases are totally against the use of antitoxin in the treatment of diphtheria. A careful study of these records will, it seems to me, convince one who is familiar with diphtheria that there are clinical features here recorded which are due to the treatment and not to the disease. These features are referable to the kidneys, nervous centres, temperature, and respiratory organs.

Injurious Effects of Antitoxin.—At the beginning of this treatment Behring told us that an injection of his serum was as little injurious as an injection of a physiological solution of chloride of sodium. The records of serious complications and results which have followed the injection of antitoxin in many known cases warrant careful consideration. In certain individuals who show a special susceptibility to antitoxin, the gravest symptoms or death may result from a relatively small dose. The predominating symptoms of these cases are referable to the nervous centres, kidneys, heart, pulmonary organs, and the temperature of the body. One feature of these untoward manifestations following the use of serum, especially when the respiratory organs are involved, is the lateness of their appearance.

The cases of Professor Langerhans' sixteen-months-old son, and Miss Valentine, of Brooklyn, are too well known to need more than mere mention here. In neither of these was any cause for death found by post-mortem examination. In the case of Miss Valentine, the coroner's physician, Dr. John M. Clayland,⁷ reported "Cause of death, convulsion, due to the injection of diphtheria antitoxin."

In the *Journal of the American Medical Association* is reported an instance which occurred in the practice of Dr. Halderman, of Portsmouth, O., in which a sleeping boy, five years old, was given a preventive dose of Behring's serum. Up to the time of the injection he was in perfect health; five minutes afterward he was dead. The account in the *Journal* states that the doctor had withdrawn to another room to refill his syringe for use on another child, when the mother noticed the boy's lips puff up, and called to him that something was wrong with "Willie." By the time the doctor had reached him, the child was dead.

Dr. C. C. Gratiot, of Shullsburg, Wis., advised a woman in apparently good health to take a preventive dose of antitoxin, as she was nursing her husband and daughter who were ill with diphtheria. Six hundred units of Behring's serum were administered. In a few minutes the woman complained of feeling faint; her pulse was almost imperceptible, she became very pale, her feet and hands were cold, breathing rapid and shallow, pupils dilated, and face covered with cold perspiration. It was six hours before she rallied.

Johannessen⁸ states that on December 9th eight patients of a hospital ward were immunized with six hundred units each of Behring's serum; seven of these children had no reaction, but the eighth, a boy of two years, with spastic spinal paralysis, had diarrhoea on the four following days. On the fourteenth day there were traces of albumin and indican, with a temperature of 103° F. The boy died on the tenth day after injection from collapse.

Alfoldi¹⁰ relates a case of a girl, three years old, who received a preventive injection of two cubic centimetres of Behring's serum, January 16th. January 18th her temperature rose to over 104° F. On the 19th there were severe albuminuria and hæmaturia, petechiæ appeared over the whole body, and on the twentieth day the child died. Alfoldi attributes death to antidiphtheritic serum.

Drs. Moizard and Bouchard¹¹ report the case of a girl of six years, who had a slight angina. Without

waiting for the result of the bacteriological examination they injected ten cubic centimetres of Roux's serum. Bacteriological examination proved that the trouble was not diphtheria. On the sixth day after the injection the child's temperature suddenly rose to 105° F. and over, there being at the same time perspiration and insomnia. During the next four days scarlatinoid eruption appeared, which extended over the whole body. On May 12th, after a very restless night, when the throat had been well for a long time, the patient was seized with general convulsions and died four hours later. Dr. Moizard states that "death in this case appears to me certainly to have been due to the preventive injection of serum, administered before the result of the bacteriological examination was known. The dose of serum was decidedly small, and as the source from which it was obtained is above suspicion death can only be attributed to the action of the serum toxins on the cerebral nervous system. The conclusion to be put upon this occurrence is that preventive injections of serum are inadmissible, and that no intervention should be permitted before the result of the bacteriological examination is known."

Dr. Le Gendre stated: "I fully agree with Dr. Moizard, and I have long ago expressed my views as to the inadvisability of resorting to preventive injections of serum."

Guinon and Roufilange¹² have reported a case which ended fatally in a child three years old, with mild diphtheritic angina. Fifteen cubic centimetres of Roux's serum were injected on the third day of the disease. The following day eruption appeared on the body and lower extremities, and mild albuminuria; the second injection, of five cubic centimetres, was followed by diminution in amount of urine and increase of albumin; the tongue and lips swelled. On the next day, after the third injection of serum, there were anuria, swelling of the eyelids, and fetid diarrhoea; three days after the third injection a fourth was given, which resulted in renewed suppression of urine. During the following day and night there were coma and convulsions, and death ensued.

Dr. Thibierge's¹³ four-year-old daughter had a benign diphtheritic angina; serum was injected and urticaria appeared on the third day, and again on the sixth and eighth days, with vomiting, articular pains, and scanty urine. On the fourteenth day there was severe vomiting, and on the eighteenth day suppression of urine, critical relapse, fetid diarrhoea, and pseudo-meningitic disturbances due to serum. The child finally recovered.

Professor Mya¹⁴ (Florence) states that serum injections frequently have no effect on simple follicular tonsillitis associated with a marked degree of hypertrophy of the glands. "I have had under observation five of these patients, in whom the renal functions were absolutely normal before treatment, who on the sixth day of the disease suddenly presented manifest symptoms of intoxication, such as anuria, etc. At the autopsy I found fatty degeneration of the viscera, incident with grave pathological changes in the lymphatic tissue."

Galler¹⁵ has reported similar cases in which on the ninth day miliary eruption appeared; two days later multiple petechiæ appeared, with œdema of hands and face and subconjunctival hemorrhages; two days later there were drowsiness, intense pain in the left leg with paralysis, petechiæ on the body, pains in the muscles of mastication and of the abdomen, effusion in the left knee-joint, with intermittent pulse. The child could not move on account of intense pain.

A similar case has been reported by Springorum¹⁶ in a girl of four years, which ended fatally.

Variot¹⁷ reports the case of a child of eighteen months who was suffering from slight pharyngeal diphtheria,

followed by croup; the child was treated by injection, two doses of twenty cubic centimetres of antitoxin, and died forty-eight hours later in a state of hyperpyrexia. Variot says "this death could not be accounted for by any of the lesions found at the autopsy. There was not a trace of membrane in the throat, which appeared to be perfectly healthy. The same was true of the pharynx. The cause of death is consequently a mystery. Whether in the absence of organic lesions we are to attribute it to serum-hyperthermia is a question which it would be difficult to answer unhesitatingly in the affirmative, seeing that we have no means at our disposal for uniformly detecting toxic substances possibly existing in the serum. This goes to prove the necessity of exercising great care in the use of this treatment in diphtheria, and strengthens me in my opinion that it should not be employed for preventive purposes."

Variot¹⁸ further states: "The serum prepared by Aronson has always produced fever, and as it caused, in a great city of Europe [probably Berlin] nine deaths, one after the other, its use had to be discontinued."

Engel Bey,¹⁹ in a report of his clinical observations in Cairo, uses the following words:

"There was a frequent impression that the already present weakness is greatly increased by the injection, and that the children fall into a state of prostration, of which they will never recover."

Lennox Browne²⁰ states that of five patients who were treated with antitoxin, two died thirty-five and forty-five hours respectively after injection, with complete suppression of urine.

Soltmann²¹ states that in nearly all cases the pulse remained frequent, small, and irregular. In four cases collapse followed immediately after the injection of serum and proved fatal.

Körte²² states that of forty patients who died early in the disease and were treated with serum from the start, no less than nineteen died from paralysis of the heart.

Trimmer²³ reports cases of collapse after injection in five cases, but all eventually recovered.

Hagenbach²⁴ reports a case of a little girl who, three days after injection of ten cubic centimetres of serum had petechia: in the skin, which began first at the neck and were distributed over the whole body; on the seventh day there was profuse vomiting, which could not be controlled. Death by collapse followed three days later. "During life we thought the petechia: had a relation to the serum injection, and the autopsy, showing hemorrhages into the mucous membranes of the intestines, and the changes in the heart and kidneys, did not change our views."

The resident physician in the diphtheria ward of the Children's Hospital at Strassburg said to me during my visit there last year: "I have seen three children who, I think, were killed by the serum."

Korach²⁵ has reported a fatal termination in the case of a three-year-old who died on the fourth day from an immunizing injection of two cubic centimetres of Behring's serum No. 1.

Hutinel²⁶ states that the rise of temperature which occurs after the injection of antitoxin is often a great danger, especially for tuberculous children. Among the deaths of children treated with serum are a great many showing tuberculosis of the lungs and pulmonary glands, and it is probable that the tuberculous process, which had been latent, became an acute process by the fever-producing injection.

Sevestre²⁷ reports a case of a little girl of five, who, two weeks after an injection of twenty cubic centimetres of serum, presented symptoms of extreme gravity—vomiting, fever, enormous swelling of the glands, marked pain in the vertebral articulations, wrists,

knees, and ankles, offensive diarrhoea, anuria, severe cardiac disturbances, alternating attacks of delirium, and collapse.

Two of the internes of the Children's Hospital at Frankfurt,²⁸ Drs. Gallus and Körte, were injected with Behring's serum the 24th and 25th of October respectively. They were ill with what appeared to be catarrhal angina (one had the Loeffler bacillus). Both were seriously ill afterward with high temperature, repeated attacks of urticaria, swollen glands, pains in joints, sleeplessness, headache, great prostration, sweating, and rapid loss of flesh (five and seven pounds each). These symptoms came on after the disappearance of local evidence of the disease and continued for about three weeks, when both young men were sent to their homes to convalesce and regain their strength.

A child aged four years²⁹ was desperately ill after an injection of thirty cubic centimetres of Roux's serum for an angina with a small white patch on either tonsil. The first injection of serum was given October 24th; October 28th the submaxillary glands commenced to enlarge, the false membrane on the right tonsil increased, and there was albuminuria. October 30th these glands continued to enlarge and the post-occipital glands began to increase. There was intense albuminuria. October 5th red spots appeared on buttocks and abdomen. November 6th the urine was scanty and still albuminous. October 7th the child was in a state of collapse the whole day with complete anuria. The child ultimately recovered.

A child of five years was admitted to Crown Prince Rudolph Hospital,³⁰ Vienna, November 15, 1894, having been ill two days with uncomplicated diphtheria. Four injections of Behring's serum were given. November 23d the child died of paralysis of the heart.

Professor Gnandinger, Crown Prince Rudolph Hospital, told me personally that he had seen more cases of paralysis of the heart in diphtheria since the use of serum treatment than he had seen during the entire eight years of his connection with the Crown Prince Rudolph Hospital.

Dr. Hutinel³¹ states: "There can be no doubt of the gravity of post-sero-therapeutic ill-effects, for I have met with two cases of death from this cause in children. The injection of Roux's serum was followed in both cases by albuminuria, anuria, etc."

Dr. C. F. Withington³² says: "In private practice I had a case in which I had a great deal of anxiety, not to say alarm from the use of antitoxin. It was a case of a lady with diphtheria involving one tonsil. She received fifteen hundred units of Behring's serum. Two days later the other tonsil began to be involved, with rapidly increasing membrane, and she again received fifteen hundred units. Four or five days after this she was in a condition of a great deal of gravity for about a week. There was first erythema, then intense urticaria; then purpura of a great deal of severity involving both legs and severe pains accompanying the course of the nerves. Her condition was one of high fever, delirium, and great prostration. She is now convalescing. The gravity of the symptoms referable to antitoxin in this case will cause me in the future to be a little conservative in its use."

One of the best practitioners on Staten Island, Dr. Scales, stated to me that he had never in all his experience been so alarmed as he was after an injection of antitoxin in a woman suffering from diphtheria. For six hours after the injection prostration was so extreme that he felt she was likely to die at any moment.

Vierordt³³ reports that "in one case of a girl of two and a half years we thought of the possibility of a bad effect from the serum. The child came in with moderately severe diphtheria of the throat. She received forty-two hundred immunizing units of Behring's serum. There was collapse and stupor. The

stupor remained till death, which resulted from heart failure. The autopsy revealed several points of hemorrhage of the mucous membrane of the intestines and the pericardium, and nephritis." Vierordt concluded that the case was not one showing harmful results of the serum, because it could be explained in different ways; but the case is an exact counterpart of numerous cases reported by other observers, in which the only explanation of the symptoms was the ill-effects produced by the serum.

Dr. Martin J. Fleming, of this city, has reported to me a case of a child, who after an injection of serum had repeated eruptions; finally eczema appeared, which persisted for two months. There was nothing in the family history or in the child's general condition to account for the eczema, the only cause being the use of antitoxin.

At the April (1895) meeting of this academy I stated that the pneumonia of the antitoxin cases of diphtheria differed from the pneumonia we were in the habit of seeing in diphtheria; that it was a totally different disease from that seen before in the course of diphtheria; that it occurred as a sequela and not as a complication.

Dr. J. W. Brannan³¹ in a report before the Society of Alumni of Bellevue Hospital, has shown that pneumonia was the cause of death in 53.22 per cent. of the fatal cases of diphtheria in the Willard Parker Hospital; whereas, before the antitoxin treatment, pneumonia was a cause of death in only 16.90 per cent. in this hospital. His report further shows that the average duration of stay in the hospital in fatal cases of pneumonia before antitoxin treatment was two days; but since the introduction of antitoxin, the average time of stay in the hospital in fatal cases of pneumonia was 13.7 days, bearing out the statement made by me in April, 1895, that the pneumonia of the antitoxin-treated cases occurred as a sequela and not as a complication of the disease. All conditions in the hospital were precisely the same in 1895 as in 1894, with the exception of the addition of the antitoxin treatment. The enormous increase of pneumonia as the cause of death in the Willard Parker Hospital during the antitoxin treatment has no other explanation than the hypodermic injection of serum albumin. These pneumonias are, as I stated in April last, septic pneumonias; clinically they have the stamp of a septic process.

In New York and elsewhere it has been claimed in defense of the serum that the unfortunate ill effects in the form of high fever and suppurations are due to streptococcus infection; but if this were really the case they should supervene while the morbid affection is in process of evolution in the throat, whereas they usually supervene after the disappearance of all throat lesions. It is now stated that the bad effects which formerly resulted from the use of antitoxin were due to the amount of serum injected, and that with the use of a more concentrated serum there will be less pneumonia and bad after-effects than formerly. This is a very weak admission. It is an admission that there are bad effects from the serum. Last year it was asserted most positively by the advocates of this treatment that there were no bad effects; that it was absolutely harmless in doses of any amount.

Antitoxin in Private Practice.—The experience of physicians in private practice is of much service in estimating the value of antitoxin.

Dr. Edwin B. Tefft (New Rochelle), a most careful and experienced practitioner, communicated the following cases to me:

CASE I.—Child, aged five years; antitoxin on first and second days; died suddenly on the third day from heart failure. Peroxide of hydrogen and salt solution locally to throat and nose. Other treatment consisted

of bichloride of mercury, iron, and stimulants internally.

CASE II.—Aged forty; treated without antitoxin; good recovery.

CASE III.—Aged twenty-seven; treated without antitoxin; good recovery.

CASE IV.—Child, aged fourteen; treated without antitoxin; recovered with slight paralysis as a sequel, which soon passed off.

CASE V.—Child, aged six, sister of Case IV.; antitoxin on second, third, and fourth days; died on fifth day.

CASE VI.—Child, aged four years, brother of Cases IV. and V.; antitoxin on first and second days; recovered.

CASE VII.—Child, aged ten years; antitoxin on second day; recovered. Other treatment in both of these cases the same as in Case I.

CASE VIII.—Child, aged twelve; antitoxin on second, third, and fourth days; died on seventh day. Other treatment same as in Case I.

CASE IX.—Child, aged twelve; treated without antitoxin; good recovery.

CASE X.—Boy, aged sixteen, brother of Case IX.; also treated without antitoxin; good recovery.

"These were all bad cases. In Case VII. I am confident recovery would have followed without the use of antitoxin. From my experience and from cases I have seen in connection with other physicians, I am not favorably impressed with the utility of antitoxin in the treatment of diphtheria."

Dr. Tefft reports five cases treated with antitoxin on the first and second day of disease, the youngest being a child of five, the oldest twelve. Three of the five died; mortality, sixty per cent. During the same period there were five cases, stated by Dr. Tefft to be equally severe, treated without antitoxin; all recovered. Cases treated with antitoxin had the same internal and local treatment as those treated without antitoxin. These antitoxin cases had a so-called specific at the very beginning of the disease, and in addition such tonic, stimulating, and local antiseptic treatment as one of our best physicians could devise—and yet show a mortality of sixty per cent., as contrasted with no deaths in five other cases treated without antitoxin.

Dr. de Kraft recently had three cases of diphtheria in one family. Two patients were treated with antitoxin at the beginning of the disease and both died. One treated without antitoxin got well. Another patient in Dr. de Kraft's practice died one hour after the injection of antitoxin.

During the spring of 1895 Dr. de Kraft saw a very severe case of diphtheria in the lower portion of the city, with another physician, in which it was decided to give antitoxin. Neither, however, having antitoxin, and not knowing just where it could be procured at the time, a physician who was known to have the serum was sent for. When he saw the child he refused to inject, saying that it would surely die and that it would do harm to the cause of serum treatment. He was willing that the child should not have a possible chance of benefit which might arise from the use of the so-called specific fluid, but he was not willing that the fame of the serum treatment should be jeopardized. The baby, however, recovered, on the ordinary medicinal treatment without antitoxin.

Dr. J. C. Shanon recently treated two patients in one family with antitoxin at the very outset of the disease and both died.

Dr. Koempel reports the case of a child taken ill on the night of April 22d. Antitoxin was given during the first twelve hours, and a second dose the following day. The child died twenty-four hours later.

Dr. J. H. Bache reports three patients treated at the beginning of the disease, two of whom died; the

third patient, the child of a physician, barely escaped death from the after-effects of the antitoxin.

Dr. P. H. Ernst³⁵ reports twelve cases treated with antitoxin, seven deaths, mortality 58.3 per cent: sixty-five cases treated without antitoxin, eleven deaths, mortality 16.9 per cent.

In all these the clinical diagnosis was confirmed by bacteriological report of the health department.

Dr. John Dorning, who is known as a careful and skilful practitioner, employed antitoxin in his private practice in seven consecutive cases of diphtheria, treated in the early part of the disease—in some of the cases during the first twelve and eighteen hours—and all the patients died. He was compelled to give up the use of antitoxin more than a year ago because of the results in private practice.

Every member of this academy has the highest regard for the opinion of Dr. Francis Huber on anything pertaining to clinical medicine or therapeutics. Two weeks ago I asked him what he thought of antitoxin, knowing that he had a large experience with diphtheria. His answer was, "Dr. Winters, it is a humbug." That is the impression of a man who used it in private practice in conjunction with his brother, each anxious to get the best possible results and do the most he possibly could in every case. These are the results obtained by "Heilserum," a so-called specific against the toxin of the diphtheria bacillus, when used in private practice at the very beginning of the disease.

The percentage mortality in the Willard Parker Hospital during the year 1895 is very misleading, owing to the mild character of many of the cases received.

Dr. J. W. Brannan³⁶ has reported five hundred and ninety-three cases admitted to the Willard Parker Hospital during the first nine months of 1895 and treated with antitoxin; mortality 26.1 per cent. During the first nine months of 1894 there were four hundred and sixty-nine cases in the hospital, or one hundred and twenty-four less than in 1895. Every practitioner knows there was much less real or clinical diphtheria in New York City in 1895 than in 1894, and yet we have as the result of bacteriological diagnosis one hundred and twenty-four more cases received into the hospital during the first nine months of 1895 than there were during the corresponding months in 1894. The mortality in four hundred and sixty-nine cases in 1894 (non-antitoxin) is reported as being 35.1 per cent., but the report of the resident physician of the hospital to the health board gives the mortality for the first quarter of 1894 as 24.5 per cent.; second quarter, 26.5 per cent.; third quarter, 19.9 per cent.; fourth quarter, 26.8 per cent.: for the year, 29.3 per cent. The mortality of 35.1 per cent. in the report referred to was obtained by including all patients who developed or contracted scarlet fever or measles and were transferred to North Brother Island, and there died of mixed infection. The mortality of the Willard Parker Hospital is recorded as follows:³⁷

WILLARD PARKER HOSPITAL.

Year.	Cases.	Deaths.	Per cent.
1888	258	60	23.25
1889	383	79	20.62
1890	292	67	22.94
1891	289	85	29.41
1892	295	79	26.77
1893	343	108	31.48
1894	699	205	29.32
1895 (antitoxin)	775	199	24.42

Could those cases be eliminated which gave no clinical evidence of diphtheria, the mortality of twenty-four per cent. for 1895 would be greatly increased.

The report of Dr. James Ewing³⁸ gives fifty-three

cases of diphtheria in which his investigations were carried on. Fifty of these patients were injected with antitoxin, nineteen died, mortality thirty-eight per cent.

Dr. Ewing's investigation in the Willard Parker Hospital was in cases in which there was clinical evidence of diphtheria, and my impression is that this report (thirty-eight per cent. mortality) would fairly well represent the actual mortality of the Willard Parker Hospital at the present time, under serum-therapy, if patients who have clinical evidence of diphtheria were subjected to this treatment, to the exclusion and elimination of those cases which have no clinical data to warrant the diagnosis of diphtheria.

In order to determine the results with reference to larger or smaller doses of serum it was decided in the autumn of 1895 to give to alternate cases as admitted into the hospital, doses of serum of one thousand, two thousand, and three thousand units respectively. There were two series of cases, known as mild and severe, having one thousand and two thousand units respectively, and another series of cases of mild and severe having two thousand and three thousand units respectively.

RECORD OF DOSE IN PARALLEL CASES.

—Lesser Amount.—		—Greater Amount.—	
1,000 Mild.	2,000 Severe.	2,000 Mild.	3,000 Severe.
Case 1	Case 1*	Case 1	Case 1
Case 2*	Case 2	Case 2	Case 2*
Case 3*	Case 3	Case 3	Case 3*
Case 4	Case 4	Case 4	Case 4
Case 5	Case 5	Case 5	Case 5*
Case 6	Case 6	Case 6	Case 6
Case 7*	Case 7	Case 7	Case 7*
Case 8	Case 8	Case 8	Case 8*
Case 9	Case 9	Case 9	Case 9*
Case 10	Case 10	Case 10	Case 10*
Case 11	Case 11	Case 11	Case 11*
Case 12	Case 12*	Case 12	Case 12*
Case 13	Case 13	Case 13	Case 13
Case 14	Case 14*	Case 14	Case 14*
Case 15	Case 15*	Case 15	Case 15
Case 16*	Case 16*	Case 16	Case 16*
Case 17	Case 17	Case 17	Case 17
Case 18	Case 18	Case 18	Case 18*
Case 19	Case 19*	Case 19*	Case 19
Case 20	Case 20*	Case 20	Case 20
Case 21	Case 21	Case 21	Case 21
Case 22	Case 22	Case 22*	Case 22
Case 23	Case 23	Case 23	
Case 24		Case 24	
Case 25			
(25—4 died)	(23—7 died, 30.4 per cent.)	(24—2 died)	(22—11 died, 50 per cent.; one died after return home.)

94 cases, 24 deaths, mortality 25.5 per cent.

In the two series marked "severe" the cases were probably of nearly equal severity, inasmuch as they were alternate cases as received into the hospital. There were twenty-three severe cases which received two thousand units—seven deaths, mortality of 30.4 per cent., and twenty-two severe cases which received three thousand units—eleven deaths, mortality fifty per cent., the mortality being higher with the larger dose of serum in a series of parallel cases. It may be stated that since these experiments no child has received doses of three thousand units.

The mortality in children of two years old and under, with and without antitoxin, is most interesting and instructive:

1894.

163 cases of children two years old and under.
54 deaths. 51.5 per cent.

1895.—ANTITOXIN.

153 cases of children two years old and under.
95 deaths. 62.1 per cent.

Thus we see that at the very time of life when the disease is most dangerous we have in the Willard Parker

* Died.

Hospital a mortality of 10.6 per cent. greater with antitoxin treatment than without.

New York Foundling Asylum.—Prof. J. Lewis Smith²⁹ reports thirty-one diphtheria patients treated with serum in the New York Foundling Asylum, twelve on the first day of disease, seventeen on the second or third day, two on the fourth or fifth day; seventeen died; mortality, 54.8 per cent. All but two of the thirty-one cases were treated on or before the third day of the disease, and twelve on the first day, and yet the mortality was nearly fifty-five per cent. Certainly the antitoxin showed no specific influence in these cases.*

Results in Municipal Hospital in Philadelphia.

—During the year 1895 there were 706 cases of diphtheria treated in the Municipal Hospital, Philadelphia. Three hundred and two of these received serum treatment, 404 were treated without serum. In the serum-treated series, 16.88 per cent. were intubation cases. In the non-serum treated series, 17.57 per cent. were intubation cases. The patients in whom antitoxin was used were injected at an early stage of the disease, from the first to the fourth day. No patient was injected who had been ill more than four days at the time of admission to the hospital. Cases that were considered hopeless on admission did not receive serum treatment. All patients that were considered hopeless when brought to the hospital were placed with the non-serum-treated cases, and some of these died within an hour of their admission. This makes the serum-treated cases a far more favorable series than those that did not receive serum. There were more children under five years of age in the non-serum-treated cases, more intubation cases; all cases considered hopeless and late and neglected cases were in the non-serum-treated series. The mortality in the 302 cases treated with serum was 28.1 per cent.; in the 404 cases not treated with serum, 25.9 per cent. Had these 302 serum-treated cases of diphtheria received the same treatment that was given to the 404 cases that did not receive serum, they certainly should have shown a lower death-rate than the 404 cases treated without serum. They were by far a more favorable series, and should have shown under the same treatment better results. It should be stated that the cases treated with serum had the same local antiseptic treatment and the same internal medication and stimulation that were given to the series of non-serum-treated cases; and yet with a so-called specific added to the treatment there is a higher death rate.

Results in Blegdam Hospital (Copenhagen).

Professor Soerensen⁴⁰ reports 51 cases of severe diphtheria treated with serum, and 46 cases of severe diphtheria treated without serum, during the same period; mortality, 33 per cent. in both series. During this period the total number of cases treated in the hospital was 385, with mortality of 16 per cent., showing that the epidemic was a mild one; but for comparison these severe cases were selected for treatment with and without serum. There was no choice of cases unfavorable to the serum, but it depended upon the supply whether it was used or not. The average age of those treated without serum was lower than those treated with serum, four to five years against five to six years. The youngest (six months old) was in the group of those not treated with serum. Among those who died who were treated with serum two were admitted on the first day of the disease, two on the second, and five on the third day of the disease. Of those treated without serum none were admitted on the first day of disease, four on the second, and one on the third day. Therefore, those who received serum were admitted earlier

to the hospital than those who were not so treated. At the time of admission to the hospital complications were more pronounced in the cases treated without serum, the air passages being affected in eight cases, while with those treated with serum the air passages were affected only three times. Severe complications of the kidneys (after admission to hospital) were observed only in those treated with serum. Rise of temperature to a high point occurred in injected cases only. The serum was used earlier in the fatal cases than in the cases which recovered: that is, the day of the first injection was on an average earlier in the fatal than in the successful cases. [This is the most extraordinary part of the report: that the serum was used earlier in the fatal cases than in the cases which recovered.] "From our experiments we cannot see any favorable action of the serum. On the other hand, we observed more severe hemorrhage, albuminuria, nephritis, toxic anuria, fever, eruptions, and more frequent and more pronounced paralysis in those treated with serum.

"The serum was also used in croup cases complicated by severe diphtheria, and in mild cases of croup for the purpose of preventing stenosis. The mortality in all cases (operated and not operated) was 28 per cent. and for operated cases 40 per cent.; but during this same period there were 87 cases of croup that were not injected; the mortality in these, for all cases (operated and not operated) was 25 per cent. and for operated cases 38 per cent.—therefore lower than in those treated with serum. The serum was generally used in mild cases to prevent possible operative interference. The serum could not prevent laryngeal stenosis. Severe diphtheria complicated with croup did very badly with this treatment. All such patients died, and the good result in milder cases is explained by the good type of the present epidemic. The mildness of the epidemic reached a height formerly unknown."

Report of the Medical Superintendents of the Metropolitan Asylums Board (London), 1895.

—This report embraces 2,182 cases of diphtheria treated with antitoxin; 615 deaths; mortality, 28.1 per cent. The medical superintendents compare this result with that of 1894, when 3,042 cases of diphtheria were treated in all the hospitals of the board (without antitoxin), 902 deaths; mortality, 29.6 per cent.*

There are divergencies in the mortality in the individual hospitals during the antitoxin and non-antitoxin years which show that the 1.5 per cent. reduction in mortality in 1895 over 1894 is not due to a single or specific factor.

In the Southwestern Hospital in 1892 there were 463 cases of diphtheria; 93 deaths; mortality, 22.5 per cent. In 1895, 316 cases treated with antitoxin; 94 deaths; mortality, 29.2 per cent.

In the Southwestern Hospital in 1893, 585 cases; 159 deaths; mortality, 27.1 per cent. In 1895, mortality in antitoxin-treated cases, 29.7 per cent.

In the Southwestern Hospital in 1894, 546 cases; 156 deaths; mortality, 28.5 per cent.

S. W. HOSPITAL.				N. W. HOSPITAL.			
Cases.	Deaths.	Per cent.		Cases.	Deaths.	Per cent.

1893	585	159	27.1	1,249	332	26.5	
1894	546	156	28.5	1,147	309	26.9	
Total,	1,594	408	25.5	3,078	779	25.3	
Cases.	Deaths.	Per cent.		Cases.	Deaths.	Per cent.	
1895 (antitoxin)	316	94	29.7	363	117	32.2	

* In this antitoxin report it is stated: "In a certain number of patients, being moribund at the time of their arrival and beyond the reach of any treatment, no antitoxin was given." These cases are therefore all eliminated from the report. There were 1,347 patients in the hospitals during the year who did not receive antitoxin treatment; of these 181 died; mortality, 13.4 per cent.

* Mortality in N. Y. Foundling Asylum, 1894 (non-antitoxin year), 24 per cent.; mortality in 1895 (antitoxin year), 45.7 per cent.

IN S. W. AND N. W. HOSPITAL.			
	Cases.	Deaths.	Per cent.
1892, '93, '94.....	4,672	1,187	25.4
ALL THE HOSPITALS.			
	Cases.	Deaths.	Per cent.
1895 (antitoxin).....	2,182	615	28.1

An examination of the above table shows the following:

1. In the Southwestern Hospital a lower death rate obtained in each of the years 1892, 1893, and 1894 in unselected cases treated without antitoxin than existed in 1895 with selected cases treated with antitoxin.

2. In the Northwestern Hospital a lower death rate also obtained in each of the years 1892, 1893, and 1894, in unselected cases treated without antitoxin than existed in 1895 with selected cases treated with antitoxin.

3. The table also shows that in each of the three years 1892, 1893, and 1894 the mortality rate in the Northwestern Hospital was a little lower than it was in the Southwestern Hospital for the corresponding year.

4. The mortality rate for 1895 in the Northwestern Hospital was 2.5 per cent. higher than it was in the Southwestern Hospital.

Such a reversal in mortality rate shows plainly the pernicious effect of selection on statistics.

5. If, with selected cases, the mortality rate under antitoxin is not lowered, it is difficult to say what the rate might have been had all the cases received uniform treatment.

At the Northwestern Hospital in 1892, 682 cases, 138 deaths, mortality 21.8 per cent. In this hospital there were 363 antitoxin-treated cases in 1895, 117 deaths; mortality, 32.2 per cent.

At the Northwestern Hospital in 1893, 1,249 cases, 332 deaths; mortality, 26.5 per cent. Mortality in 1895 in antitoxin cases, 32.2 per cent.

At the Northwestern Hospital in 1894, 1,147 cases, 309 deaths; mortality, 26.9 per cent. Mortality in 1895 in antitoxin cases, 32.2 per cent.

Diphtheria cases were not admitted to the Metropolitan Asylums Board Hospitals until October 23d, and it should be noted that during the seven years that diphtheria patients have been received into these hospitals the mortality has steadily and uniformly declined from 59.3 in 1888, 47.7 per cent. in 1889, 33.5 per cent. in 1890, 30.6 per cent. in 1891, 29 per cent. in 1892, 30.4 per cent. in 1893, 29.2 per cent. in 1894. The one exception was in 1893, the explanation for this being an insufficient number of beds to accommodate the diphtheria patients: hence it is stated in the report for 1894, page 203: "The attention of the managers is specially directed to the fact with regard to diphtheria, a most unsatisfactory deficiency of beds has existed during a considerable portion of the year (1893), and that for many weeks the ambulance department was very frequently compelled to defer the removal of diphtheria cases." In the autumn of 1894 a new hospital (Pountain) for fever patients was opened with about five hundred beds. Hence, we find in the *London Lancet* the statement that 3,529 cases of diphtheria were treated in 1895 in the hospitals of the board as against 3,042 cases in 1894. The natural reduction of mortality which has taken place in these hospitals from year to year since 1888, owing to the board hospitals receiving a larger percentage of the notified cases in London and dealing with a better class of the population, was not even realized from 1894 to 1895. Indeed, it seems probable, when one studies carefully the reports of the Metropolitan Asylums Board from 1887 to 1894 and compares them with the mortality in the Managers' hospitals in 1895, that the mortality was higher with antitoxin than it it would have been without.

The age of the patients brought under treatment is

an important factor for consideration in determining the value of any method of treatment for diphtheria, the mortality being progressively less with the increasing age of the patient. We find that there were 244 children under two years of age in all the hospitals of the Metropolitan Asylums Board in 1894 (without antitoxin), whereas there were only 219 under two years of age in 1895 (with antitoxin). There were 1,171 children under five years of age treated in the board hospitals in 1894: 1,013 in 1895. There were 2,246 under ten years of age in 1894, and only 1,829 under ten years in 1895. The children under ten years treated in 1894 exceeded the total number of cases treated in all the hospitals with antitoxin in 1895. Had the ages been equal in the total number of cases treated during these two years, the mortality would in all probability have been higher with antitoxin in 1895 than it was in 1894 without antitoxin, seeing that the difference was only 1.5 per cent. even with the enormous age factor in favor of antitoxin-treated cases. The excess of children under two, under five, and under ten years in 1894 (non-antitoxin year) greatly vitiates the value of the report of the antitoxin treatment.

We find in the report of the medical superintendents on antitoxic serum a lack of uniformity in the results which is opposed to the theory of there being any single or specific factor at work in the inferred reduction of mortality under antitoxin treatment. For instance, at the Northwestern Hospital the mortality in those treated on the second day was 28.9 per cent. and at the Southwestern Hospital 3.8 per cent. There was but one hospital where the mortality was as high among the patients who came under treatment on the second day of the disease in 1894 (non-antitoxin) as it was in the antitoxin cases treated on the second day of the disease at the Northwestern Hospital. The mortality among those brought under treatment on the second day of the disease in all the hospitals of the board during the year 1894 (non-antitoxin) was only 27 per cent.; whereas at the Northwestern Hospital the death rate in 69 cases brought under treatment with antitoxin on the second day of the disease was 28.9 per cent. Had these 69 children received a specific, it certainly must have given a lower death rate than occurred in 539 cases during the year 1894 under ordinary methods of treatment.

Laryngeal Cases.—The most interesting portion of the report of the medical superintendents refers to tracheotomy cases. The mortality in these cases shows the same variation that is seen in the cases as a whole. At the Western Hospital the mortality in tracheotomy cases treated with antitoxin was 40.5 per cent.; at the Northwestern Hospital, 64.2 per cent.

There were 225 tracheotomy cases in all the hospitals treated with antitoxin; 113 deaths; mortality, 50.2 per cent. During the year there were 30 tracheotomy cases in all the hospitals that did not receive antitoxin; 12 deaths; mortality, 40 per cent. The mortality in all the hospitals in the tracheotomy cases treated with antitoxin in 1895 was 50.2 per cent. The mortality in all the hospitals in the tracheotomy cases not treated with antitoxin during the year 1895 was 40 per cent. Where is the specific influence of the antitoxin here? It cannot be said that the tracheotomy cases which were not treated with antitoxin were mild cases. The tracheotomy cases treated with and without antitoxin during the year 1895 were cases of the same degree and offer a very good field for comparison of results. The mortality in tracheotomy cases treated with antitoxin in 1895 was 10.2 per cent. higher than it was with those not treated with antitoxin. This is just the result to be expected when a depressant like antitoxin is added to the treatment of cases of diphtheria so serious as to require tracheotomy.

At the Northwestern Hospital in 1895 28 tracheotomy cases were treated with antitoxin; 18 deaths; mortality, 64.2 per cent. In 1892¹² there were 58 tracheotomy cases in this hospital; 33 deaths; mortality, 56.8 per cent. In 1893¹³ 78 tracheotomy cases, 44 deaths; mortality, 56.4 per cent. (One patient cured was a child thirteen months old.) In 1894 79 tracheotomy cases; 47 deaths; mortality, 59.4 per cent. There were in the Northwestern Fever Hospital during 1892-93-94, 215 tracheotomy cases; 124 deaths; mortality, 57.6 per cent. The mortality in this hospital in tracheotomy cases treated with antitoxin in 1895 was 64.2 per cent. During the year 1895 four tracheotomy cases in the Northwestern Hospital were treated without antitoxin and all recovered; as compared with mortality of 64.2 per cent. in the tracheotomy cases treated with antitoxin. Nothing could be more conclusive of the depressing and dangerous effect of antitoxin in that severe form of diphtheria of the larynx and trachea which necessitates tracheotomy than the records of the Northwestern Fever Hospital for the years 1892-93-94-95.

Antitoxin in Laryngeal Diphtheria.—About the only claim made for antitoxin at the present time by its advocates is that it has a favorable influence in laryngeal diphtheria, that it relieves stenosis, that it obviates the necessity for operative interference, that the mortality is lower in non-operated and operated cases treated with serum, and that the tube can be removed earlier when operation becomes necessary. If antitoxin does not cause a "melting away" of the membrane, as was first claimed, and does not lessen the duration of the membrane in the visible portions of the throat, what reason have we for supposing that it influences the duration of the membrane in the larynx?

Roux does not believe that serum is of any use in pseudo-membranous bronchitis. If it is not of use in pseudo-membranous bronchitis, how can it be of use against pseudo-membranous laryngitis?

Soltmann¹¹ (Leipzig) states that in 89 cases of diphtheria treated with serum the diphtheritic process extended downward in 13 cases, even to the involvement of the smallest bronchi.

The mortality in the Willard Parker Hospital for the first nine months of 1895 in intubation cases treated with antitoxin was 68 per cent., and for the last quarter 76.9 per cent. During the first quarter of 1896 there were 31 intubation cases; 21 deaths; mortality, 67.7 per cent. In April there were 11 intubation cases; 8 deaths; mortality, 72.7 per cent.* In May there were 16 intubation cases; 11 patients have died; mortality, 68.75 per cent. One patient was discharged; 4 are in hospital. One of these was tracheotomized June 12th, intubation not having been successful; two more of those in hospital are still very ill, and only one of the four now in hospital has clear prospects of recovering (June 15th).

In the Municipal Hospital, Philadelphia, 71 intubation cases were treated without serum in 1895; 40 deaths; mortality, 56.3 per cent.

Dr. P. H. Ernst¹⁵ has reported nine cases of intubation treated without serum; two deaths; mortality, 22.2 per cent.

Dr. W. W. Seymour¹⁶ recently stated before the Academy of Medicine that in his last ten intubation cases he had eight recoveries. In three of these cases antitoxin was used and one of these proved fatal. In seven cases antitoxin was not used, and of these only one was fatal. His mortality in intubation cases

treated with antitoxin was 33.3 per cent., and in intubation cases not treated with antitoxin 14.2 per cent.

Widerhoefer¹⁷ gives a mortality of 43 per cent. for intubated cases (before serum treatment).

Von Ranke¹⁸ gives in 326 intubation cases a mortality of 57.4 per cent. (before serum treatment).

Meisenbach¹⁹ reports a mortality in tracheotomy cases of 57 per cent. (before serum treatment) in the Philadelphia Children's Hospital.

In Strassburg²⁰ in 397 tracheotomies (1891-94) the mortality was 44.3 per cent.

In Geneva²¹ from 1872 to 1888 the mortality in tracheotomy cases was 49 per cent.

In Basel²² in 333 tracheotomy cases there were 197 deaths; mortality, 59.2 per cent.

In the University College Hospital²³ (London) the mortality in tracheotomy cases in 1894 (non-antitoxin year) was 47 per cent.

Sonnenburg²⁴ states that in 13 tracheotomy cases treated with serum the mortality was 37.8 per cent., but during a period when serum could not be obtained the mortality in 35 tracheotomy cases was 37.1 per cent.—slightly better without serum. This statement by Sonnenburg shows the very great importance of taking into consideration the character of the epidemic in estimating the value of a mode of treatment.

Kohts²⁵ (Strassburg) reports a mortality of 29.1 per cent. in tracheotomy cases treated with serum, and a mortality of 25 per cent. in tracheotomy cases treated without serum.

Is not the very high mortality in intubation cases treated with serum in the Willard Parker Hospital when compared with the results in intubation cases without serum in the Municipal Hospital, Philadelphia, and in intubation cases reported by Widerhoefer and Von Ranke before serum treatment, and in tracheotomy cases in Philadelphia and in all parts of the world before serum treatment, a most positive warning against the use of this treatment in this serious and dangerous form of diphtheria? The divergencies in the results in laryngeal cases treated with serum is opposed to the theory of there being a specific agent at work. For instance, in Soltmann's¹⁶ intubation cases treated with serum the mortality in June was 16.7 per cent.; in May it was 88.9 per cent.; in February 22.2 per cent.; in March 28.6 per cent.; in April 42.9 per cent. If serum had any influence on the low mortality in June of 16.7 per cent., it should be shown as well in the month of May; whereas, during that month we find a mortality of 88.9 per cent. The low mortality of June is due to the character of the cases (see Dr. Ernst's results without serum) and not to the serum treatment. If the antitoxin could bring about this low mortality in one month it certainly could in another.

In Soltmann's report we find the same variations in mortality in diphtheria of throat and nose. The mortality in these cases treated by serum was in February, 5 per cent.; March, 60 per cent.; April, 7 per cent.; May, 21.4 per cent.; June, 14.3 per cent.; July, 25 per cent. If the mortality of 5 per cent. in February were due to the action of a specific agent, we should find the same mortality in all uncomplicated cases of diphtheria of throat and nose throughout the entire period reported by Soltmann; whereas we find a variation ranging from 5 per cent. to 60 per cent., which variation is due to the character of the cases. I mean the low mortality of 5 per cent. was due to the character of the cases treated, and not to the treatment applied. It must be necessary to a method of treatment for it to be accepted as a specific, that its results be uniform in all parts of the world when applied to severe as well as to mild epidemics. Any considerable lack of uniformity of results in a method of treatment shows

* It has been stated (New York Med. Jour., February 15, 1896) that the mortality for operative cases in 1894 was 85 per cent.; but it is impossible to give the exact mortality of the operative cases in the year 1894, because many of the histories of the institution are missing and are not available.

that the treatment fails to exert any influence when applied to severe cases, and we may suppose that the good results are due to the character of the epidemic and not to the treatment.

A very striking feature of the serum treatment is a lack of uniformity of results, according to the day of disease on which treatment by serum is begun. Heubner⁷⁷ reports that in cases in which treatment was begun on the second day the mortality was 6 per cent.; Soltmann, 4 per cent.; The Southwestern Hospital⁵⁸ (London) in 52 cases, 3.8 per cent.; Seigert,⁵⁹ 20 per cent.; the Willard Parker Hospital⁶⁰ in 130 cases, 25.1 per cent.; the Northwestern Hospital (London) in 69 cases, 28.9 per cent. In cases in which treatment was begun on the third day, Heubner's mortality was 4.5 per cent.; Willard Parker Hospital in 116 cases, 34.1 per cent.; Southwestern Hospital (London) in 45 cases, 33.3 per cent. From these varied results we are led to believe that the day of disease in which the patient is brought under treatment has much less to do with the results than the character of the epidemic. The individuality of the patient, individual susceptibility and resistance to the action of the toxin, has far more to do with the results than the day of disease on which the patient is brought under treatment.

Why Antitoxin is Popular.—Why is it that antitoxin has to-day the hold on the profession which it has? Certainly many prominent members of our profession have a strong affection for antitoxin. The fame of antitoxin is largely due to the influence of two hospitals, viz., the Empress Frederika Hospital, Berlin (Baginsky's), and the Hospital for Sick Children in Paris (Roux and Martin). Baginsky⁶¹ reports 525 cases treated with serum; 83 deaths; mortality, 15.6 per cent. From March 15, 1894, to March 15, 1895, Baginsky had 525 serum-treated cases and during the same period 126 cases not treated with serum. Before serum treatment began in 1894 224 cases of diphtheria were admitted to the hospital, or 875 cases of diphtheria received into the Empress Frederika Hospital in fourteen and a half months. Compare these figures with the previous records.

During the years 1890-93 there were 1,063 cases of diphtheria in this hospital (Empress Frederika) and during the serum period 875 cases in fourteen and a half months. It must also be borne in mind that this enormous increase in number was at a time when, as was stated to me in Berlin, diphtheria was not epidemic but existed only in sporadic form. The Empress Frederika Hospital is a general hospital for children, with medical, surgical, and contagious disease departments, there being separate pavilions for the contagious diseases. We find recorded in Baginsky's monograph on diphtheria serum the case of a boy brought to the surgical department of the hospital February 25th with a fractured femur; March 19th there was a yellow coating on the left tonsil and Loeffler's bacillus was found. He was transferred to the diphtheria ward, and 4.5 c.c. of antitoxin were given. March 20th 4.5 c.c. were again given. March 23d he was perfectly well. Again, a baby seven months old was brought to the surgical department March 15th on account of club foot. March 24th there was a white coating the size of a lentil on the right tonsil, and the Loeffler bacillus was found. She was transferred to the diphtheria ward and 5 c.c. of antitoxin were given March 25th. March 26th the dose was repeated. March 31st she was perfectly well. Case III. was that of a girl of five years, whose throat was red, but without membrane. The Loeffler bacillus was found. She was transferred to the diphtheria ward July 13th and 5 c.c. of antitoxin were given. She was discharged July 17th.

Of the first hundred cases in Baginsky's book the average time of stay in hospital was ten days. Should

statistics to influence the profession and the public be made from such cases?

When I visited the Empress Frederika Hospital while in Berlin, I was first invited to attend the Dispensary Clinic for diseases of children, which opportunity I availed myself of. Such care in the management of cases of slight illness I do not think can be seen anywhere else in the world. The waiting-room for children is under the charge of a trained nurse. Every child has its temperature, pulse, and respiration taken by the nurse and its clothing removed; it is then carefully wrapped and taken before the physician. There again you see the same minute, painstaking care in every case. Noticing this great care and that not in a single instance was the throat examined, I thought it strange. The doctor told me that the throat was not examined in this room, because the throat of every child was examined before being brought to this room, and if there was any affection of the throat the child was referred to the diphtheria polyclinic. A clinic for walking cases of diphtheria was a revelation to me. The next hour I visited the room where the diphtheria polyclinic is held, under the supervision of the same physician. Every child brought to the dispensary department of the Empress Frederika Hospital, if it presents any throat lesion, is placed in an isolation room of the hospital which they now have for these cases; it is immediately injected with antitoxin, and if Loeffler's bacillus is found, it is placed in the diphtheria pavilion and receives further serum treatment. It is in this way that the enormous number of cases, as compared with previous years, is taken into this hospital for serum treatment. When there is a lack of serum or when there is no serum, these walking cases of throat affection are not detained in the hospital, as it is not deemed safe to do so when they cannot be immunized and protected against their surroundings. It is this method of conducting the diphtheria department of the Empress Frederika Hospital which accounts for the reported low mortality and for the difference in mortality during periods when serum is used and when it is not used. It was this very feature of the reports from the Empress Frederika Hospital which made the strong impression on Virchow. But Virchow had not studied the details; he accepted the percentage mortality without knowing how such percentages were obtained.

At the hospital for sick children in Paris, it was impossible to ascertain the number of cases treated before and since the use of antitoxin; but we find at the Trousseau Hospital that the number of cases admitted before the antitoxin treatment averaged about eight hundred a year; the highest nine hundred. During the first year of antitoxin treatment there were between fourteen hundred and fifteen hundred.

In connection with the subject of Paris statistics, the following from the *Paris Medical Week*, January 10, 1896, page 24, is interesting: "The most remarkable fact of the last month of 1895 is a sudden increase in the number of deaths from diphtheria [in Paris] to twenty-three, which is identical with the average of the last five years. The number of cases of this disease reported, however, does not differ materially from the number notified during the weeks immediately preceding." The *MEDICAL RECORD* (February 15, 1896) in commenting on this report says: "This naturally brings up the question again: have we been passing through a period of mild diphtheria and will antitoxin prove less efficacious when the virulence of the epidemic is pronounced?" The mortality in Paris has been as high as thirty-two per week during some weeks of 1896.

Variot (Paris) states that bacteriology has included a great number of cases which previously were not considered as cases of diphtheria.

Von Ranke⁶² (Munich) reports 102 cases; mortality, 18.6 per cent. Von Ranke had 162 cases of diphtheria in six months, whereas in the same hospital they have averaged 146 yearly during the last seven years.

Landau⁶³ (Frankenberg) reports 448 cases treated by serum in six months; 100 deaths; mortality, 22.3 per cent. In this same hospital they had averaged 132½ cases per six months for the last fifteen years, whereas during the serum period (from February to July inclusive) 448 cases were admitted.

Rauchfuss (St. Petersburg) reports 101 cases treated with serum in four months; mortality, 3.4 per cent., previous mortality, 55 per cent.; but he had 101 cases in four months under serum treatment, or at the rate of .303 per year. During the previous twenty-five years they have averaged in this hospital but 142 cases per year.

Vierordt⁶⁴ (Heidelberg) reports a mortality of 25.4 per cent. in diphtheria treated by serum. Serum treatment was begun October 31st, and in four months he received into the hospital 70 cases of diphtheria. I find from the hospital report that they had received into this hospital during the previous ten months but 56 cases.

The interne at the Children's Hospital (Heidelberg) told me that there was a great influx of cases from the Neckar Valley after the serum treatment began. Many apply to the hospital now who on account of the expense of the serum would not hitherto have applied. During the first ten months of 1894, without serum, 56 cases were received into the hospital, and during the succeeding four months, under the influence of serum treatment, 70 cases; and this at a time, as I was personally informed when in Heidelberg, when diphtheria was sporadic and not epidemic.

For increase in the number of cases during the serum period it remained for Dr. Ernest Germonig, of Trieste, to outdo all others.

Germonig⁶⁵ reports that from the 24th of August, 1894, to the 31st of January, 1895, a period of a little over five months, 362 cases of diphtheria were treated with serum in the Civil Hospital (Trieste). In this hospital they had in 1892 78 cases of diphtheria; in 1893 110 cases; the first eight months of 1894, 149 cases (before serum treatment). In five months and one week (serum treatment), 362 cases.

In 75 cases of diphtheria treated with antitoxin in the University College Hospital,⁶⁶ London, the mortality was 28 per cent.

Two hundred and forty-five patients treated with antitoxin in the American Urban Hospital,⁶⁷ Berlin, gave a mortality of 28 per cent.

Kossel⁶⁸ reports 233 cases; 54 deaths; mortality, 23.1 per cent. Some of these patients had flecks the size of a pinhead on the tonsils; no swollen glands; no fever.

Soltmann⁶⁹ (Leipzig) reports 181 cases of diphtheria with the Loeffler bacillus, treated with serum; 44 deaths; mortality, 24.3 per cent.

Contrast this with Heubner's⁷⁰ statement: "The mortality at my polyclinic (Leipzig), for fifteen years, for children of all ages and throughout the entire year, through severe and mild epidemics, was 22.5 per cent. This experience was with the same population as that from which hospital patients are drawn. Therefore the mortality was higher than it would have been in good private practice."

Report after report might be quoted, showing that the mortality at the present time under serum treatment ranges from 23 to 28 per cent., and even to 33 per cent. (Copenhagen) and 45 per cent. (New York Foundling Asylum).

Behring promised us that his serum would reduce the mortality to one-tenth of its former rate.

If antitoxin is a specific against the toxin of the Loeffler bacillus, the cardiac paralysis, the albuminuria, and the paralytic phenomena of diphtheria should no longer be seen. Albuminuria occurred in 40.9 per cent. of the cases treated with antitoxin in all the hospitals of the Metropolitan Asylums Board⁷¹ during 1895.

Albuminuria occurred in 24.1 per cent. of the cases in all the hospitals of the Metropolitan Asylums Board in 1894 (non-antitoxin year), and in 25.4 per cent. of the cases in 1892.

Soltmann⁷² found albuminuria in 72 per cent. of cases after the injection of antitoxin, which did not have albuminuria before the injection.

Post-diphtheritic paralysis occurred in 23.2 per cent. of the cases treated with antitoxin in all the hospitals of the Metropolitan Asylums Board in 1895; post-diphtheritic paralysis occurred in 13.2 per cent. of the cases treated in all the hospitals of the Metropolitan Asylums Board in 1894 (non-antitoxin year).

Heubner (Berlin) reported that in cases treated by him in which 1,100 immunizing units had been given, post-diphtheritic paralysis occurred in 7.5 per cent.; whereas, in cases in which 1,700 immunizing units were given, post-diphtheritic paralysis occurred in 12 per cent. of the cases.

Complications and sequelæ, which should be prevented by antitoxin, are greatly increased since the use of this treatment, and to an extent never before known.

Perregeaux⁷³ has reported of cases at the Trousseau Hospital that articular manifestations were observed at the hospital in eleven cases; after patients had returned to their homes, in nineteen. Diphtheritic paralysis occurred at the hospital twice; among patients who had left the hospital, twenty-one cases were found. Persistent and permanent albuminuria was found in six cases. In other words, it is not known when patients are free from a liability to after-effects from the disease or its treatment when antitoxin is used.

A child at the Willard Parker Hospital, which had recovered after an intubation and was sent home, within forty-eight hours after arriving at its home was taken with convulsions; it was seen by three physicians, but all treatment proved unavailing, and the child died in convulsions. This case is an exact counterpart of a case reported by Moizard (Paris). It is not known when after ill-effects of this treatment will supervene.

Dr. Chantemesse⁷⁴ states: "I have endeavored to ascertain whether it is not possible to avoid the ill-effects due to hypodermic injections of serum in general, by having recourse to some other method of introducing the remedy. For this purpose I have in twenty patients tried sero-therapy by means of intestinal injection. The effects of this injection appear to be as marked as those of hypodermic injection. In the twenty cases treated in this manner the preventive power of the same dose of serum was substantially the same, whether it was introduced under the skin or by the rectum."

Certainly it is not possible to get any therapeutic properties from the injection of antitoxin into the rectum, and yet here we have the statement that in twenty patients the results were precisely the same as when given hypodermically. The inevitable conclusion is that it has no curative properties when administered in either manner. From the beginning of this treatment at Buda-Pest, until the present time, not one fact has been presented which would tend to show that the serum treatment has any exact scientific value or scientific basis. We have, after all this period, no information to enlighten us as to the nature or the action of Behring's remedy. The theory of this

treatment based on laboratory work assumes that the result of infection by a specific bacillus is always the same, and independent of the organization of the individual; whereas the exact opposite is true. The same causes produce essentially different results in different individuals. Again, inasmuch as streptococci, staphylococci, etc., play a prominent part in every case of severe diphtheria, it is useless to treat the disease with a remedy which can at best be useful only in cases of pure Loeffler infection. Even in these cases of pure infection, to be thoroughly effective, it must be applied at the time or during the first twenty-four hours of infection. A positive clinical diagnosis is nearly impossible during the first twenty-four hours. A bacteriological diagnosis cannot be obtained in less than twenty-four hours, and then the mere presence of Loeffler bacillus in the throat is no proof of the existence of diphtheria.

Kohts⁷⁵ (Strassburg) sums up his conclusions on the serum treatment at the Congress für Innere Medizin, München, April, 1895, as follows:

"The mortality of patients treated with Behring's heilserum is for tracheotomy cases 29.4 per cent.; for those not operated on, 7.6 per cent.

"This result is less favorable than in the year 1891, when the mortality of tracheotomy cases was 25 per cent. without antitoxin; for those not operated on, 6.9 per cent.

"Secondary affections, as disease of the kidneys, affections of the heart, and paralysis, are not prevented by the serum. The result by injection of heilserum during the first two days of the disease does not differ from the results obtained without serum when the patients come under treatment within the first two days of disease. When there was coincidence of severe case of diphtheria with severe chronic and acute disease, pneumonia hæmorrhagica, thrombosis of the heart, and sub-pleural hemorrhages were observed."

After a thorough study in various hospitals in Berlin of the use of diphtheria serum, Passed Assistant Surgeon F. J. B. Cordeiro,⁷⁶ U. S. Navy, in a report to the surgeon-general of the navy, concludes that, so far, proof is lacking of the value of the antitoxin in the treatment of diphtheria:

"1st. A large number of children treated with both small and large immunizing doses have, within a few weeks, acquired diphtheria, and some of them have died of it. We do not possess a single scientific proof that a case of diphtheria was ever prevented by the immunizing process.

"2d. Children, who during the first sickness have been treated with large doses of serum, have a short time after acquired diphtheria anew. They were not rendered immune either by their sickness or by the largest doses of the antitoxin.

"3d. In a large number of cases, children have been treated on the first or second day of their illness with the fullest dose of the antitoxin, and have died.

"4th. It is certain that a large part of those who have died, notwithstanding the serum treatment, did not die from the effects of a mixed infection, but directly from the specific effects of Loeffler's bacillus.

"5th. Heart and other post-diphtherial paralyses are also seen in early and fully treated cases, and they occur as often as they did before the serum treatment.

"6th. Of a fever fall by crisis in the first twenty-four hours, and of a pronounced antipyretic effect of the serum, most observers have seen nothing or next to nothing.

"7th. The separation of the membranes follows in the cases that run favorably in the customary manner; but often there is an extension of the local process and a renewal of the already separated membranes during and after the serum treatment.

"8th. The burden of proof lies with Behring and his

coworkers. The world eagerly and only too willingly received this proof. We know that the former extravagant promises are out of the question: but we should be grateful to have it demonstrated that the serum can reduce the mortality by even one per cent. As yet we have not the slightest basis on which to found an expectation that fewer children will die in the future of this disease on account of the serum treatment."

One of the strongest arguments against the antitoxin treatment of diphtheria is the attitude of those who are living in hospitals and watching its results, who formerly were earnest advocates of the treatment, and who, after experience, have from conviction become opposed to it.

Dr. William M. Welch (Municipal Hospital, Philadelphia), who has injected over three hundred patients, stated to me that he would not have antitoxin used on himself if he had diphtheria; that if his children had diphtheria of any type, he would not allow them to be injected; and if left to act independently and from his own conviction, he would never inject another patient.

Dr. Steinsieck (North Brothers Island Hospital) says he would not have antitoxin used on himself; that recently he has thought it all over as to what he would do in case his children had diphtheria, and he has decided he would not have them injected with antitoxin, no matter how severe or what the form of the disease might be.

Dr. Warmuth, Dr. Tyler, and Dr. Bemis, of the Municipal Hospital, Philadelphia, were believers in antitoxin, and are now opposed to it.

Dr. Hardin, of Washington, and Dr. Levy, of Richmond, came to the Willard Parker Hospital thorough believers in antitoxin, and are now opposed to it.

Dr. Warmuth (Municipal Hospital, Philadelphia) had diphtheria and refused to have antitoxin used on himself.

Dr. Levy and Dr. Hess, of the Willard Parker Hospital, had diphtheria and refused to have antitoxin.

Not one of the nurses of the staff of these hospitals would have antitoxin used on themselves for immunizing purposes.

Variot states that the doctors and nurses of the Trousseau Hospital (Paris) would not have antitoxin used for immunizing purposes, though one of the doctors had a severe diphtheria.

It has been said that I have been prejudiced against the use of antitoxin. My impressions with reference to the use of antitoxin were gained first in the autumn of 1894, when I saw Dr. Halliday come under treatment at the Willard Parker Hospital. He was brought to us as soon as the diagnosis of diphtheria was made, partly for isolation and partly to get the benefit of the antitoxin. He had an uncomplicated, but severe, diphtheria, involving most of the throat. He was a strong, healthy young man of perfect habits. He was given antitoxin as soon as admitted—given the full dosage, I understand—and in addition, every other possible treatment, of course, that could be suggested. At the end of two weeks and one day he died of a straight, uncomplicated diphtheria, the antitoxin not having had the slightest influence on a single symptom from beginning to end. This made me wonder, for the man seemed to have every possible chance to be saved by this specific. I was so impressed by it that I went to Dr. A. L. Loomis, and talked over the matter with him on three different occasions. He wanted me to come out then and express my opinion, but I said: "No; there is a possibility that I am mistaken, and I do not wish to deprive any one of the use of it." In that autumn only five patients with diphtheria were treated with antitoxin. Four out of the five died, and the fifth was desperately ill. He had a peculiarly long and tedious convalescence. It was these five

cases that led me to study with the greatest care and anxiety—an anxiety such as I have never experienced in connection with any other subject—the action of antitoxin.

With reference to a prejudice, it is monstrous to speak of it—a prejudice against anything which could do any good in such a disease as diphtheria! A man who would have a prejudice against a specific for diphtheria, should not be allowed to practise medicine. If there is a specific for diphtheria, I want it; no member of this academy, no member of the profession in any portion of the world needs it more than I do; and every man who knows me, knows that it would not be possible for me to cast a word of doubt upon any remedy which could be of the least possible use in the treatment of diphtheria. I could not possibly have brought myself to the position in which I find myself to-night had it not been for my strong conviction regarding the injurious effects of antitoxin. Could I have found that antitoxin did not do any harm, even though it was valueless in the treatment of diphtheria—even though it did not reduce the mortality—I would never have said anything against it. It is because I believe that it is dangerous that my convictions compel me to speak. The time will come, gentlemen, when every member of this academy will feel with reference to it as I do to-night, and you will come to it from conviction, as various members have already.

HOW THE FACTS ABOUT THE ANTITOXIN TREATMENT OF DIPHTHERIA SHOULD BE ESTIMATED.¹

BY W. H. THOMSON, M.D., LL.D.,

PROFESSOR OF THE PRACTICE OF MEDICINE, NEW YORK UNIVERSITY.

THE grounds for scepticism on the part of physicians in questions connected with therapeutics are natural enough, when the complexity of the conditions inseparable from such problems is taken into account. This is particularly the case when the treatment of acute infectious diseases is in debate. Here an element of uncertainty meets us at the outset, in the fact that most acute infectious diseases run a course specifically defined in each, and naturally ending in the recovery without treatment of a greater or less majority of those attacked by them. Therefore, until this element is given its proper place, or, in other words, unless the percentage of recoveries without treatment can be approximately estimated and duly allowed for, no trustworthy comparison between different lines of treatment can be justly made.

Another factor in the problem is diagnosis. It happens that this is quite a factor in the case of diphtheria. Other microbic infections beside diphtheria produce anginose affections in the throat, accompanied by exudations which in many patients cannot be distinguished by their clinical characters or initial accompaniments from those of diphtheria. It is claimed that diagnosis here is dependent upon identification by bacterial cultures, and therefore that conclusions or statistics not so verified are unreliable.

Another consideration is that all infectious diseases depend for their development upon the animal body which receives their germs. In the majority of persons those germs do not develop at all, as was known in the case of small-pox itself before the days of vaccination. Their entrance in others is followed by the most varying results; in some the yield to the seed sown is so small that they cause but little disturbance; in others it is considerable with considerable disturbance; in others the growth is luxuriant from the beginning with corresponding severity in the symptoms. How, therefore, are we to know beforehand which are

¹ Read at the discussion at the New York Academy of Medicine, June 4, 1896, of the paper of Dr. J. E. Winters.

to be the mild cases and which the severe ones among those who are infected? The mild would get well and many of the severe would die in any case. We all have occasionally seen in these diseases what we term malignant cases, in which the fatal outcome scarcely could have been prevented by treatment any more than after certain surgical accidents. Therefore, these two classes, the mild and the severe respectively, ought to be estimated separately in order to pronounce correctly upon the effects of treatment. But how often can this be done in practice?

Another factor is that pathogenic microbes themselves change in their degrees of virulence within such wide limits that uncertainty arises from this source alone. An instructive illustration of this is found in the behavior of one form of them which is specially pertinent to our present subject, as it undoubtedly often joins forces with the diphtheria microbe in its attacks, and that is the streptococcus pyogenes. "Starting from a streptococcus harmlessly inhabiting the buccal cavity, we may pass experimentally (by cultivation in successive rabbits) through all stages till we obtain an organism of such exalted virulence as to be capable of producing a rapid and general infection."¹ This fact in the life history of microbes offers a plausible explanation of the seasonal variations in severity of infectious diseases, rendering them much more difficult to treat in one year than in another. Now, neither of these features of infectious diseases—that is, different development in different persons and the same agent varying in virulence at different times—find the least counterpart in chemical reactions, which, instead, can always be predicated according to their defined conditions. It is wholly illogical, therefore, to suppose that any alleged remedy against an infectious disease could ever be a specific against it in the fashion that acids and bases react specifically against each other in chemistry, and hence that its results should be the same with every physician who uses it and everywhere. There are no varying acids nor varying bases in chemistry, nor does chemistry know anything of seasonal variations. But it is precisely these elements of variability which must be taken account of fully in all discussions about remedies against infectious diseases. It is curious to note how this palpable difference between agents which act according to unvarying physical laws and agents which act according to the ever-varying laws of growth is ignored by the opponents of the diphtheria antitoxin, who repeatedly assume that this complex serum derivative should have the properties of an inorganic chemical body, always of the same composition and potency from the beginning, on the one hand, and that diphtheria itself should become a purely chemical disease on the other, to be chemically neutralized by the antitoxin.

Still another element in the course of many infectious diseases (notably of diphtheria, as already stated) comes in to disturb our calculations, and that is what is termed polymicrobial infection. Thus, to what extent may the claim be allowed to the advocates of the diphtheria antitoxin that it may fail in many of the fatal cases because, while it is efficacious against the toxin of the diphtheria bacillus, it could do nothing against the toxin of the streptococcus?

Another element in the problem also should not be lost sight of, and that is time, as regards the administration of a supposed remedy. Our knowledge of the structural damage which the diphtheria toxins are capable of producing before death show that no chemical or corrosive poison can surpass them in the causation of important tissue changes. Arsenic itself could not more hopelessly destroy living tissues than diphtheria does in the case of muscle and nerve fibre,

not to speak of glandular cells. The best antidotes to arsenic would be useless after some of the characteristic changes have been already caused by this poison, and the same must be said of any supposed neutralizer of the diphtheria toxin—that it would be equally useless if it came too late.

Thus, as the matter stands, there are so many considerations which have to be taken into account, first on one side and then on the other, ere we can come to any conclusions on a question like the one before us to-night, that to many it may seem a hopeless undertaking to settle it at all. Nevertheless, we are prepared to show that this discouraging anticipation is quite unwarranted on account of certain conditions which now obtain in the medical world and which allow of even such a complex question as the efficacy of the diphtheria antitoxin to be very fairly tested. Preliminary, however, to adducing this evidence, we insist that decisions on therapeutic questions, including the use of antitoxin, must rest on the question of comparative success, and on that alone. Unless that postulate be granted, there can be no decision about the use of any remedy whatever. In the instance of the antitoxin, the advocates on the negative side often argue as if cases of failure were sufficient to establish their contention. But failures of a remedy are, *per se*, no proof that it is not a remedy. Quinine, for example, often fails to cure ague. Is it on that account not the remedy for ague? Vaccination likewise often fails to prevent small-pox. Is it on that account not the preventive against small-pox? Where would mercury stand as a remedy for syphilis if all one need do to prove its inefficacy would be to walk through the wards of a hospital and show how many syphilitics there are as badly off as ever, if not worse after they have taken a through course of it? We can justly maintain, instead, that the opponents of the antitoxin treatment may be cheerfully allowed to detail case after case of failure with antitoxin, without thereby affecting the decision in any non-partisan mind when the whole evidence is in, because that evidence is of a kind which excludes both failures and successes alike which do not come within the conditions laid down, and which conditions alone determine the verdict.

The conditions are these: Diphtheria is a widespread disease which has been characterized by a pretty uniform range of mortality and of the conditions which influence its mortality in all civilized countries of the globe. Therefore, the verdict about any alleged remedy for it should depend upon the findings of a jury whose members should not only be competent, but also so numerous and of such difference in locality and nationality that all personal or local influences can be safely left out of account. The summoning of such a jury would have been impossible in former times, but the recent impressive incident of Koch's tuberculin shows that it can be now, as well as demonstrating that the medical fraternity of our age constitutes the only real international fraternity in the world. In that case the competency of the jury was proven by the fact that, notwithstanding the interest in the disease concerned was quite equal to that manifested in regard to diphtheria, and the reputation of the originator of the supposed remedy was the most calculated to influence the jury favorably, yet the verdict was rendered in the negative virtually within four months.

The antitoxin treatment of diphtheria, therefore, had to come before the same jury with the disadvantage of a presumption against it on account of the failure of its predecessor in serum therapeutics. It has now been on trial about a year and a half, with reports upon it coming from scientific observers both in public institutions and in private practice, from Austria, Germany, Holland, Belgium, Denmark, Russia, Japan,

¹ Bullock: London Lancet, April 11, 1896.

France, Italy, the British empire, including Australia, and, finally, from all America. It is the general verdict, if such there be, of these reports which any candid physician will care to consider. In questions of therapeutics personal opinions or supposed personal experience are so beset with fallacies that errors can be minimized only by the calculus of very large averages, and if the elements for these are not yet enough we must be content to wait until they are. No one voice, or, for that matter, a score of voices, however loud or vehement, are sufficient to affect the final verdict, for observations alone and not individuals have any standing in this court.

As it is both wearying and difficult for an audience to listen to tables of figures, we will endeavor to shorten this task by limiting it to one aspect of the subject only, namely, the verdict of hospital reports on the comparative mortality in the treatment of diphtheria with and without antitoxin. My sources for this summary are Prof. William H. Welch's admirable paper in the *Johns Hopkins Hospital Bulletin*, July-August, 1895, and also a remarkably complete communication on the whole subject of the statistics of the antitoxin treatment brought up to May, 1896, by Dr. Arthur R. Guerard, of this city. I have been privileged to read this paper, which for wealth of material and careful analysis of the different branches of the subject is so thorough and valuable that I hope it will soon be published in full.

Beginning with Austria, we quote first from the official hospital reports for the years 1894-95, the period just before and since the introduction of the antitoxic serum:

St. Anne's Hospital, Vienna: Treated without antitoxin, 760 cases; died, 385, or a mortality of 50.68 per cent. Treated with antitoxin, 159; died, 40, or a mortality of 25.15 per cent.—a reduction of more than 50 per cent. Treated to the end of June, 1895, 560; mortality, 97, or 19.1 per cent.—a reduction of about 65 per cent.

We may here compare these statistics with those of the Kaiser and Kaiserin Frederika Hospital, Berlin: Treated without antitoxin, 217 patients; died, 103, or a mortality of 47.4 per cent. Treated with antitoxin, 384; died, 64, or a mortality of 16.6 per cent.—a reduction of 75 per cent.

The official reports of the other hospitals for this period unfortunately give the total mortality both with and without antitoxin, but even with this element, which reduces the mortality from what it should be if the tables included the deaths without antitoxin alone, the antitoxin reports taken separately show a decided gain. Thus:

St. Joseph's Hospital, Vienna: Total cases treated, 299; deaths, 151, mortality 52.6 per cent. Treated with antitoxin, 42; deaths, 11; mortality 26 per cent.—a reduction of 50 per cent. from the figures of the total of both without and with the antitoxin.

Leopoldstadt Hospital, Vienna: Mortality with and without antitoxin, 34.9 per cent.; mortality with antitoxin alone, 26.9 per cent.

Crown Prince Rudolph Hospital: Mortality with and without antitoxin, 36.5 per cent.; with antitoxin alone, 20 per cent.

Kaiser Franz Joseph Hospital, Prague: First mortality table, 28 per cent.; with antitoxin alone, 13.2 per cent.

University Clinic, Prague: First mortality table, 36.2 per cent.; with antitoxin alone, 20.8 per cent.

Anna Hospital, Prague: First mortality table, 13.7 per cent.; with antitoxin alone, 9.9 per cent.

Child's Hospital, Buda-Pest: First mortality table, 47.1 per cent.; with antitoxin alone, 17.5 per cent.

From other parts of Germany the official hospital reports for the same period show the same general uniformity of decline. Thus:

Child's Hospital, Dresden: First table, mortality, 45.6 per cent.; with antitoxin alone, 28.8 per cent.

New Hospital, Leipzig: First table, 32 per cent.; with antitoxin alone, 14.5 per cent.

Child's Hospital, Frankfort: First table, 28 per cent.; with antitoxin alone, 12 per cent.

Olga Hospital, Stuttgart: First table, 34.8 per cent.; with antitoxin alone, 12 per cent.

Child's Hospital, Nuremberg: First table, 38.3 per cent.; with antitoxin alone, 1.0 per cent.

Child's Hospital, Lübeck: First table, 56 per cent.; only three cases treated with antitoxin; all recovered.

From Switzerland there is a report from the Child's Hospital, Hettingen, Zürich: First table, mortality 19.6 per cent.; with antitoxin alone, 3.4 per cent.

The total figures of these tables are 4,472 patients treated, of whom 2,511 had no antitoxin and 1,961 had antitoxin alone. Only two of these hospitals, as above stated, give the comparative mortality of those who did not and those who did have antitoxin treatment, and yet with all that the mixed tables of mortality of the whole 4,472 cases treated give a mortality of 37.2 per cent. compared with a mortality of 17.2 per cent. among the 1,961 who were treated with antitoxin alone.

Other hospital reports given by attending physicians in Austria:

Unterholtzen: With antitoxin, 37 cases; deaths, 8, or 21.6 per cent. Previous mortality without antitoxin stated at 66.7 per cent.

Heim: 27 cases; deaths, 6, or 22 per cent.; previous mortality, 52.5 per cent.

Monti: 25 cases; deaths, 1; mortality, 4 per cent.

Ganghofner, Franz Joseph Kinder Clinic in Prague: 110 cases treated; deaths, 14; mortality, 12.7 per cent. Treated without antitoxin, 144; deaths, 62; mortality, 43 per cent.

Von Engel, Brünn, Bohemia: 39 cases treated with antitoxin; deaths, 10, or 25.5 per cent.; 62 cases treated without antitoxin; deaths, 31, or 50 per cent.

Jakenbowski, Prague: 100 cases, 30 deaths, or 30 per cent.; previous, 50 per cent.

Germonig, Hospital at Trieste: 224 cases treated with antitoxin; 44 deaths, or 20.3 per cent. Treated without antitoxin, 65; deaths, 33, or 50 per cent.

Bókai reports 120 cases; deaths, 31; mortality, 25.8 per cent.; mortality previous to antitoxin, 60.2 per cent.

From other parts of Germany we have hospital reports by way of Munich.

Siegel, 100 cases treated with antitoxin; mortality, 12 per cent.; mortality without antitoxin, 50.3 per cent.

Rumpf, Munich: 22 cases; mortality, 2, or 8 per cent.; previous, 25 per cent.

Ehrlich, Kossel, and Wassermann: 233 cases treated with antitoxin; 53 deaths, or 23 per cent.; previous mortality, 54.8 per cent.

Baginsky: 525 cases with antitoxin; mortality, 83, or 15.6 per cent.; mortality without antitoxin, 48 per cent.

Von Mering: 74 cases; deaths, 4, or 5 per cent.; previous, 30 per cent.

Körte: 121 cases; mortality, 40, or 33.3 per cent.; previous mortality, 57.4 per cent.

Schroeder: 63 cases; deaths, 8, or 12.7 per cent.; previous, 33 per cent.

Moeller: 76 cases; mortality, 27, or 35 per cent.; previous mortality, 43.8 per cent.

Von Ranke: 225 cases; 43 deaths, or 19.1 per cent.; previous, 50 per cent.

Hilbert: 11 cases; no mortality with antitoxin.

Vierordt: 63 cases; 16 deaths, or 25 per cent.; previous, 54 per cent.

Börger: 100 cases; mortality, 8, or 8 per cent.; previous mortality, 25 per cent.

Tiemmer: 147 cases; 13 deaths, or 8.8 per cent.; previous mortality, 40 per cent.

Sonnenburg: 107 cases; deaths, 22; mortality, 20.4 per cent.; previous mortality, 27.6 per cent.

Soltmann: 181 cases with antitoxin; 44 deaths; mortality, 24.2 per cent.; previous mortality, 80 per cent.

From Switzerland, Seitz at Constance reports 27 cases treated with antitoxin with 1 death, or 3.8 per cent.; previous mortality among 293 cases treated without antitoxin, 88, or 30 per cent., and Von Musal 58 cases with only 2 deaths, or 3.4 per cent.

Holland, Van Noorden: 81 cases; deaths, 19, or 23 per cent.; previous, 30 per cent.

Van Neo: 52 cases; 12 deaths, or 23 per cent.

From Belgium, Choron at Brussels reports 13 cases; 4 deaths, or 30.8 per cent.

Christiania Hospital, Sweden: 212 treated with antitoxin; 21 deaths; mortality, 9.9 per cent. Without antitoxin, 576 cases; 114 deaths; mortality, 19.2 per cent.

From Denmark Soerensen reports 385 cases treated with antitoxin in the Blegdam Hospital with 61 deaths, or 16 per cent. Previous mortality not stated, but it could scarcely have been so low as 16 per cent.

From Russia, Rauchfuss: 34 cases treated with antitoxin; 7 died; mortality, 21 per cent.; previous mortality, 52 per cent.

Geloczy: 55 cases; deaths, 15, or 27.3 per cent.

Stinzing: 59 cases; 12 deaths, or 20.3 per cent.; previous mortality, 25 per cent.

From Japan, Kitasato, of Tokio: 353 cases; 31 deaths, 8.78 per cent.; previous, 56.5 per cent.

From Australia there is a report as late as February, 1896, by Drs. Clubbe and Lichfield, of 100 cases treated at the Sidney Children's Hospital with antitoxin and compared with that of 100 consecutive cases just preceding them without antitoxin. All diagnoses were verified bacteriologically. Of those without antitoxin the death rate was 51 per cent. Of those with antitoxin the death rate was 23 per cent. We may add that they give 59 tracheotomies with a mortality of 67.7 per cent. without antitoxin, and 48 tracheotomies with a mortality of 39.5 per cent. with antitoxin.

Turning now to France, we have the report of Roux and Martin, Hôpital des Enfants Malades, of 300 cases treated with antitoxin. Mortality, 78, or 26 per cent.; previous mortality, 50 per cent.

Le Gendre, Hospital Trousseau: 17 cases; mortality, 2, or 12.5 per cent.; previous mortality, 55 per cent.

Mayzard and Perregaux Hospital: 231 cases; 34 deaths; mortality, 14.7 per cent.; previous mortality, 55 per cent.

Sevestre Hospital: 150 cases; deaths, 15, or 10 per cent.; previous mortality, 55 per cent.

D'Espine: 60 cases; mortality, 6, or 10 per cent.

Le Breton and Magdeleine Hospital: 258 cases; 31 deaths, or 12 per cent.; previous mortality, 55 per cent.

Dreyfus, Hospital Lyons: 51 cases; 5 deaths, or 9.2 per cent.

From Italy, hospital reports from Tantucci and Mucci: 13 cases; 3 deaths, or 23 per cent.; previously, 57 per cent.

Pietororo: cases treated 20; deaths, 4, or 20 per cent.; former mortality, 50 per cent.

Giarré and Matteucci: 46 cases; deaths, 18, or 28.2 per cent.

From England the earliest hospital report was from Goodall, Washbourne, and Card: 177 cases treated; deaths, 37, or 20.8 per cent.; previous mortality, 30.8 per cent.

Winkfield, 22 cases; deaths, 4, or 18.2 per cent.; previous mortality, 36 per cent.

Matthews: 61 cases; deaths, 10, or 16.3 per cent.; previous mortality, 30.8 per cent.

Gayton: 43 cases; deaths, 2, or 4.6 per cent.

Bruce: 68 cases; deaths, 10, or 14.7 per cent.

Hall: 11 cases; deaths, 3, or 27 per cent.

Fraser: 95 cases; deaths, 22, or 23 per cent.

Johnston: 105 cases; deaths, 15, or 15.4 per cent.; previous, 35.0 per cent.

Raw: 16 cases; deaths, 2, or 12 per cent.; previous, 47 per cent.

Ruffer, 274 cases; deaths, 37, or 13.5 per cent.

Sidney Martin, 75 cases; deaths, 21, or 28 per cent.; previous, 37.8 per cent.

In America, Withington, of Boston, reports 50 cases; deaths, 13, or 16 per cent.; previous mortality, 30 per cent.

Louis Fischer, of New York, hospital and private practice, 225 cases; 35 deaths, or 15.5 per cent.

Mason, 306 cases; 81 deaths, or 26.4 per cent.; previous, 48 per cent.

McCollom, 844 cases; 96 deaths, or 11.3 per cent.

Welsh, of Philadelphia, 302; deaths, 85, or 28.1 per cent., against previous mortality of 25.9 per cent. He is the one reporter with an unfavorable showing, except Springoram, in Germany, who reports 206 cases with 78 deaths, or 37.9 per cent., against a mortality of 25 per cent. without antitoxin.

We can sum up, therefore, this list of reports from 85 hospitals in every part of the world giving the treatment with antitoxin of 9,893 cases, with 1,820 deaths, or a mortality of 18.3 per cent. In 53 of these hospital reports there are given statistics of 7,277 cases with a mortality of 20 per cent. under serum treatment in which definite comparisons are made with the mortality previous to the use of antitoxin of 44.3 per cent.; thus justifying the contention that so far as hospital practice goes antitoxin has caused a reduction of fully 50 per cent. in the general death rate.

We have advisedly limited this review to hospital reports, just because it affords the best chances for the opponents of antitoxin. First, because hospital cases are much less likely to be brought in early for antitoxin treatment. Secondly, because mild cases are apt not to be brought in at all. Thirdly, because it is the uniform report from all parts of the world that the proportion of laryngeal cases is far greater in hospital than in private practice cases. On the other hand, hospital statistics afford a much more certain gauge of the previous mortality before the antitoxin treatment was used than could be obtained from the practice of physicians at large, who unfortunately so often neglect to record their cases.

Moreover, it should be noted that taking the world at large, we are more apt to have the best-trained observers on hospital staffs. Hospital experience, especially when extensive, tends to engender a safe scepticism about remedies. Indeed, the diphtheria antitoxin by no means took the profession by storm, as its predecessor, tuberculin, on its first promulgation did, but rather it had to meet with a cool reception at best both in Europe and elsewhere.

Another deduction from these statistics of a mortality of 18.3 per cent. shows that antitoxin is certainly no specific in the sense in which Dr. Winters uses the term. Whoever reports treating diphtheria with antitoxin has a number of deaths, some more, some less. Dr. Winters laid much stress upon this fact, and endeavored to substantiate by it his contention that antitoxin is no specific by citing the very different percentages of recoveries given by different hospital physicians, one percentage in Vienna, another in Berlin, another in Paris, etc. His inference, therefore, so far as we could understand him, was that if antitoxin were the specific which Von Behring alleges it

to be, then it ought not to vary in its action anywhere. As we have before remarked, such a proposition involves two things. First, that antitoxin is as definite a body in its composition and in its properties as tartar emetic, which will produce emesis alike in Paris and in Berlin. Secondly, that diphtheria may equally take on unvarying characters, so that it will then show just the same percentages of recoveries or deaths in one place as in another.

We need, therefore, only reply that the question now at issue is not whether antitoxin be a specific or not, simply because there are no specifics in the sense in which Dr. Winters uses the term, and therefore antitoxin cannot be a specific. Instead, the subject in debate is whether the treatment of diphtheria by antitoxin, when compared with other methods previously employed, shows a greater percentage of recoveries or not. All discussion not limited to this plain question is a waste of words.

We have not alluded to the great mass of testimony which is steadily accumulating from private rather than from hospital sources, because others may this evening have better opportunities than I have to adduce this evidence. No one who follows such reports in our journals will long doubt, I think, how the verdict is trending. Thus, from 33 reports in medical journals of private practice collated by Dr. Guerard, statistics are given of 3,760 cases treated with antitoxin with 296 deaths, or 7.8 per cent. These added to the 9,893 above given from hospital reports, make a total of 13,653, with a total mortality in both hospital and private practice of 15.5 per cent.

We have not alluded, either, to one of the severest tests to which the antitoxin treatment can be subjected as to its efficacy, and that is in laryngeal diphtheria. To do this part of the question justice would require a separate paper. All that we need do now is to challenge the opponents of antitoxin to answer the verdict of the medical world on this point. It will not do to report individual cases of distressing failure with antitoxin in this or that man's experience, whether in hospital or elsewhere. The answer must be why so many of the first and most eminent physicians and surgeons, not here and there, but in every civilized country unite in proving by comparative statistics of their own experience a most marked improvement, both after operations and in the prevention of the necessity for operations, in laryngeal cases since they tried antitoxin. It is ludicrous to ascribe this to an epidemic of self-deception which since the autumn of 1894 has spread its wave more universally over the medical world than ever did Asiatic cholera in its march among mankind. If so, the very ablest and best-trained men in our profession have been its victims. Rather than be forced to such a sad conclusion, it seems much more probable that a really great advance in the practice of medicine now marks the close of the nineteenth century in the introduction of the serum treatment of diphtheria and that it is a promise of greater triumphs still in this progressive branch of therapeutics.

The Chaput and Murphy Button Compared.—

Chaput claims, according to the *Gazette Médicale de Liège*, that his technique is more rapid, only one suture being required instead of two; that his largest button has a smaller circumference than Murphy's smallest; that it is safer, as it does not sphacelate the intestine as does Murphy's; that it may always be inserted in good order, no matter how thick the walls of the stomach or intestine; that while Murphy's cannot be detached, this one may easily be detached by means of a sound; that it has no complicated mechanism and yet cannot be so easily imitated as the Murphy button.

A CRITICAL ANALYSIS OF DR. WINTERS' CLINICAL OBSERVATIONS ON THE ANTITOXIN TREATMENT OF DIPHTHERIA.¹

By JOHN WINTERS BRANNAN, M.D.,

ATTENDING PHYSICIAN TO BELLEVUE AND THE WILLARD PARKER HOSPITALS.

MR. PRESIDENT AND MEMBERS OF THE NEW YORK ACADEMY OF MEDICINE: When asked some weeks ago to take part in the discussion of the antitoxin treatment of diphtheria, it was only after considerable hesitation that I decided to accept the invitation. There were several reasons for my hesitation. In the first place, my experience with antitoxin, like that of Dr. Winters, is practically confined to hospital practice, and I believe that the time has passed when hospital experience can contribute much of value to the subject under discussion this evening. One year ago the case was different. At that time we had to rely entirely upon the experience of hospital physicians, who alone had a large number of cases at their disposal. Although the testimony of those connected with these institutions has been, with one or two exceptions, favorable to the use of antitoxin in diphtheria, it was nevertheless soon recognized that the conditions of hospital practice limited greatly the value of the remedy. Antitoxin must be administered early in order to secure the best results, and we all know that cases do not, as a rule, reach the hospital until several days have elapsed from the beginning of the disease. It is in private practice only that the disease can be recognized and treated at the moment when antitoxin exerts its greatest effect. Fortunately, we have now at our command the experience of a large number of private practitioners, and it is they alone who can speak with authority on this subject. There are in this room this evening many physicians who have treated from twenty to one hundred or more cases of diphtheria with the new remedy, and I do not think that either Dr. Winters or myself is competent to express an opinion in their presence on the real value of antitoxin.

A second reason for my reluctance to engage in this discussion lay in the fact that I could hardly criticise Dr. Winters' observations of antitoxin without at the same time commenting upon the attitude which he has publicly assumed toward the administration of the Willard Parker Hospital, an institution with which I am connected in the same capacity as himself. If Dr. Winters' position is sound and his observations are correct, the city of New York has been maintaining a hospital to which children have been taken and subjected to a method of treatment which is not only useless, but has in many instances led directly to the death of those children. This has been distinctly stated by Dr. Winters at various times in his writings, and cases apparently proving the same have been described by him with the greatest detail. As these statements have been made more than once in this Academy of Medicine, it is here that they must be met and disproved if possible. It is with regret that I feel compelled to enter upon this task, but having so decided I shall perform it to the best of my ability.

A few words are first necessary as to what led to the use of antitoxin in the Willard Parker Hospital, and as to who is responsible for its administration. In the autumn of 1894 the board of health, in view of the favorable results claimed to have been obtained abroad by the use of the remedy, decided to give it a thorough trial in the hospitals under their charge as soon as a sufficient supply of serum could be obtained. The hospitals of the health department differ from the other hospitals of the city of New York in that they are provided with resident physicians, men of

¹ Read at a meeting of the New York Academy of Medicine, June 4, 1896.

mature years and of proved experience in the class of diseases which they are called upon to treat. These resident physicians are directly responsible to the board of health and only indirectly to the board of visiting physicians attached to the hospitals. The board of health, also, in addition to the medical men who compose it in part, has a number of physicians trained in their specialties to assist it in the efficient management of its hospitals. When the board of health determined to make use of antitoxin, the medical board, of which Dr. Winters and I are members, had been in existence only one year. It was eminently fitting, therefore, that the use of the new remedy should be mainly entrusted to those men who were making of it a special study, and who had proved their efficiency in the conduct of the hospitals before our medical board had been called in to assist them. Our position in the matter, therefore, has been rather that of advisers and consultants. We as a body were entirely in favor of the step taken by the board of health, and the treatment has gone on without interruption, no matter which one of us has happened to be on duty as visiting physician to the wards of the hospital. I state these facts simply to make it evident that all the visiting physicians of the Willard Parker Hospital stand on the same plane with regard to the use of antitoxin. No one of us has any special interest in its use other than to determine its real value in the treatment of diphtheria. All of us, with the single exception of Dr. Winters, have from the beginning been in favor of the thorough trial of the serum treatment, which is still going on in the Willard Parker Hospital. Having stated the above by way of explanation, I shall now take up the position of Dr. Winters, as shown by his paper read in this academy at the last meeting, with some reference also to his previous expressions on the subject. In doing so, I wish it understood that I am attacking his position, not himself. All the members of the medical board have the greatest friendliness for Dr. Winters, but we believe that he has made a grave mistake, and that he has done great wrong to the hospital of which he is one of the attending physicians, and that his words have caused widespread harm among the people of New York and of the whole country.

Before considering the evidence submitted by Dr. Winters in support of his views, let us see whether he entered upon his observations in the hospital with a mind open to conviction and free from bias. One cannot read the arguments of any of the vigorous opponents of antitoxin without being struck by the fact that they all start with a distrust of the bacteriological diagnosis of diphtheria and with a reluctance to accept the help offered by the bacteriologists to the clinicians. Dr. Winters is no exception to this rule, and as long ago as December, 1894, it was evident to the other members of our board that he had strong doubts of the curative power of antitoxin and was prepared to find it of no value. The systematic use of antitoxin was not begun until January 1st of the following year, and from the very beginning he had no faith in its virtues and was daily proving to himself that he was right in his opinion. He, however, kept his counsel and no one had any inkling of what was to take place on that memorable evening of April a year ago. After barely three months of observations on some one hundred and fifty hospital cases, Dr. Winters had decided for all time that antitoxin was absolutely without value, and, in addition, produced great harm, even to the extent of causing death in those to whom it was administered. From that time to this he has become more fixed in his convictions and has confirmed them by a personal investigation of the hospitals in Europe. I, unfortunately, was not present at the meeting last year but I have read and reread his

vivid descriptions of patients who have died of antitoxin poisoning in the Willard Parker Hospital. Though I was not present at that meeting, I was present two weeks ago and I am here to-night.

I shall now take up some of the statements made by Dr. Winters in his last paper—first, those bearing on his observations in the Willard Parker Hospital; and, second, those relating to his visit to Europe last summer.

The Character of Dr. Winters' Evidence in the Willard Parker Hospital.—The advocates of the use of antitoxin in diphtheria insist that it must be given early in the disease and in adequate dosage in order to secure efficient action. Dr. Winters claims that even under these conditions antitoxin does not cure diphtheria. Further, he asserts that it may cause the death of the patient, as shown by the fatal result in mild cases in which it was administered in the Willard Parker Hospital. In proof of these views he cites some twenty-five or thirty cases of diphtheria of favorable prognosis in which it was given on the first, second, or third day of the disease. These cases were taken from the spring months of 1895 and 1896. Lack of time prevented his giving full details of these cases in his paper of two weeks ago, but he gave the following summary or what he called the "gist" of the cases. The formula ran somewhat as follows:

"Patient, M. C.—, one day sick, small bit of membrane on the tonsil, favorable prognosis, antitoxin injected, death on the fourteenth day."

I have taken the records of the hospital and collected all the cases with fatal termination admitted in the months of January, February, March, and April, in the years 1895 and 1896, in which antitoxin was administered on the first, second, or third day of the disease. In 1895 there were nineteen such cases in which antitoxin was given on the second or third day of the disease. All cases in which treatment was begun on the first day resulted in recovery. In order to judge of the character of these cases from the standpoint of prognosis, I have first arranged them according to the age of the patient. Of the nineteen patients twelve were two years of age or less, two were between two and three years of age, one was four years old, two were five years old, one was seven years old, and one was forty-five years old. It will thus be seen that of the nineteen patients only five were above the age of three years. Now let us study the lesions in these patients. Twelve of the nineteen had laryngeal stenosis, requiring intubation or tracheotomy in all; seven of these twelve had pneumonia in addition. In five of the non-laryngeal cases there was also pneumonia. It thus appears that of the nineteen patients, seventeen had laryngeal stenosis or pneumonia or both. The single adult had impending delirium tremens on entrance. This description of these cases shows that they cannot be called mild in type nor could a favorable prognosis be given of them. In fact, the records state distinctly that the prognosis on entrance was good in only six, doubtful in five, unfavorable in eight. Now let us take the fatal cases admitted on the first, second, and third day of the disease in the early months of 1896—thirty-three in all. These patients averaged even less in age than those of the previous year. Seven were under one year of age, thirteen more were less than two years of age, four were just two years of age, five more were between two and three years of age, making twenty-nine in all, leaving only four patients over three years of age. The grade of severity of the cases is indicated by the fact that twenty-two patients had laryngeal stenosis on entrance, requiring operation in nineteen. Fifteen of the thirty-three had pneumonia, two suffered from sepsis, one (the only adult) was intoxicated on admission. The prognosis at time of entrance was

given as good in only two, doubtful in twenty, unfavorable in eleven. In view of the above, the "gist" of these cases selected by Dr. Winters should be about as follows:

"M. C—, two years old, two days sick. No membrane visible, marked croup, retraction of the chest, cyanosis. Intubation required. Prognosis doubtful. Antitoxin injected. Death on the fourteenth day. Broncho-pneumonia on autopsy"; or,

"M. C—, ten months old, three days sick. Throat full of membrane, covering tonsils, soft palate, uvula, and posterior pharynx; nose not plugged, but full of foul discharge; bilateral cervical adenitis; septic rash over body. Prognosis doubtful. Antitoxin injected. Death in nine days from sepsis."

It may be well to give a brief analysis of two or three of these fifty-two cases of the spring months of 1895 and 1896:

CASE I.—William Ashley, eleven years old, three days sick, admitted February 3, 1896. Large sheet of membrane covering tonsils and soft palate and pushing forward the soft palate from behind. Odor septic. Nose plugged so that air could not pass through nor could it be irrigated; bilateral cervical adenitis. Prognosis doubtful. Antitoxin injected.

February 24th, hemorrhagic spots on neck and legs; retraction of chest marked, owing to obstruction of the nose by membrane and of the throat by tonsils and membrane. Stiff rubber tube inserted between tonsils and breathing thus much improved. More hemorrhagic spots in afternoon.

February 25th, patient died of sepsis.

CASE II.—Harry Tarakosky, one and one-half years old, three days sick, admitted February 24, 1896. Croup, cyanosis, retraction of chest, and stridulous breathing; abscess of neck, which had been opened before admission; no membrane in throat. Prognosis doubtful. Intubation. Antitoxin. Death in three days of exhaustion.

The following case is given in order to show one type of disease in which antitoxin, in my opinion, should not be used:

CASE III.—John Leddy, thirty-two years old, three days sick, intoxicated on admission, with marked tremor. Much membrane on both tonsils, uvula, and arches of the palate. In spite of intoxication prognosis recorded as good. On the following day the patient, who had become sober, asked to have antitoxin injected, and one thousand units were given him, this small dose being considered sufficient. In ten minutes after the injection the patient became cyanosed and almost pulseless, and in five minutes more an urticarial rash appeared, covering the entire body with erythematous patches and wheals. Patient's circulation improved under stimulants, but he became violently delirious and died twenty-four hours later. On autopsy diphtheritic membrane was found extending from the pharynx down through the larynx to the lower end of the trachea, though there had been no symptoms of laryngeal or tracheal obstruction during life. Advanced nephritis, cedema of the lungs, and cirrhosis of the liver were also noted. This case would seem to show the necessity of caution in the use of antitoxin in alcoholic patients.

I have gone into the above cases somewhat in detail, as Dr. Winters insists that we should weigh, not count, our cases. These cases have been both weighed and counted, fifty-two in all, comprising all the fatal first, second, and third day cases, in the period selected by himself, the spring months of 1895 and 1896. Were he to select the other eight months of the sixteen during which antitoxin has been used, the results would be the same. Dr. Winters also insists that we should study the fatal cases, not those that result in recovery. Therefore he has not told you that for every eight of the

first-day patients who died, ninety-two recovered; and that for every twenty-four of the second-day patients who died, seventy-six recovered; and that for every twenty-seven of the third-day patients who died, seventy-three recovered.

In his paper of two weeks ago Dr. Winters stated that because of the depressing effects of antitoxin upon the heart, alcoholic stimulation was now resorted to to an extent which was never known in former days. The observation of the other attending physicians to the hospital is directly to the contrary. Since the introduction of antitoxin we have noticed that the treatment of the patients has apparently been much simplified. There has been less need of irrigation of the nose and throat, less necessity for the use of iron and other tonics, as well as a smaller consumption of alcoholic stimulants. For fear, however, that our observations were wrong and that Dr. Winters was right, I have secured a statement from the clerk of accounts and supplies of the Health Department, giving the amount of alcoholic stimulants used in the Willard Parker Hospital in the year 1894 and in the sixteen months since January 1, 1895, when the systematic use of antitoxin was begun. In 1894 there were 14,088 ounces of whiskey consumed in the hospital. In 1895 and the first four months of 1896, there were 18,240 ounces of whiskey consumed. In 1894, with 700 cases of diphtheria and 259 of scarlet fever, there was an average daily attendance of 59.38 patients, giving a daily consumption of alcohol per patient of .65 ounce, or about two-thirds of an ounce. In 1895 and 1896 to May 1st, there were 1,099 cases of diphtheria and 274 of scarlet fever, with an average daily attendance of 85.8, giving a daily consumption of alcoholic stimulants per patient of .43 ounce, considerably less than one-half of an ounce. It appears, then, that there has been less alcoholic stimulation since the introduction of antitoxin instead of an increased amount as observed by Dr. Winters.

It was stated by the writer of the paper two weeks ago that during the past year there has prevailed in the hospital a new type of uncontrollable diarrhœa. Here again Dr. Winters' observations are at variance with those of the rest of the attending staff. In the fifty-two cases which I have had occasion to analyze this evening, a slight diarrhœa is mentioned in just three. There has been but one severe case of diarrhœa during the past winter—a case of colitis—which lasted for some weeks, the patient finally recovering. I should say that we have had more trouble with constipation of the bowels than with diarrhœa. Frequently when a rise of temperature would make us apprehensive of a complication such as broncho-pneumonia or otitis media, a dose of laxative salts or an enema would bring the temperature down to normal. The ward charts of perhaps a majority of the cases show a record of laxatives ordered by the resident physician.

It has been stated by Dr. Winters on more than one occasion that he had observed a peculiar type of broncho-pneumonia during the past year in the hospital, and that there was much suppression of urine and an increased amount of albuminuria, with other signs of renal disease. It has seemed to the rest of us that the broncho-pneumonia was quite of the usual type so commonly seen in the infectious diseases of childhood. Suppression of urine has occurred with about the usual frequency and has generally been relieved by local applications and the use of diuretics. Albuminuria has perhaps been noted somewhat more often, owing possibly to the more careful examination of the urine, but it has seldom been accompanied by casts or other evidence of serious involvement of the kidneys. Cardiac weakness has not been observed more frequently than in former years. Post-diphtheritic paralysis, with the exception of temporary par-

esis of the palatal muscles, has been noteworthy by its absence. I can recall but one case in the past sixteen months in which serious paralysis occurred. In that case the respiratory muscles were involved and the patient died.

It has been stated that since the introduction of antitoxin, cases of a milder type have been admitted to the hospital, many of them having no clinical evidence of diphtheria. In my opinion, cases admitted to the hospital during the past sixteen months have been fully as severe as in the year 1894; the records show that in that year over one-third of the patients had no membrane in the throat or only a small patch on the tonsils. I remember that in the spring and autumn months of 1894 it was with difficulty that I could find patients to show students the characteristic diphtheritic deposit in the throat.

In commenting upon the present mortality of intubated cases in the Willard Parker Hospital—seventy-two per cent., Dr. Winters stated that a former resident of the Willard Parker Hospital reported a mortality of but fifty per cent. without antitoxin in laryngeal cases. Note the two classes of cases compared by him, intubated cases under antitoxin compared with laryngeal cases without antitoxin, laryngeal cases including both operated and non-operated cases. Not even Dr. White, the resident physician referred to, and whom all know to be a most skilful operator, claimed to have saved fifty per cent. of intubated cases without antitoxin. The percentage of mortality as given by him was eighty-five per cent., which are the proper figures to be compared with the present percentage of seventy-two.

In order to show the fatal effects of even a small dose of antitoxin, Dr. Winters cited the case of a child who had been exposed to diphtheria in Bellevue Hospital, had been given an immunizing dose of the serum, and had been sent to its home in Brooklyn, where it died shortly afterward, presumably from the effects of the antitoxin, as it did not develop diphtheria.

The facts of the case are as follows: The patient, Elsie Biershank, four years old, of 200 Freeman Street, Brooklyn, was admitted to the first division of Bellevue Hospital, April 3, 1896, with a history of convulsions. During her stay in the hospital she had occasional convulsive attacks. Another child in the same ward having developed diphtheria, it was deemed advisable to immunize the other children. This was done, but the supply of antitoxin not being sufficient it was given to those most exposed. Elsie Biershank was one of the children who received no serum, and was discharged before a fresh supply could be obtained. This is the statement made to me at the close of the meeting two weeks ago by Dr. E. H. Wright, the house physician of the first division of Bellevue Hospital. The further history of the case is as follows: The patient was discharged and remained well until April 29, when, after exposure to cold, she was taken with dyspnoea. Dr. J. A. Jenkins, of 271 Jefferson Avenue, Brooklyn, was called and made the diagnosis of inflammation of the base of the brain and croup. The child died at 8:30 P.M. of the same day. These are the facts of this case of antitoxin poisoning.

I have not referred to Dr. Winters' general criticisms of the results of immunization, as they will be dealt with by other speakers this evening.

There was one curious omission in Dr. Winters' paper. Although he has attributed the death of patients in a number of instances to antitoxin and has described the clinical features of antitoxin poisoning, he has failed to describe the post-mortem findings in such cases. We have made an especial effort during the past year to secure autopsies in the hospital, and a large number have been made. Dr. Winters was pres-

ent at many of these, and portions of the organs were obtained by him and sent to a laboratory for thorough histological investigation. I have heard of as many as one hundred and fifty microscopical sections having been made of the various organs, and I naturally expected a report from him of the lesions caused by antitoxin and resulting in the death of the patient. He has, however, presented none. It is possible that it may be contained in the portion of his paper which lack of time compelled him to omit at the meeting two weeks ago. I have been present at many of the autopsies myself, and have noted with care the appearances of the various organs. I do not profess to be an expert pathologist, but I have had some experience in gross pathology. Nothing was observed by myself or by any of the gentlemen present at these autopsies which had not been seen over and over again in patients dying of diphtheria and its complications before the use of antitoxin. I believe that Dr. George P. Biggs, the pathologist of the hospital, has expressed himself to the same effect. In view of the importance of this branch of our subject I shall here give somewhat at length the report made by Professor Kolisko, of the University of Vienna, of the results of seventy-five autopsies made by him on patients dying of diphtheria who had been treated by antitoxic serum. Kolisko's competency is attested by the fact that previous to the introduction of antitoxin he had made one thousand autopsies on patients dying of diphtheria during the twelve years from 1882 to 1894. His conclusions are as follows:

1st. He is convinced that the serum influences the diphtheritic process most favorably.

2d. He states that the membranes in the throat, larynx, trachea, and bronchi are more easily separated and are often already loosened or converted into a soft pulaceous mass; he had seen the same thing before the serum treatment, but never to such an extent, or with such uniformity, or so soon after the onset of the disease. It is necessary, however, that a certain period of time shall have elapsed after the injection of the antitoxin. He estimates this period as at least twenty hours. Adequate doses are also required. No such loosening of the membranes is observed after small doses. This favorable effect of the serum is especially noted when the membrane is still in the croupous stage, lying rather superficially upon the mucous membrane. When the process has penetrated deeply into the tissues the effect is much less, or absolutely *nil*.

3d. The anatomical changes in the internal organs are the same as under former methods of treatment. Purulent bronchitis and pneumonia, fatty and parenchymatous degeneration of the heart are constantly observed. The changes in the kidneys are absolutely the same, both as regards the grade of severity and the time of their appearance. Kolisko states that in former years he had often observed that for a period of time every case of diphtheria would be complicated with nephritis, and then for weeks no renal changes whatever would be seen. He has had exactly the same experience since serum has been used. Cases of the largest dosage may perhaps show no nephritis, and those of the smallest dosage may present degenerative changes. He is positive that antitoxin has no effect on the kidneys.

4th. Kolisko lays stress upon the important clinical fact that the diphtheritic process may remain localized at some hidden point, as in a crypt of the tonsil or in the nasal cavity for a considerable time, and then suddenly break out with great virulence, with fatal termination. Microscopical examination often shows a localized lesion of several days' duration in cases of seemingly rapid course in which the disease had set in suddenly in individuals apparently healthy. Such

cases illustrate how we may be deceived when we believe that we are injecting a case on the first or second day of the illness.

In his paper, two weeks ago, as well as in his former publications, Dr. Winters attributed certain statements condemning antitoxin to various physicians attached to the hospitals of the health department of this city. The resident physician of one of these hospitals was quoted as saying that he was sure that at least one of the patients under his care had died from the effects of antitoxin. I am assured by many of these physicians that they do not hold the views attributed to them by Dr. Winters, nor did they authorize him to repeat any of their statements. They differ among themselves in their opinions of the value of antitoxin, but no one of them believes that he has seen death result from its administration. The fact that Dr. Winters should attribute such statements to these men who hold official position under the health board shows how little he appreciates the significance of his own expressions on the subject.

Let me now read to you an extract, taken from the MEDICAL RECORD of April 20, 1895:

"I will ask you to go with me for the time being to the Willard Parker Hospital and see some of the effects of antitoxin which I have witnessed there. Babies have been brought to that hospital with slight clinical evidence of diphtheria; babies, with the exception of a slight exudate in the throat, and perhaps a slight croupy cough, that were apparently healthy and with rosy color. They remained in good condition for perhaps ten days or two weeks after receiving antitoxin, when one day as you enter the ward you hear a moan, and approaching the crib you find the baby lying on its side with its head retracted, its arms and legs flexed, and moaning piteously. This is the condition in which I have seen many of the little babies in the Willard Parker Hospital. The temperature chart shows a record of 105° to 106.8 F., and a note of the night nurse tells that the patient has hardly slept at all. What is this condition? It is due to the action of the antitoxin on the blood. *Horse serum dissolves human blood corpuscles, and thereby produces new elements of decomposition. The condition of the babies just spoken of was one of antitoxin septicemia, and brought about by the influence of the antitoxin on the blood.*

"Autopsies asked for but not granted in any of these cases. Physical examination revealed no evidence of organic disease in either of these cases; they were unquestionably cases of antitoxin poisoning."

The above words were spoken by Dr. Winters in this academy on the evening of April 3, 1895, in the course of a discussion in which he was asked to take part by the gentlemen who had been using antitoxin in the Willard Parker Hospital during the three previous months. Compare the description of these unquestionable cases of antitoxin poisoning with the nineteen fatal cases of the early months of 1895, which have been analyzed above. They are the same cases. Comment is unnecessary.

European Evidence of Dr. Winters.—I shall now take up the evidence obtained by Dr. Winters in the course of his visit to Europe last summer. Who are the great European opponents of antitoxin? Hansemann, of Berlin, Kassowitz, of Vienna, and Lennox Browne, of London.

Hansemann² read a paper condemning antitoxin early in December, 1894, at a meeting of the Berlin Medical Society. Hansemann was attached to the University of Berlin in the capacity of instructor and was also a demonstrator of anatomy. In addition, he held the place of assistant to Virchow, and it was

this last circumstance which gave importance to his words. In the New York MEDICAL RECORD of December 29, 1894, an editorial entitled "An Attack on Diphtheria Antitoxin," was given great prominence. The editorial states that "Hansemann's paper carries especial weight because the author is announced as the assistant to Professor Virchow, and his work and conclusions are presumably endorsed by the dean of modern pathology." In the discussion, however, which followed the reading of Hansemann's paper, much to the surprise of some of those present, Virchow announced himself as having become convinced of the value of diphtheria antitoxin. Some months previously Virchow had expressed great scepticism of the specific nature of antitoxin, and it was not known that he had changed his views. He had, however, been so impressed by the reduction of the mortality of diphtheria under the serum treatment in the Berlin Children's Hospital during the previous six months, that he was obliged to admit that the serum had curative value, although he refused to accept Behring's explanation of its action. Other speakers at the meeting, such as Von Bergmann and Baginsky, disputed Hansemann's conclusions, and proved that the great weight of evidence was against him. From that day to this, Hansemann has not said one word in regard to antitoxin, though he has continued to publish articles on other medical subjects.

Kassowitz¹ made his protest against antitoxin in January, 1895, at a meeting of the Vienna Medical Society. Like Hansemann, he did not believe in the specific nature of the antitoxic serum. His own personal experience of the remedy was limited to eight cases, all of which recovered, but, in his opinion, showed no effect from the treatment. He had also made an elaborate study of the mortality figures of the various children's hospitals of the world, and was convinced that they proved nothing in favor of antitoxin. Kassowitz was answered by Widerhofer, the chief exponent of the serum treatment in Vienna, and it was done so thoroughly that Kassowitz has expressed no further interest in the subject.

I do not know whether Lennox Browne has changed his views of antitoxin or not. I think, however, we can safely leave him to the English, who, though they may be slow, usually come to sound conclusions in the end. Perhaps when they have successfully analyzed the recent report of the London Metropolitan Asylums Board they will be able to convince even Browne that diphtheritic antitoxin has some value.

Let us now turn to the European authorities quoted by Dr. Winters. He first mentions Dr. Cortheron, whom he describes as a London graduate, who afterward studied in Paris under Roux, and subsequently took charge of a diphtheria hospital in London. Dr. Cortheron, after watching the effects of the antitoxin treatment for a few months, went to the medical superintendent of his hospital and protested against further use of the remedy, saying that it certainly did no good—the children died just the same. Dr. Winters' next authority is Dr. Grant, "an Edinburgh student, who studied in Paris under Roux, and subsequently took charge of a diphtheria hospital in London." Dr. Grant told Dr. Winters that his experience with it had convinced him of its uselessness and of its injuriousness in certain directions. It would appear from the above that neither of these two young physicians had had any experience with diphtheria previous to the introduction of the serum treatment. Such evidence as this can hardly outweigh that of such men as von Ranke, Baginsky, Heubner, Widerhofer, Roux, Bokai, and many others who, after an experience of from ten to twenty years in the treatment of diphtheria with

¹ Wiener medizinische Wochenschrift, 1895, pp. 185, 246, 257, 291, 336.

the older methods, have now pronounced unanimously in favor of antitoxin.

Dr. Winters quoted one other European authority, Variot, whom he called a "firm believer in antitoxin," but who had, with greater experience, come to doubt its value. If Dr. Winters will turn to the *Journal de Clinique et de Thérapeutique Infantile*, 1895, No. 9, he will see that even as early as March, 1895, Variot was inclined to dwell upon the untoward effects of antitoxin, rather than upon its curative powers. Variot there ascribes to antitoxin various hurtful effects, such as excessive elevation of temperature, increased pulse rate, weakness of the heart, and arrhythmia. The last number of the *Index Medicus*, issued a few days ago, shows that Variot has continued to dwell upon the unfavorable side of the serum treatment. The following are some of the titles of papers written by him during the year 1895, and published in the French journal referred to above:

1. Are we justified in employing the diphtheritic serum for immunizing purposes in man? p. 181.
2. Observations on the new formation of diphtheritic membrane after injections of serum, p. 241.
3. Remarks on cases of diphtheria associated with tuberculosis, treated by serum and followed by death, p. 281.
4. Uselessness of diphtheritic serum in sixteen cases of toxic diphtheria followed by death, p. 381.
5. Remarks on the pathogenesis and diagnosis of the eruptions following upon injections of serum, p. 881.

There are several more titles of papers, which I shall forbear reading, not one of which indicates a favorable attitude toward antitoxin. Variot could never have been justly called a "firm believer in antitoxin." In fact, I should have included him among the opponents of antitoxin had it not better suited my argument to bring his name in at this place.

Dr. Winters mentioned two continental hospitals as having been visited by him, but, if I remember rightly, his observations extended only to the out-patient department of those hospitals. In Berlin he was much impressed with the methods by which all patients with slight affections of the throat applying to the hospital for treatment were promptly sent into the wards of the hospital, to be there subjected to the administration of antitoxin. In Paris he again noted the loose methods of administration of one of the great children's hospitals, by which children with no clinical evidence of diphtheria were allowed to pass into the hospital, to be there included as real cases of diphtheria and treated as such. It does not appear that Dr. Winters passed any considerable time within the wards of any of the great continental hospitals, in order to judge for himself whether or not the statistics of reduced mortality, of which we have heard so much, had been honestly compiled. I may note in passing that Dr. Winters, though he admits that in every part of the world the use of antitoxin has been followed by an apparent reduction in the mortality of diphtheria, claims that if such reduction be really due to the specific action of the serum it should be uniform everywhere. As he gives no reasons in support of this contention, I would simply ask "Why?"

In his paper of two weeks ago Dr. Winters stated that all the earlier claims for antitoxin had been abandoned. A very short search of the medical literature of the last few months would convince Dr. Winters that directly the contrary is the case. I shall cite a few only of the recent writings on the subject, taking them from such widely separated places as Massachusetts, England, Germany, and Japan.

Dr. J. H. McCollom,¹ of the Boston City Hospital, in an address in February last, at the Boston City

Hospital Club, gave a résumé of the experience in his hospital during the previous year. He stated that, under the serum treatment there had been but 96 deaths of 844 patients treated, or a mortality of 11 per cent., as compared with 40 per cent. in previous years. Of 79 patients intubated only 36 had died, a mortality of 45 per cent. In the previous year of 86 intubated patients 74 had died, a mortality of 86 per cent. He stated also that there was a great change for the better in the appearance of the diphtheria wards, due to the favorable effect of antitoxin on the patients. His whole address was enthusiastic in praise of the new remedy.

Turning now to England, we have the report of the Metropolitan Asylums Board. Although this report leaves much to be desired from the standpoint of clearness, there are some results which are unmistakable. Among these the following are most striking: The mortality in laryngeal cases is reduced, under the serum treatment, from 62 per cent. to 42 per cent., and in operative cases the death rate has fallen from 70 per cent. to 50 per cent. The conclusions, which are signed by all the superintendents of the six hospitals, are as follows: "We are of the opinion that in antitoxic serum we possess a remedy of distinctly greater value in the treatment of diphtheria than any other with which we are acquainted."

In Germany the most recent decided expression of opinion on the value of antitoxin is by Professor Bäumler,¹ of Freiburg. In his opening address, as president of the Congress of Internal Medicine, at Wiesbaden, April 8, 1896, Professor Bäumler said that "the antitoxic serum represents the most important therapeutic advance of modern medicine." He continued that "after eighteen months' trial in Europe and America, the fact is established that the serum treatment is an extraordinarily effective method of curing diphtheria, and is not injurious if given with the necessary precautions."

I shall also refer here to a paper by Dr. Crohn,² of Halberstadt, because he states that he wrote it on seeing the notice in the Berlin papers of the death of the son of Professor Langerhans. Fearing the effect upon the public mind of the words of Professor Langerhans, Crohn believed it to be the duty of every one who had had experience with diphtheria antitoxin to publish that experience. Dr. Crohn had had occasion to use antitoxin in one hundred and fifty cases of diphtheria in private practice. He had had but five deaths in the whole number, although, in his opinion, he would have had at least twenty without serum. The five deaths occurred in cases which had not been seen early or had not been recognized as diphtheria. He had not had any evil effects beyond eruptions, joint pains, and temporary albuminuria, although forty of the cases were severe. In his opinion, "He who does not admit the value of serum, must be bound by theoretical considerations, and cannot have seen an epidemic in which the serum has been properly given, in sufficient dose, in the beginning of each case." Dr. Crohn also used antitoxin for immunizing purposes, and states that of three hundred children immunized not one was injuriously affected beyond urticarial rashes. Of the three hundred patients not one took diphtheria within four weeks of the injections. Seven had the disease after from four to six weeks. All were mild cases, lasting three days only.

Perhaps the most conclusive evidence of the appreciation of antitoxin by the Germans is afforded by their changed views in regard to intubation. The Germans have been reluctant to accept intubation in place of tracheotomy because they feared that the pro-

¹ Centralblatt für innere Medizin, April 25, 1896, p. 430.

² Deutsche medicinische Wochenschrift, April 23, 1896, p. 208.

¹ Boston Med. and Surg. Jour., February 13, 1896, p. 178.

longed stay of the tube would injure the larynx. Von Ranke and others now state, however, that the use of antitoxin permits the earlier removal of the tube, and that they can now make use of intubation with advantage where formerly they employed tracheotomy.

Finally, we have the report of Kitasato.¹ Among 353 cases treated in Tokio there were only 31 deaths (8.78 per cent.). The death rate in Japan in previous years averaged 56 per cent. Of 110 cases injected within forty-eight hours of the onset of the disease, all recovered. Kitasato noted the early separation of the false membrane as well as a fall of temperature, almost critical in many cases.

In the foregoing analysis of Dr. Winters' clinical observations I have not attempted to estimate the exact value of antitoxin in the treatment of diphtheria. I have kept steadily in view the task I set myself at the outset, the task of proving that the children in the Willard Parker Hospital have not been injuriously affected by the administration of antitoxic serum. This purpose I believe I have accomplished. Incidentally it has also been demonstrated that the position of Dr. Winters in regard to antitoxin does not stand the test of critical examination. His descriptions of cases of antitoxin poisoning in the Willard Parker Hospital have no sound basis of fact, and they have not been confirmed by other observers, though they were published to the world more than a year ago.

DIPHThERIA WITH AND WITHOUT ANTITOXIN.²

WILLIAM L. STOWELL, M.D.,
NEW YORK.

THE study of infectious diseases is one of the most important and interesting in medicine.

The astonishing claims made for this new remedy, antitoxin, led me to review my records of cases and to some extent the literature for the same period.

From March, 1888, to March, 1895, inclusive, I treated 176 cases for Demilt Dispensary without antitoxin. As this period in part antedates the bacterial diagnosis, I counted the tonsillitis cases for the same period. There were 551 cases of tonsillitis. In earlier years many membranous cases in scrofulous children were called exudative tonsillitis; therefore no tonsillitis cases are among the diphtherias. The mortality for the seven years was 13.06 per cent. During the year from March, 1895, to March, 1896, I treated 64 cases with 5 deaths; a mortality of 7.8 per cent. The mortality of the total number, 240 cases, was 11.25 per cent. This compares more than favorably with the report of the health inspectors, who treated 255 tenement-house cases with antitoxin, with a mortality of 15.69 per cent.³

Saltmann, of Leipsic, reports 122 antitoxin cases with a mortality of 18 per cent. However, in 1884-85 the physicians of Leipzig collected 1,141 cases under general treatment with a mortality of 15 per cent. before antitoxin was known. In 1,321 cases collected by the *British Medical Journal* in 1858-59 the mortality was 14.28 per cent. without antitoxin.⁴ These were average years in all respects, and tend to show that from 10 per cent. to 15 per cent. is the ordinary mortality in Germany and England as well as in America.

Such cases form a better practitioner's standard than statistics from hospitals, because the latter receive

many very severe cases, while mild ones remain at home.

It seems a singular coincidence that the number of cases of diphtheria should increase so markedly with the establishment of bacterial cultures in 1893. During the three years previous to that year the number of reported diphtheria cases in this city was 4,359, 4,974, and 4,654 respectively. The numbers then jump to 6,469, 9,155, and 9,925 for the next three years, *i.e.*, to the end of 1895.

Similar reports come from Berlin, the cases treated in that city being 3,502 and 3,772 in 1891 and 1892; but bounding to 4,296 in 1893 and to 5,240 in 1894. The ratio of deaths had a corresponding fall from 36.7 per cent. in 1893 to 28.5 per cent. in 1894. The antitoxin used in the hospitals could not so change the death rate of the entire city.⁵

My personal experience showed me that many persons never presented clinical evidence of disease. A case in point is the C— family. A boy of five years had diphtheria on October 12th. The Klebs-Loeffler bacilli were found. On November 7th the rooms were fumigated. One week later the inspector reported bacilli in the throats of the mother and another child. A week later he reported a fourth child, though neither children nor mother believed themselves ill nor took any treatment. Such instances swell the number of reported cases to 9,925.

In the New York Infant Asylum when diphtheria existed there "a systematic examination of the throats of the healthy children showed that diphtheria bacilli were present in so large a number that in order to isolate these nearly one-half of the inmates were quarantined."⁶

We know that the bacilli are in many places and in many throats without giving rise to symptoms. Klebs-Loeffler bacilli were found upon the floor of the diphtheria ward of Boston City Hospital, on scrapings from the shoes of attendants and upon their hair.⁷

Roux and Versin found identical bacilli in 26 of 50 healthy children. They believed them to be Klebs-Loeffler bacilli deprived of their virulence.⁸

Park says: "As is well known, cultures of living bacilli vary from day to day in their virulence."⁹

Something more than the presence of bacilli is needed to constitute the disease diphtheria. Koplik gives more practical advice when he says: "It is proper to regard all specks on the tonsil as suspicious and liable to be diphtheria." "Virulent diphtheria may coexist with follicular tonsillitis." There certainly is an intimate relation between diphtheria and tonsillitis, and I feel sure that in future we shall diagnose fewer cases of tonsillitis and more of diphtheria. In fact, while making the distinction, I have for years given to exudative tonsillitis the same iron treatment I would prescribe for its congener, diphtheria.

The number of deaths from diphtheria in this city in 1894 was 2,359; in 1895, from the same cause, 1,634. The two years are compared, and by some persons antitoxin is credited with the fall in mortality.¹ This is not entirely fair, as 1,634, a low rate in a mild year, is compared with the fatal list of 1894, the greatest diphtheria death list on record in this city, *i.e.*, 2,359. The nearest approach to this was in 1875 when 2,329 died. The following year, in 1876, the diphtheria deaths fell to 1,750 and in 1877 dropped to 951, a fall of 800 in a year, and no enthusiasm was created. In 1881 the diphtheria deaths were 2,249,

but fell the next year 724 points to 1,525. These and many marked fluctuations may be seen by any one who will consult the health board reports.

Fractional reports are very misleading.

Farr lays down the rule "that the determination of mortality requires an extensive area of observation, both in space and time. . . as the causes affecting life are so various that we can only hope to unravel their influence by a general analysis through a series of years."¹

In the reports of the health department regarding the Willard Parker Hospital, we, as New Yorkers, may take just pride. The mortality in that institution as published in the official reports has averaged 24.08 per cent. from 1889 to 1895 inclusive, the time parallel to my records. In 1894, 703 patients with diphtheria entered, of whom 195 died; mortality 27 per cent. In 1895, 822 entered with diphtheria and 190 died, a mortality of 23.10 per cent. The gain is, therefore, less than 4 per cent. for 1895, an antitoxin year, as compared with the most fatal year on record. Many tables quote a series of 32 cases treated at this hospital with a mortality of 25 per cent. against a previous mortality of 42 per cent. By reference to the original article² it is seen that these were cases of three years and under and not representative of all treated. By reference to the table showing percentage of deaths to age in 1894, we find under two years 70.07 per cent. and the same in 1895, namely, 70.59 per cent. From two to four years we have 46.28 in 1894 and 41.50 in 1895, and that with only eight months of 1895 in the count.³ The gains were nearly all made in children over four years old. Much is said of the wonders of 1895 with antitoxin and its low fatality, 23.10 per cent.; but the mortality was still less in 1888, 1889, 1890, and 1893 without antitoxin.

The hospital's best years are in the enthusiasm of the moment forgotten. Lennox Browne⁴ gives the statistics of the Asylums Board hospitals in London from 1888 to 1894, the same period just quoted. During the six years 11,598 cases of diphtheria were treated, with a mortality of 30.3 per cent. During 1895 the same hospitals treated 2,182 cases by antitoxin with 615 deaths, *i.e.*, 28.1 per cent. There were 1,347 more cases treated in the same places and year without antitoxin. It is only when these 1,347 cases without antitoxin are included that the mortality falls to 22.5 per cent.

The report from the Boston City Hospital for December, 1894, and January, 1895,⁵ is an honest example of antitoxin enthusiasm. Eighty patients were given antitoxin, with a fatality of 16 per cent. At the same time 40 were treated without serum, "partly because of the patients entering moribund in five cases, in six because the patients entered very late in the disease. It seemed wise to withhold it in favor of more promising cases, but the majority of cases was mild." The treatment of these mild moribund cases resulted in 30 per cent. of deaths. The health officer who came to Randall's Island hospital declined to give antitoxin to those whom he thought would die, because "it would increase the percentage of deaths." Nor would I inject such cases. The point I insist upon is that all the deaths under any treatment and all hopeless cases are compared with antitoxin, but that it is given when there is promise of good results and withheld in hopeless cases. The advantage of early treatment has been insisted upon for every method ever recom-

mended. Of course the time to put out a fire is at its beginning.

Before giving my results in treatment I will quote what success has attended other remedies than antitoxin.

Huebner¹ reports 117 cases treated by antitoxin with 10.2 per cent. mortality. He had 46 complicated cases, with 21 per cent. mortality. Yet in 1889 he reported a reduction of scarlatina diphtheria from 35.5 per cent. to 10 per cent. by injecting carbolic acid into the tonsils.²

Hennig gives a collective report of 1,054 cases, with a mortality of 2.7 per cent. by the same carbolic-acid treatment.³

Seibert's mortality with chlorine injections was only 5.7 per cent. in 35 cases.⁴

Hübner,⁵ of Frankfort, extols frequent applications of chloride of iron locally. He treated 52 cases with a mortality of 3.8 per cent. Six of them were thought hopeless.

Rosenthal reports 79 genuine cases treated by the same iron treatment; mortality, 8.8 per cent.⁶

Flahaut reports 40 cases in which petroleum was brushed on the throat every hour or two. There were no deaths.⁷

Larcher reports 42 with same treatment and 2 deaths; mortality, 4.7 per cent.⁸

Loeffler himself uses alcohol, toluol, and ferric chloride locally. He reports 71 cases in private practice with no deaths. Also 30 hospital cases with 16.66 per cent. mortality.⁹

Jacobi reports 40 consecutive cases treated with mercury and iron. Mortality, 2.5 per cent.¹⁰

The diphtheria cases at the New York Foundling Asylum from 1890 to 1893 inclusive are especially interesting, as all showed the Klebs-Loeffler bacilli.

The treatment was trypsin, papoid, and hydrogen peroxide. The results were a mortality of 50.7 per cent. in 1890, 52.2 per cent. in 1891, reduced to 38.3 per cent. in 1892 and to 27.64 per cent. in 1893—321 cases in all. Dr. J. L. Smith in reporting them modestly remarked: "Results due in part to change of type and also improved treatment."¹¹ These ratios surpass that of antitoxin and they are neither ancient nor foreign history. Their mortality in 1895 with antitoxin was 45 per cent. Billington reported a total of 225 cases in dispensary tenement practice. The diagnosis was corroborated by Dr. A. H. Smith, Dr. W. T. White, and others. The treatment was iron internally, with carbolic acid and lime water locally. The result was a mortality of 8.4 per cent. in cases fairly tested.¹²

But I will pause. In one evening's work I noted more than 7,000 cases with a mortality of 8.8 per cent., and this without including reports of 571 cases with only 6 deaths, and the like. Most of them are from private practice.

Examining my own cases for the year 1895, I was surprised to find so many more than in previous years.

The explanation is not difficult. With the profession at large, I found myself more particular about exudates in the throat than in former years and more ready to say "diphtheria." The bacterial culture would often help and often fail. Of the 64 cases 14 were reported in the negative as to Klebs-Loeffler bacilli.

Two of these 14 were fœtid cases. In two the germs were found on subsequent examination. Two had extensive exudate and nose bleed. Another had exudate on the palate, uvula, and tonsils. Another was the mother of four children with diphtheria, one of whom died of the septic form. The mother complained of the inflammation of her throat, but no membrane presented. Two died without culture reports, yet the bureau of records did not discredit the diagnosis.

Two cases not in my diphtheria report are of interest—a brother and sister who were typical scarlatina patients. Both had exudate in the tonsils which

clinically was not diphtheria. However, cultures showed Klebs-Loeffler in one but not in the other. Both recovered without treatment. Another girl had scarlatina with marked exudate in the throat and bad discharge from the nose. Loeffler bacilli were found and paralysis developed later.

The general mildness of the cases is shown by the fact that only two were intubated. One of these had pneumonia during the week that he wore the tube. He recovered after a hard struggle.

My treatment during 1895 was the same as for several years previous. A few initial doses of calomel, tincture of ferric chloride throughout, strychnine when

needed as a late stimulant, but no alcohol. Locally, peroxide of hydrogen, fifteen volumes, reduced to half strength by water and a little soda sometimes added. This is sprayed or syringed according to circumstances. Practically no remedy will so readily find and, so thoroughly clear the many tortuous chambers of the naso-pharynx as the hydrogen peroxide. With the same class of patients and the same remedies I unconsciously lowered my mortality from 13 per cent. to 7.8 per cent. Had this been a new treatment these results would have been wonderful.

In reviewing the results of antitoxin treatment I find that I could not escape the unusual complications.

A table will show the frequency of broncho-pneumonia, nephritis, etc., with and without antitoxin:

HOSPITAL OF NEW YORK FOUNDLING ASYLUM.

1894, no antitoxin: 133 cases, 32 die = 40.62 per cent., with broncho-pneumonia.

1895, with antitoxin: 94 cases, 43 die = 79 per cent., with broncho-pneumonia.

CASES IN LONDON. (Brit. Med. Jour., April 4, 1896.)

1894, no antitoxin: 50 cases, 1.6 have broncho-pneumonia.

1895, with " 80 " 3.6 " " "

WILLARD PARKER HOSPITAL.

1894, no antitoxin: 24 cases, 16.9 per cent. with broncho-pneumonia.

1895, with antitoxin: 66 cases, 53.2 per cent. with broncho-pneumonia.

1894, no antitoxin: 1 case, 0.7 per cent. has nephritis.

1895, with antitoxin: 3 cases, 2.42 per cent. have nephritis.

The increase of broncho-pneumonia is so marked that we must believe that the presence of antitoxin favors the development of pneumonia germs.

The proportions of laryngeal stenosis and sepsis fell off in 1895 as compared with 1894.

The paper by Dr. Welch¹ has had a wide reading because of the great number of cases tabulated. But if the premises are wrong the conclusions cannot be right. The paper is based on the reports of antitoxin advocates, and those alone. The only comparison is with the deaths these same men think they had before antitoxin, when all deaths were counted.

No. 68 in his tables reports 225 cases, with mortality of 15.5 per cent. vs. about 55 per cent. previously—an accurate statement against a guess. This author says: "I have therefore reduced my mortality somewhat by not injecting hopeless cases of septicaemia."²

No. 69 is a report of 255 cases, "mostly in tenebments." Mortality, 15.69 per cent. vs. 25 per cent. to 45 per cent. previously—hundredths of a per cent. against a sliding scale of 25 to 45 per cent. The only published records I can find of similar cases are by Smith, Billington, and Stowell, which aggregate 495 patients, with mortality of 10.50 per cent.

No. 70 is of 164 hospital cases, with a fatality of 27.4 per cent. vs. 32 per cent. previously. The official reports of the same hospital have averaged 24.08 per cent. since 1888, as published by the health board.

No. 82 is Mason's report of 306 cases in Boston City Hospital, with a mortality of 26.4 per cent. As stated previously in this paper, 40 cases were eliminated in this hospital in the six weeks from December 13th to January 31st, and their mortality was 30 per cent.

In Dr. Welch's Table II. the mortality in operative cases with antitoxin is given as 61 per cent. vs. "90 per cent. (?) previously"—another inference. Lovett³ recorded all the operations from 1886 to 1891—in all, 719 cases; mortality, 74.13 per cent.

In Table II. Kraske is reported as treating 16 cases

by tracheotomy and antitoxin; mortality, 31.25 per cent. Previously he did twelve tracheotomies without antitoxin. The mortality was 6.25 per cent. better without antitoxin than with it, yet Dr. Welch says: "Kraske's exceptional series is of so few cases [only 5 (?) with and 12 without serum] as to be without significance." If such numbers have no significance, thirteen reports based on the same and smaller numbers should be dropped from Table I., and fifteen reports, *i.e.*, one-third, from Table II. of operative cases.

Körte reports 81 recoveries to 40 deaths, *i.e.*, 33.1 per cent. mortality, but the original article says 10 moribund cases at the same time were not injected.

Heim¹ reports his cases in two groups: one of 27 cases, mortality 22.2 per cent., one of which cases was on hand when the report was made. Group 2: "21 cases, 4 of which died and 12 of which are on hand at time of report, but 10 of them will surely get well, giving a probable mortality of 28.5 per cent." Only half of this report appears in the table.

In four hospitals the mortality rose as the supply of serum failed, and fell when serum was resumed. Naturally so, as all suspected cases get serum and all moribund and hopeless ones are eliminated. When there is no serum there is no elimination of hopeless cases. A chain is no stronger than its weakest links.

As a method to convince myself of the value of antitoxin, I resolved to use it entirely in my service at the Randall's Island hospitals and at Demilt Dispensary during the following year. If it will do as claimed (Welch)—reduce my mortality by one-half and give me 3.5 instead of 7.8 per cent. for 1896—I shall be glad to report myself next year a hearty advocate of the treatment.

Thus far my mortality with antitoxin at Demilt has been 12.5 per cent., and at the hospital 53 per cent. This study of my personal experience will, of course, convince no antitoxin advocate; but with more than 7,000 creditable cases to agree with mine, it seems that the "behind-the-times" physician has good ground for a conservative view.

For immunizing nothing is better than fresh air and sunlight. My cases last year occurred in fifty families. In only eight of them did the cases duplicate. As Rotch² says: "With extreme care there is not much danger of the spread of diphtheria in a household, as its tendency is not to disseminate itself in the surrounding atmosphere."

This study of my own and others' cases convinces me of the following points:

That diphtheria is very variable in extent and severity, both epidemically and clinically.

That the diagnosis of true or false diphtheria requires as much care bacteriologically as clinically.

That the unusual number of cases recorded is in part due to bacterial cases without symptoms and the general alertness of physicians now to report suspicious cases.

That the same causes plus elimination give the apparently low ratio of deaths.

That cleanliness and ventilation will immunize as well as hypodermic serum.

Diphtheria is a treacherous disease under any treatment. Selected cases and faithful treatment of any reasonable kind lead to success. Jules Simon was correct in saying: "Efficiency of remedy not only, but fidelity in its use" give results.

25 WEST THIRTY-SIXTH STREET, NEW YORK.

Ether Collapse.—One part of camphor to ten parts of olive oil used hypodermically is effective in ether collapse. One grain of camphor may be given.

PERSONAL EXPERIENCE IN THE TREATMENT OF DIPHTHERIA WITH AND WITHOUT ANTITOXIN.¹

By P. H. ERNST, M.D.,

NEW YORK.

SINCE May, 1895, I have treated in private practice and as visiting physician to the Demilt Dispensary seventy-seven cases of diphtheria. I report only those cases in which the clinical diagnosis was sustained by the bacteriological report from the board of health. Of these seventy-seven cases twelve were treated with antitoxin, and sixty-five were treated without antitoxin. In all cases iron was given, with the local application of peroxide of hydrogen to the nose and throat; mercury was not used, except an occasional dose of calomel to act on the bowels.

I wish to say that most of these cases were of dispensary patients, and that their sanitary surroundings and nursing were often of the very worst. A brief account of the twelve cases treated with antitoxin is interesting.

CASE I.—J. S—, aged four years. Ill two days; membrane on tonsils and pharynx; some dyspnoea, showing involvement of larynx. In twelve hours laryngeal obstruction became so severe I resorted to intubation, with relief of dyspnoea; at the same time I injected twenty cubic centimetres of Gibier's antitoxin. On the fourth day I removed the tube, but three hours later had to reintubate. Another injection of ten cubic centimetres of antitoxin was given. The membrane did not disappear until the tenth day, when the tube was removed and the child recovered.

CASE II.—M. K—, aged five years. Had complained of sore throat for several days; examination showed tonsils and palate covered with pseudo-membrane. Three hours later I gave injection of fifteen cubic centimetres of Gibier's antitoxin. The next day marked dyspnoea showed extension of membrane to larynx; the same night intubation had to be done for the relief of the dyspnoea. I removed the tube on the seventh day. Convalescence was very slow and at the end of three weeks the patient developed a bronchopneumonia, which terminated in a cavity of the right lung.

CASE III.—A. K—, aged three years. Ill two days; when I saw her there was diphtheritic membrane on tonsils and palate. I injected fifteen cubic centimetres of Gibier's antitoxin; the throat cleared of membrane on the eleventh day and she recovered.

CASE IV.—A. L—, aged eight years. Had been ill two days; diphtheritic membrane on tonsils, pharynx, and in nose; glands of neck much swollen. I gave twenty cubic centimetres of Aronson's antitoxin. Next day the membrane had extended; the patient grew worse, and died on the third day, with marked meningeal symptoms.

CASE V.—P. B—, aged twelve years. Ill seventeen hours; diphtheritic membrane on tonsils, palate, and pharynx; cervical glands swollen. I immediately gave injection of ten cubic centimetres of antitoxin prepared by the board of health. The patient grew steadily worse, and two hours before death had convulsions. He died twenty-eight hours after injection of antitoxin. No examination of urine had been made.

CASE VI.—W. G—, aged six years. Parents stated that the child was in perfect health until 5 P.M.; he then complained of headache and vomited. I saw him two hours later. Examination of throat showed a small patch of membrane on the left tonsil. Ten hours later and twelve hours after the child was first taken ill, I injected five cubic centimetres (or fifteen hundred units) of antitoxin prepared by the board of

health. The membrane continued spreading and covered both tonsils and palate; death ensued twelve hours later.

CASE VII.—G. B—, aged two and one-half years. Had been ill three days before I saw her; membrane on tonsils and palate; cervical glands swollen. I gave injection of ten cubic centimetres of board-of-health antitoxin. As there was no improvement in twenty-four hours, I gave another injection of five cubic centimetres of antitoxin. The child died on the fifth day.

CASE VIII.—G. S—, aged two years. Diphtheritic membrane on tonsils only; had been ill twelve hours. I injected ten cubic centimetres of Aronson's antitoxin. Next day the membrane had extended to the pharynx and dyspnoea showed invasion of the larynx. Another injection of antitoxin was given; stenosis increased and it became necessary to intubate. This was done, with relief to dyspnoea. The third injection of antitoxin was given without the slightest sign of improvement in the child's general condition or the appearance of the throat. He died on the fifth day. Two brothers of this child were suffering from diphtheria at the same time; they were treated without antitoxin and both recovered.

CASE IX.—J. K—, aged three years. Had been ill four days; when first seen examination of throat showed pseudo-membrane on tonsils and palate. Fifteen cubic centimetres of Aronson's antitoxin were injected. Next day the membrane had invaded the larynx. Intubation was done for the relief of laryngeal obstruction; the membrane cleared away on the seventh day and recovery followed.

CASE X.—M. M—, aged twenty months. Diphtheritic membrane on tonsils only. I gave injection of ten cubic centimetres of antitoxin prepared by the board of health. The child died in convulsions fifteen hours after injection.

CASE XI.—B. F—, aged nine years. The child was ill twenty-four hours before I saw her; tonsils, palate, and pharynx covered with pseudo-membrane; glands of neck much swollen. I at once gave injection of ten cubic centimetres of antitoxin (board-of-health preparation). No improvement was noted; the child died on the fourth day.

CASE XII.—G. K—, aged three and one-half years. Ill two days; tonsils and palate covered with membrane. I gave injection of five cubic centimetres of antitoxin of board of health. The throat gradually cleared of membrane; the child was well on the tenth day.

Of these twelve cases treated with antitoxin I considered eight as severe and four as mild in character. Four patients were intubated, one of whom died. Ages of those who died: Three were from twenty months to two and one-half years old, one six years, one eight years, one nine years, and one twelve years. The ages of those who recovered ranged from three to five years. Recovered, five; died, seven. Mortality, over fifty-eight per cent.

A description of a few of the cases treated without antitoxin is in order:

CASE I.—J. R—, aged five years. Had just recovered from measles; membrane on tonsils and pharynx; glands of neck much swollen. The throat cleared on the eighth day. On the tenth day there was suppression of urine, and the child died of uræmic convulsions.

CASE II.—J. C—, aged two and one-half years. Had been ill several days; membrane on tonsils and pharynx; severe dyspnoea showed invasion of larynx. The child had rickets, and was anæmic; the cervical glands were much swollen, and his body was covered with large sores, supposed to be pemphigus. Intubation gave relief to dyspnoea. On the fourth day I removed the tube; three hours later I was called to re-

¹ Read before the New York Academy of Medicine, June 4, 1896.

insert it. The following day broncho-pneumonia was diagnosed and treated. The pneumonia resolved; the tube was removed on the tenth day and the child made a good recovery. This was the worst case I ever saw, and recovery was little short of miraculous.

CASE III.—R. S.—, aged two years. Membrane on tonsils and palate; laryngeal obstruction became so severe that intubation was done. The tube was removed on the fourth day; dyspnoea gradually subsided, and the child was well on the twelfth day.

CASE IV.—J. A.—, aged three and one-half years. Had been ill three days without medical care; pseudo-membrane on tonsils and pharynx; glands of neck much swollen; dyspnoea severe. The same night I saw the child it almost died from laryngeal obstruction. Intubation was done, the tube being removed on the fifth day. Twelve hours later it again became necessary to intubate. The tube was removed on the eighth day; recovery was complete.

Forty-two of the sixty-five cases treated without antitoxin were of a severe form, while twenty-three I considered mild in character. Eleven patients were intubated, with four deaths. Of the total number of sixty-five cases treated without antitoxin there were eleven deaths, giving a mortality of seventeen per cent. Five deaths occurred in children between the ages of six months and two years, two between two and four years; one was five years, one six, and two ten.

When I began the use of antitoxin I had implicit faith in its remedial effects, but careful observation of the cases just enumerated convinced me that antitoxin does not exert the slightest favorable influence on the course of diphtheria. In fact, it is my opinion that the antitoxin patients who recovered had a more protracted convalescence, the anemia especially being more marked and less amenable to treatment than in those who recovered without antitoxin.

Progress of Medical Science.

Painful Temporary Paralysis in Children.—Dr. Brunon discusses painful temporary paralysis occurring in young children. Out of twenty-two cases two had paralysis of the lower extremities, all others having the arm only involved (*British Medical Journal*). In all there was an absolutely sudden onset, sometimes following the slightest traumatism; often no cause was observed. The paralysis is complete from the onset; amelioration is gradual. The child screams when the slightest examination is attempted. No anatomical lesion is found except occasional creaking of the joints. Recovery takes place in from twenty-four hours to a week. Most authors take the view that there are in such cases anatomical lesions such as subluxation, stretching or twisting of ligaments. Brunon believes with Chassaignac that in the cases in question any idea of fracture, dislocation, or tearing of ligaments may be dismissed, as no deformity, ecchymosis, or interrupted movement of joints can be found. A differential diagnosis is needed between this and the form of paralysis due to partial dislocation of the head of the radius, a pathognomonic sign of the latter being the impossibility of supination. In the cases under consideration all hung limply by the side and could be freely flexed, pronated, or supinated. The initial lesion may be an injury to ligaments, but examination fails to localize the injury. Pain is general from shoulder to finger tips. The condition appears to be due to a reflex inhibitory action, of which other examples are numerous and which affords a rational explanation of the paralysis. An intellectual factor, the memory of the initial pain, explains the persistent crying of the child, the fear of being touched. There

is no pain when the child is not handled. Much depends on the influence of suggestion made by those in charge of the child.

Blood Changes in Syphilis in Relation to Therapy.—Dr. Reiss has studied the hematic changes observed in a number of syphilitic patients who were under systematic mercurial treatment. Two hundred cases in all were observed, and in most of these subcutaneous injections of sublimate were administered. The results of his investigations have been published in the *Deutsche Medizinische Zeitung*, March 2, 1896, and may be briefly summarized as follows: The red-blood corpuscles are diminished in number even in the earlier stages of primary syphilis. When the cutaneous manifestations appear this diminution becomes more marked and gradually increases as the disease advances. Even after treatment has been begun this corpuscular decrease continues for a certain length of time. The number of leucocytes remains unchanged during the period of primary invasion. Later on, when the skin eruptions appear, a gradually increasing leucocytosis is observed. In regard to the reduction of the proportion of hæmoglobin, it begins as early as the first appearance of induration in the primary sore. Later on it steadily increases. But the appearance of the eruption has no further perceptible effect in this connection. Under mercurial treatment a steady increase in the proportion of the red corpuscles is observed. After a systematic course of mercurial treatment the proportion of leucocytes to other corpuscles is found to be normal. Pushed beyond a certain limit, mercurial treatment no longer results in an increase of red corpuscles. On the contrary, a reduction in their number is noticeable. The blood plaques of Bizzozero are in no way affected either by the disease or by mercurial treatment. It will be seen that these observations merely confirm what has been generally accepted by the profession as explaining the beneficial effects of mercurial treatment in syphilis.

Gonorrhœal Immunity.—Dr. Janière recently endorsed the theory of Guiard to the effect that gonorrhœa is a self-limited disease, recovery following after a varying length of time, without any treatment other than ptisanes, bath, and hygiene (*American Journal of the Medical Sciences*). Abortive treatment does not succeed rapidly and fully until the period of acute inflammation has passed. A patient, either male or female, apparently though not really cured, is capable of transmitting a subacute gonorrhœa—that is, the colorless drop of secretion is capable of inoculation if it contains a few gonococci. He believes that the gonococcus during its evolution modifies its culture medium—i.e., the urethral mucous membrane. It continues to grow there, but becomes more and more attenuated and latent, until it finally disappears. Unless this be true, a gonorrhœa untreated would last indefinitely, the cocci multiplying and reinoculating themselves in the infected urethra continuously. When the virulence begins to diminish abortive treatment succeeds. If, on the other hand, this attenuated gonococcus comes in contact with a healthy mucous membrane in another individual it is immediately rejuvenated, prospers, and produces acute gonorrhœal symptoms, since it finds there a suitable culture medium, which is not exhausted like that whence it came and where it was about to die. The objectors to this theory say: If you admit that the rôle of the culture medium is thus superior to that of the microbe, how can you explain acute attacks in men having gleet? How can their exhausted mucous membrane become reinoculated? Guiard believes reinfection is impossible in cases where the gleet discharge contains cocci. He, however, reserves his opinion regarding this form of relative immunity until further facts are procured.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 20, 1896.

THE ANTI-VIVISECTION BILL OF THE DISTRICT OF COLUMBIA.

THE anti-vivisection bill of the District of Columbia, concerning which so much has been said and written and against the passage of which so many protests from leading medical societies have been made, is apparently holding its own against the opposition of the entire medical profession of the country. So far as has been learned, the United States Senate is committed in its favor, and there will be a struggle in the House the coming autumn to secure its passage. The influences behind it are all-powerful, and although it is nominally backed by the Humane Society of the District alone, the latter organization has the endorsement of the National Humane Society, with active working branches throughout the different States. The bill itself is ingeniously framed with the apparent intention of conceding everything reasonable to experimental scientists, but is in reality intended to hamper them in every possible way by the restrictions as to details of procedure in given cases, which are virtually under the supervision of laymen, whose knowledge of requirements is naturally biased by preconceived notions of antagonism. The movement is founded almost entirely on the erroneous assumption that most if not all experimental work in the line of vivisection is founded on cruelty and that parties interested in its development are necessarily brutal. Any appeal based on such arguments is very apt to enlist the active co-operation of every humane individual, lay or scientific, and to be convincing to every one who may give the subject casual attention. For the purpose of enlisting popular sentiment against present methods numerous stories are told of cruelties perpetrated in physiological laboratories which are calculated to arouse indignation and to stimulate every laudable instinct of antagonism against their continued perpetration. Especially is this evident in connection with some of the so-called horrors of foreign vivisection. While some of these may have enough of truth in them to call for action, they are nevertheless so highly colored with impossibilities as to lose their true force on calm examination. The profession of medicine is humane by instinct, its training is such as to stimulate and develop sympathy for the weak and suffering, and why it should be charged with such an entirely opposite character it is more than difficult to imagine. Its highest mission is the avoidance of pain and suf-

fering in all conceivable varieties of these conditions, and that any exceptions should be made in the case of helpless animals passes every reasonable conception. So far as mere cruelty is concerned, which is never necessary, the profession is only too willing to lead any and every movement calculated to lessen its infliction rather than be forced by a few cranks to act on the defensive. It does not become us to go over the old story of the benefits which mankind has derived from laboratory investigation, of the knowledge of living processes that otherwise would never have been known, the countless number of lives saved as the result of such work, the extent to which preventable diseases has been limited, the improvement in operative methods which has guaranteed safety to the human subject, the increased number of valuable therapeutic agents added to our materia medica, the practical knowledge of toxicological actions of valuable remedies, and the indispensability of animals in the proper scientific proving of bacteriological problems upon which in future may depend the wider and grander possibilities of orrhoterapy. All these are so much matters of history as to require no reiteration, nor does it serve any practical purpose to offer arguments on facts which are either purposely misinterpreted or boldly denied. All such matters were settled long ago by such as are best able to judge. What concerns the profession now, however, is the means to the end of defeating the intentions of the advocates of the bill in question. Unless something more is done than appears to have been done already, Congress may pass the bill, and it may be both too late for protest and past the time for prayer. There is no doubt that if this bill becomes a law it will be the basis of a similar law for every State. Every physician should in his individual and public capacity use every influence upon members of Congress to avoid the chance of trusting such vital scientific interests to the mere chances of a passing vote. When the bill comes before the House the friends of progressive science should be ready and in waiting.

INCOMPATIBLES FROM THE DRUGGISTS' STANDPOINT.

PHYSICIANS are very apt to be critical as to the work of the druggist who compounds their prescriptions. In a series of articles and discussions in the *Journal of Medicine and Science*, several druggists have presented their side of the question, and show that doctors sometimes do not prescribe in an ideal way. Mr. T. J. Stevens, of Portland, Me., after making some observations upon the subject of "Incompatibles, Chemical and Therapeutical," states that a rather common mistake is made in prescribing the salts of the alkaloids. The addition of an alkaline hydrate to a solution of these salts causes them to precipitate. He had, at the time of his writing, a prescription containing a mixture of morphine sulphate, bromide of soda, and cinnamon water, in which the bromide of soda decomposed the morphine salt, precipitating the pure alkaloid. Another noteworthy incompatibility is that of

tannin with the salts of the alkaloids. A prescription was received containing tannic acid and sulphate of morphine. This produces an insoluble tannate of morphine. Another curious thing, that still continues to be prescribed, is "colorless tincture of iodine," made by the addition of hydrate of potassium to tincture of iodine. This is really a solution of the alkaline iodides. Mr. Stevens remarked that the medical profession is unusually generous in supplying material for his discourse, and soon after getting his morphine and bromide prescription he received one containing calomel and syrup of iodide of iron. The calomel is decomposed by the iodides or bromides and metallic mercury is liberated, which is described as "a powerful poison"—a statement to which we can hardly agree; but, all the same, it is not what the patient is expected to receive when calomel is prescribed. A frequent incompatibility is the addition of tincture of iron to some bitter tonic containing tannin, by reason of which the patient receives a more or less agreeable preparation of ink. If water is added to tincture of cannabis indica in a prescription, as is sometimes done, the resin of the cannabis rises to the top and the patient gets a very strong dose, unless the bottle is well shaken.

The Portland physicians seem to be, on the whole, however, rather careful prescribers. The occasional mixing up of mucilage of acacia with spirits of nitre or other strongly alcoholic fluids, and the addition of iodine to oil of juniper, are examples of what might be considered "breaks" in the matter of proper prescribing.

In the discussion by physicians, which followed that of the druggists, the possibility of making mistakes or prescribing incompatibles does not seem to be very much considered. The burning question in Portland seems to be, rather, whether a physician should prescribe at all or should dispense his own drugs. Radical opinions were expressed upon both sides, but the general view was the very sensible one, that both practices should be adhered to.

LAPAROTOMY FOR PTOSIS.

THE activity of the surgeon as regards the opening of the abdominal cavity has undergone many changes, with, however, a constant tendency to an increase in the indications for the operation. From laparotomy, at first simply for ovarian tumors, the operation extended to the entire removal of the ovaries and annexæ, and then to that of the uterus and pretty nearly all the pelvic organs. An important diversion was made when the operation for appendicitis became popular. Later, the vogue became and still exists to operate upon the kidneys, although this, of course, does not usually involve entering the abdominal cavity. For a long time operations upon the liver, stomach, or bowels have been frequently undertaken.

Perhaps the latest extension of the application of abdominal section is to the treatment of Glénard's disease. Mr. Frederick Treves, in a recent number of the *British Medical Journal*, gives a description of

this trouble, and reports a case in which he opened the abdomen for the purpose of relieving the condition. Glénard's disease, or abdominal ptosis, has been described in these columns a number of times. It can hardly be called a disease at all, but is a series of symptoms, more or less definite, depending, it is supposed, upon relaxation of the abdominal wall and of the supporting ligaments of the viscera. The right bend of the transverse colon is first to fall, then the stomach is drawn down, then the rest of the transverse colon, and, finally, the whole mass of the small intestine becomes prolapsed. The liver and kidney become loose and are described as "floating." The result of these conditions depends necessarily upon the extent to which the ptosis has involved the viscera. There are general disturbances of an anæsthetic character, nervousness and hysterical phenomena, and dyspeptic obstruction of the bowels, sense of weight and dragging, and pain over the region of the viscera.

Mr. Treves' case was that of a young woman who had suffered from this condition for a long time. He advised the operation of laparotomy, and found that the liver and stomach were low down. The great omentum was rolled up into a round and rigid cord, and fixed in a collection of old tuberculous glands, situated in the mesentery of the ileum. These glands were removed and the viscera replaced. The patient made a good recovery and was much improved.

Mr. Treves' case will probably set surgeons to work upon this new field, which, we trust, will be explored with wisdom and caution.

THE DISCUSSION OF ANTITOXIN BEFORE THE ACADEMY.

THE interest manifested in the discussion of the use of antitoxin in diphtheria before the New York Academy of Medicine at the last two meetings of that body has called forth such a large quantity of valuable material on the subject that we have been compelled, contrary to our custom, to devote an unusual amount of space to one topic. This has been done in view of the apparent necessity for giving all parties concerned an impartial hearing, and in thus presenting the fullest authoritative report possible under the circumstances. We venture to say that never before in the history of antitoxin have so many and valuable facts been presented in a single number of any journal, bearing upon the practical applications of the agent to so large and varied a number of cases. The data thus collected have their own importance in enabling our readers to judge for themselves as to the real value of this new but extensively tried treatment for diphtheria. The pros and cons have a fair presentation, and the disputants show an earnestness of purpose and purity of motive in the presentation of their respective sides which must commend itself to the thoughtful consideration of every seeker after truth. It is fair to state, however, that all the available testimony has not yet been offered, as in a future issue we shall publish a carefully prepared report from the American Pædiatric Association, comprising an analysis of many thousands of cases bear-

ing upon the present questions at issue. In view of the great popularity of the antitoxin treatment, the whole subject deserves the most careful study, the most impartial examination of facts, and the greatest deliberation in arriving at a calm and just conclusion. It is for the sake of affording the necessary means to such an end that the *MEDICAL RECORD* virtually devotes one of its issues to the discussion in question, to the necessary omission of its more usual variety of contents. Whether or not any apology is necessary under the circumstances, we leave our readers to determine.

News of the Week.

Contract Medical Practice in California.—At the recent meeting of the California State Medical Society in Los Angeles, a resolution was introduced to the effect that in the opinion of the society it is contrary to the spirit and letter of the code of medical ethics to perform contract lodge practice, and that in the future no physician be admitted to membership in the society who holds such a position, and that members who may now be thus engaged be warned that a renewal of their contract will be construed as contrary to the spirit of this resolution. This was referred to the executive committee, which reported favorably, and it was decided by the society to bring the resolution up for consideration at the next meeting.

Two Suits against Ohio Doctors are reported in the *Columbus Medical Journal*. In her petition in the first case the plaintiff states that she was ill and required the use of hot applications to her body, and her sufferings were so intense that the defendant, as her physician, deemed it advisable to use anæsthetic remedies and narcotics, so that the plaintiff became unconscious, and while in such condition defendant caused hot plates and irons to be placed upon and about her, heated so hot that they burned her feet to a crisp, leaving wounds and sores from which she has never recovered. In the second case a woman sues for \$10,000 damages sustained by the death of her husband. She alleges that the surgeon told her her husband was suffering from appendicitis and that it would be necessary to perform an operation upon him to save his life. She gave her consent, but for a week after the diagnosis had been made and the arrangements made for the operation, her husband was allowed to suffer until he became weak and emaciated, and was then carried ten miles in an ambulance into the country for operation. She claimed that her husband was under the influence of the anæsthetic for an hour and a half, the effects of which, with the alleged unskillfulness on the part of the surgeon, are said to have been the cause of the patient's death on the day following the operation.

Medical Nomenclature.—There seems to be a tendency, in the coinage of new words to express new thoughts, to choose the most cumbrous word to the exclusion of one that is euphonious and correct in its

formation. Thus, the barbarous sero-therapy or serum-therapy appears to have gained the field in place of the much better "orrhotherapy." Organo-therapy is another wretched word, which might well be replaced by "opotherapy" (from the Greek word for juice), as suggested by Professor Landouzy, of Paris.

A Scientific Objection to a Hygienic Measure.—

It is not often that a public measure of known sanitary value is opposed because its action cannot be satisfactorily explained, yet this is what Dr. Patrick Manson has recently done. He has been delivering the Goulstonian Lectures on malaria, and in his last lecture warns the Indian government against the unwisdom of sanctioning the expenditure of large sums of public money on certain drainage schemes which have been proposed for rendering salubrious some pestiferous districts, and bases his opposition to the scheme on the ground that our knowledge of the plasmodium malarie is incomplete. He holds the theory, which has been advanced also by Marchiafava, that the plasmodium is conveyed to man by the mosquito, and his idea appears to be that, because this pestiferous insect is not driven from a locality as soon as this is drained, therefore drainage is of doubtful utility as a sanitary measure, in regard, at least, to malaria. But the mosquito does not create the plasmodium, and if the latter be exterminated, it is difficult to see how the mosquito can still transport it.

The Medical Profession Passed By.—In the list of "birthday honors," that is to say, of persons upon whom a knighthood or baronetcy is conferred by the Queen on her birthday, there appears the name of no medical man in civil practice this year, although some army surgeons have received decorations. It is seldom that some one of the British profession is not so honored each year, and there is more or less keen disappointment in consequence.

Autotoxic Insanity.—At a meeting of the Medical Society of London, on May 11th, Dr. Allan McLane Hamilton, of this city, read a paper on the connection of autotoxis with certain forms of insanity, in which he considered at length the dependence of certain forms of psychic disturbance on the absorption of the soluble products of intestinal putrescence. The following were the conclusions of his paper: (1) Urines rich in indican contain very little or no preformed sulphuric acid, and are toxic; (2) when the sulphate ratio is materially changed it probably indicates autotoxis in connection with an increase in the amount of combined or ethereal sulphates; (3) such indications are generally found with acute insanities in which rapidly developing symptoms occur; (4) fugacious and changing illusions and hallucinations, unsystematized delusions, confusion, and verbigeration in connection with insomnia, pallor, intestinal indigestion, constipation, and rapid exhaustion are due to autotoxis; (5) paranoiac states, or those in which concepts are the main feature, chronic stuporous conditions, and certain forms of dementia have little to do with the formation of the intestinal products of putrefaction; (6) various post-febrile, traumatic, alcoholic, or drug insanities

are those in which autotoxis is most constant; (7) the variations in the excretions of combined sulphates keep pace in the changes with the progress of an established insanity, *aac's* and epileptiform attacks being directly connected with putrefactive processes: (8) 'the most successful treatment consists in lavage, intestinal douches, gastric and intestinal antiseptis by means of hydrochloric acid, borax, salicylate of soda, charcoal, guaiacol, or naphthalin, in small and repeated doses, associated with the administration of a combination of the red marrow from the small bones, blood, and glycerin.

Passaic River Pollution.—The Passaic River pollution commission, consisting of Dr. Herold, of Newark, Dr. Marsh, of Paterson, W. T. Hunt, of Newark, and W. G. Scott (secretary), of Paterson, which has been gathering statistics as to the quantity of refuse daily dumped into the river by the cities along its course, recently held a conference with the health officers and property owners of towns along the river, in order to obtain information as to its effects upon the public health and real estate values in these towns. The unanimous opinion was that the Passaic River was in a frightful condition. According to the report of this conference in the *Evening Post*, property values have become depreciated in both the towns, and prominent residents have been obliged, because of the stench arising, to close their houses and move elsewhere. All along the river roads stand a string of mansions which are deserted by their owners. Within the recollection of young men the river was a clear stream and the fishing industry cut a considerable figure. Now it is a dirty, noisome mass of sewage. It was formerly a favorite boating resort, but the boat-houses along its shores are being abandoned and turned to other uses. The residents along its banks are obliged to close their windows even on hot summer nights in order to keep out the smells. It is impossible to rent desirable houses, and property owners are consequently unable to pay taxes. The sewage, instead of being carried out to sea, is floated back and forth on each tide until it is deposited to decompose. The acids formed have so eaten the boilers of some of the factories that the owners have had to put down artesian wells to secure a water supply that they could use.

The British Medical Journal of May 23d is a Jenner centenary number, the greater part of its space being devoted to the life and works of Jenner and to a discussion of vaccination. Among the special features the most interesting is the reproduction of thirty colored plates by George Kirtland, contrasting the sore resulting from small-pox inoculation with that following vaccination, the differences being shown day by day from the second to the sixteenth day inclusive. The plates were published in 1802, and were accidentally discovered in a London bookstall some ten years ago by Mr. G. W. Collins. Little seems to be known of Kirtland except that he was an artist who did good work, having among other things illustrated Freeman's "Mechanism of the Horse's Foot," published in 1796, in which work the author speaks of

him as "a draughtsman who could represent with accuracy anything that was set before him." The reproduction in the *British Medical Journal* is excellently done.

Diphtheria Antitoxin in Hungary.—Prof. J. Bókai, of the Stefania Hospital, in Budapest, has treated four hundred and two children suffering from diphtheria with antitoxic serum of German, French, and Hungarian make respectively. He noted a mortality of 22.5 per cent. In those cases which required operative measures the mortality rose to 44.5 per cent., while in lighter cases it sank to 10½ per cent. Taken as a whole, the mortality from diphtheria in Budapest attained in pre-antitoxic times an average of from 34 to 37 per cent., while in the days of serum treatment the mortality is 21 per cent. It is also to be noted that formerly only from 8.6 to 15.2 per cent. of the diseased escaped operative interference, while under serum treatment 26 per cent. of the cases did not require any operation for laryngeal obstruction. In 22 per cent. a more or less marked exanthema followed the injections, especially those which had been effected with Hungarian serum.—*The Lancet*.

Curious Methods of Hospital Begging in London.

—In commenting on the expressed disapproval by the Hospital Sunday Fund of street collections on Hospital Sunday, *The Lancet* says that on a recent Sunday in a certain part of London there was a street procession organized in aid of a hospital, the name of which is charitably withheld. In addition to the usual bands and banners of friendly societies which accompany these processions, there were tradesmen's carts, decorated with flowers and vegetables, the name of the owner of the vehicle being, of course, conspicuously visible. But the principal "attraction" was a man on what was supposed to be a sick-bed, and attended by two nurses, one of whom was a qualified nurse and the other a person masquerading in a nurse's costume.

Jefferson Medical College.—At the annual meeting of the Philadelphia chapter of the Alumni Association of Jefferson Medical College, on June 1st, Dr. Allen H. Hulsizer was elected *President*, Dr. John Lindsay *Secretary*, Dr. William B. Atkinson *Corresponding Secretary*, and Dr. H. Hansell *Treasurer*. It is announced that the trustees of the college have purchased the property immediately adjacent to the college on the north extending to Sansom Street, so that it has now secured control of all the property on the west side of Tenth Street from Walnut to Sansom. Mr. William M. Singerly has given \$6,000 to Jefferson Medical College Hospital. The provost of the University of Pennsylvania, Mr. C. C. Harrison, and also Mr. Thomas McKean, have each contributed \$1,000. Dr. Daniel Baugh has been elected a member of the board of trustees.

Poisonous Fish.—The item with this title in a recent issue, which, when we found it, had become a newspaper waif of unknown paternity, was originally, we are informed, published in *Our Animal Friends*.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 4, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

THE meeting was devoted to the completion of the programme of May 21st, when Dr. C. G. Coakley read a paper, "Statistics of Diphtheria," and Dr. Joseph E. Winters one, "Clinical Observations on the Antitoxin Treatment of Diphtheria, and a Report of Personal Investigation of This Treatment in the Principal Fever Hospitals of Europe during the Summer of 1895" (see page 877).

Personal Experiences with the Antitoxin Treatment.—The discussion was opened by a paper by Dr. P. H. ERNST with this title (see page 907).

Diphtheria with and without Antitoxin.—Dr. W. L. STOWELL read a paper on this subject (see page 903).

How the Facts about the Antitoxin Treatment Should be Estimated.—Dr. W. H. THOMSON opened the general discussion with a paper bearing this title (see page 893).

Dr. GEORGE L. PEABODY said the criticisms which he had thought of making upon Dr. Winters' paper had already been stated by Dr. Thomson. It certainly was not fair to claim that a remedy was no remedy at all because the reduction in mortality produced by it was not uniform in all parts of the world. Some doctors did allow antitoxin to be used upon themselves; he himself received a large dose last winter, and with no unpleasant effects except a local urticaria, which soon passed off. If deaths had occurred he believed the cause must have been some extraneous substance. As with other remedies, some persons were more susceptible to its benefits and exceptional effects than others. Dr. Peabody had given antitoxin and had seen it given frequently, and thought one who had seen the diphtheritic child come out of a semicomatose state under its influence and within forty-eight hours sit up in bed and play with toys must have been impressed with its remedial power. Dr. Peabody said he was awaiting further testimony.

Dr. ANDREW H. SMITH sent a communication, which was read by the secretary, containing statistics received from Washington regarding diphtheria throughout the country and in Washington before and since the introduction of the antitoxin treatment. It was remarkable how the reduction in mortality had gone hand in hand with the administration of antitoxin. Where a considerable quantity had been used the death rate had been low; where but little or none was used the death rate had been about the same as in former years. The figures from boards of health in various cities gave 5,125 cases treated with antitoxin, with a death rate of ten per cent.; without antitoxin in the same places 2,936 cases, with a death rate of 41 per cent. Of 2,400 children who were given immunizing doses, 19 developed mild diphtheria within two days after the treatment. No other effects were noted. In Washington the mortality had been reduced more than one-half. The secretary also read limited statistics received from Chicago. Dr. Smith said in his communication that personally he was in favor of antitoxin.

A Critical Analysis of Dr. Winters' Clinical Observations on the Antitoxin Treatment of Diphtheria, was the subject of the remarks made by Dr. JOHN WINTERS BRANNAN (see page 897).

Dr. H. W. BERG thought that if there was more broncho-pneumonia since the introduction of the anti-

toxin treatment the explanation lay in the fact that more patients lived a sufficient number of days to develop that complication. Dr. Winters had spent much time and money to make out a case against antitoxin, yet, after all the evidence had been summarized, Dr. Berg felt that there was not much to it. In the first place, it was all based on hospital cases, which were well known to be the least favorable for antitoxin treatment. "A judgment based on hospital statistics was necessarily and absolutely fallacious." Yet, as Dr. Brannan had said, they had had fair results at Willard Parker's compared with the pre-antitoxin period. In private practice he had found antitoxin the most marvellous remedy for diphtheria which he had ever used.

Dr. AUGUST CAILLÉ said he had come prepared to prove that Dr. Winters' communication had no scientific value whatever, but some of the other speakers had already done that. Dr. Winters had not given the latest figures; these had been given to-night, and went to show that even in hospitals the reduction in mortality had been very great. Dr. Caillé had recently returned from the meeting of the American Pædiatric Society at Montreal, and had some of the figures of a collective investigation as to the use of antitoxin in private practice, by which it appeared that the mortality from diphtheria when treated early with antitoxin was less than five per cent. Dr. Caillé's own experience had been very favorable indeed, and the cases which had been most convincing were those of diphtheritic croup. His former mortality in this class of cases had been seventy per cent., whereas under antitoxin he had had ten croup cases recover in succession, an experience which he had never had before. Dr. Joseph O'Dwyer had written him of like favorable results, and said that where he used to put the tube in he now took it out.

Dr. Caillé thought we should not take this whole matter very seriously. It seemed that opposition was one of the accompanying features in the evolution of scientific medicine. It existed with regard to vaccination even to-day, as well as on the day of its birth.

Dr. ERNST, of Boston, said that he and his colleagues in Boston had been extremely interested to know on what grounds the attacks on antitoxin were based. He had charge of the production of antitoxin for Boston, and was in a position to give the statistics of its use up to date. Returns had been made to him in 1,164 cases, all told. Of these, 983 were from the Boston City Hospital, 181 in private practice. Of the 983, 831 recovered, 152 died, making a mortality of 15.6 per cent., compared with a mortality of about 40 per cent. for years previously. Of the 181 cases in private practice, 161 recovered, 15 died, or a mortality of 8.2 per cent. That was exceedingly interesting, because the general mortality taken from the report of the board of health showed for no year the past twenty years a lower mortality than 26.5 per cent. Dr. Ernst had reports of 346 cases in which antitoxin had been used for immunizing purposes, 273 of which were in the Children's Hospital, where it was the routine practice to immunize nurses, patients, and resident staff once a month. During the last eighteen months they had succeeded in completely obliterating two epidemics by that procedure; 84 cases were in outside practice. In no instance had there been a report of albuminuria or unfavorable result. He thought that alone ought to be a sufficient answer to the charge that antitoxin had produced the ill-results charged against it. There had been no report of diphtheria developing after the use of immunizing doses.

Dr. GEORGE McNORTON, of Brooklyn, said he had been called in consultation to 89 patients with laryngeal diphtheria, all of whom except 5 were intubated; 59 recovered, 30 died, just about reversing his figures

during the period when antitoxin was not employed—72 cases, with 48 deaths, 24 recoveries.

DR. W. H. PARK said that of two thousand cases in which antitoxin had been used for immunizing purposes in the city there had been no symptoms except in two: in one of these convulsions, in the other hyperpyrexia. In only six did diphtheria develop between the sixth and the thirtieth day. A number of hospital epidemics had thus been wiped out. Recently they had sent out notes to a number of physicians who had reported fatal cases, and of 25 fatal cases it was stated that antitoxin was not used in 15, and in only 1 of the 10 in which it was used was it used early; in that instance only 500 units—an insignificant dose, in Dr. Park's opinion. Regarding experience at the Willard Parker, he must agree with Dr. Brannan, not having seen the ill effects mentioned by Dr. Winters, which were said not to have existed before the introduction of antitoxin.

DR. HEROLD, of the board of health of Newark, gave some figures regarding diphtheria in Newark prior to and since the board of health had begun to supply its physicians free with antitoxin in July, 1895. The figures showed a marked reduction in mortality for the period during which antitoxin had been used.

DR. H. F. KOESTER had injected for the board of health of New York in 200 cases in tenement houses; 160 recovered; 40 died, a death rate of 40 per cent. Properly, 12 of the fatal cases should be excluded from the list, which would leave the mortality 14 per cent. During the same period he immunized 214 cases, in none of which he saw bad results. Since then his immunization cases had been increased to 355. Four developed diphtheria within twenty-four hours, showing that infection had already taken place. They recovered. During another period he had injected 60 diphtheria patients, 15 per cent. of whom died. There was occasionally a rash, but less frequently since the more concentrated serum was being used.

DR. J. M. MABBOT believed the actual number of deaths from diphtheria had not diminished markedly since the introduction of the antitoxin treatment. There was now frequently a bacteriological diagnosis where formerly physicians would not have considered it diphtheria. He thought that where antitoxin had been used in private practice it was usually in mild cases, in which a favorable result could be expected. He was awaiting further experience before feeling assured of the value of this treatment.

DR. WINTERS, in closing, corrected some errors in the statistics given by Dr. Thomson for England and Germany, which seemed to present the case against antitoxin instead of for it in those particular hospitals. Likewise in the case of Boston, an analysis of the facts presented a different picture from that made by the statistics which Dr. Ernst had just read. It was stated that the mortality in that city for 1895 was 14.4 per cent., while for 1893 it was 32 per cent. But Dr. Ernst had neglected to state that in 1895 there were 112 more deaths from diphtheria in that city than in 1893. All the reports from over the world had a similar stamp. Where there was a decreased mortality reported, there was an increased total of cases, not a decrease in the actual number of deaths. Due consideration must also be given variations in the type of the disease.

Replying to Dr. Brannan's remarks, he said that if one would sit down and study carefully the chart of each case at the Willard Parker, he would find a different clinical picture from what had existed in cases of diphtheria prior to the use of antitoxin. Whether it was due to the serum or not he could not positively say, but he could conceive of no other cause. He was sorry Dr. Dorning was not present, who said he had been compelled to give up antitoxin in private

practice, because all of the seven patients on whom he had used it had died; that so able a practitioner as Dr. Francis Huber was not present to give his experience, having declared to him that it was a humbug; and so with others.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, May 30, 1896.

W. R. PRYOR, M.D., CHAIRMAN.

Anencephalia, Acrania.—DR. SARA WELT-KAKELS presented a fœtus of about the twelfth week without brain or upper cranial bones. The cause of the abortion was endometritis.

Multiple and Pedunculated Fibroid of Uterus.—DR. H. T. HANKS presented a uterus with multiple fibroids, one of which, springing from near the cervix, had become pedunculated and twisted, interfering with its nutrition and starting fatty degeneration in its walls. It could be felt up near the umbilicus through the thin and relaxed abdominal walls. The woman had borne four children, had had two miscarriages; the last labor occurred a year and a half ago when, on account of the obstruction, the child had to be removed piecemeal. Dr. Hanks thought the tumor must have so obstructed the pelvis that a child of usual size could not possibly have passed. The operation was by suprapubic hysterectomy. The patient was doing well.

Quintuplets.—DR. HIBBE presented photographs of five babies of one labor and of the placenta, which had been given him during a flying trip south. All that he had learned of the case was that the mother was thirty-nine years old, had borne seven children, had had no trouble up to the sixth month of her last pregnancy, when she consulted Dr. Mathews on account of her great size. Labor came on at the eighth month. Dr. Mathews found the os dilated, the membranes ruptured. The first fœtus presented by the feet, the second by the head, the third, fourth, and fifth by the feet. Two were boys, three girls; one lived four days, two ten days, three twelve days, and two were still alive. The mother had made an uninterrupted recovery.

Fibroids and Induction of Labor.—DR. MARX said in connection with Dr. Hanks' case that the question had been in his mind for some time whether in cases of uterine fibroids complicating pregnancy it would not be wise always to do elective labor about six weeks before term, and thus anticipate possible trouble, especially risk to life from hemorrhage. Some years ago he had nearly lost a case from hemorrhage, in another he had found it necessary to make Dührssen's incisions into the cervix on account of the same complication, and this experience had led him to induce labor in three other cases.

DR. HANKS thought Dr. Marx's suggestion could not be accepted as a general rule. Every case should be managed according to its individual merits.

DRS. EDGAR, JEWETT, and GRANDIN agreed with Dr. Hanks. At the present day we ought to be able to take care of post-partum hemorrhage, should it arise at term.

Dr. Edgar asked Dr. Hibbe if there was but one placenta in the case of the quintuplets, and Dr. Hibbe replied that it seemed so from the photograph. Dr. Edgar had never heard of such a case; usually a quintuplet pregnancy was the result of triplets and twins, and there were two placentæ. Dr. Jewett thought there might be two placentæ here, fused.

Medical Treatment of Eclampsia.—DR. SIMON MARX read a paper upon the medical treatment of eclampsia, and was followed by Dr. Grandin who dealt with the surgical treatment. He said the patho-

genesis of eclampsia was surrounded by much doubt. The uncertainty regarding its cause modified men's views regarding its treatment. The urine in every case of pregnancy ought to be examined monthly or bi-monthly for albumin and as to quantity and proportion of solids. It was too late to wait for convulsions, for one could not say that the woman would not die in the first attack. Albumin was significant, but its absence did not preclude eclampsia. One must consider all the symptoms and signs in order to prevent eclampsia or successfully meet it when it occurred.

They divided the cases into four classes: 1, cases of acute toxæmia depending on heart disease; 2, cases depending on acute exacerbation of chronic nephritis; 3, cases depending on acute degenerative kidney changes; 4, cases in which albumin or casts appeared in the urine, a true uræmia.

In the first class, so long as the heart's rhythm was good, and the general condition seemed satisfactory, there was nothing to be done except to wait and watch. As soon, however, as the heart showed a tendency to become rapid and irregular, in spite of cardiac stimulants, one should not temporize, but empty the uterus at once. Among the remedies mentioned as having proved useful in these cases, according to the indications, were nitroglycerin, strychnine, and caffeine in the absence of cerebral symptoms. In the second class, depending on acute exacerbation of chronic nephritis, it was useless to prescribe absolute rest and exclusive milk diet, for the patients would rebel. It was not until they had tried nitroglycerin that they had found it to fulfil an ideal indication, that of cerebral anæmia, to which they attributed eclamptic seizures. It could be given in doses of from $\frac{1}{100}$ to $\frac{1}{50}$ of a grain every two or three hours throughout pregnancy, if necessary. In the case of a physician's wife they had given seven hundred grains of nitroglycerin during the course of pregnancy, and she gave birth to her child without an eclamptic seizure, which she had not done in a former pregnancy. Her condition was one of chronic nephritis. It was their custom to let these patients bleed freely after the second stage of labor.

Speaking of the next class, the mere presence of albumin and casts, or occurrence of constitutional symptoms during the course of pregnancy, should lead the physician to put the patient to bed at once and stimulate every emunctory to action and rid the system of poisonous substances supposed to be circulating in the blood. Catharsis should be produced with calomel and jalap, followed by a saline; or a saturated solution of salines might be given per rectum, or even hypodermically. A hot bath, the tub covered with a blanket may be followed with sweet spirits of nitre. They were absolutely opposed to jaborandi and pilocarpine. A milk diet should be given, and as much water as the patient would drink. They abstained from the use of potash salts because they were cardiac depressants. Digitalis was objected to in acute but not in chronic kidney cases. They objected to the use of the tincture of chloride of iron. Of value were caffeine, one to five grains; nitroglycerin, sulphate of sparteine, nitrites, chloral. They questioned the value of veratrum viride in cases in which it had been supposed to be of use. Under those conditions surgical measures would answer better. After labor, however, if the pulse were full and bounding, they administered veratrum. It should not be used in valvular lesion, weak, dilated, or fatty heart. As to venesection, if it were indicated, let it be from the uterus by emptying that organ.

In acute toxæmia, where albumin and casts appeared in the urine, a true uræmia, nearly all malignant cases died. It was good treatment to empty the uterus at once.

The Surgical Treatment of Eclampsia.—DR. EG-BERT H. GRANDIN read this paper. Surgical treatment of eclampsia began where judicious medical treatment had been tested and failed to control the premonitory symptoms, or where the urgency of the symptoms did not admit of the institution of medical treatment. The indications for drugs had been pointed out in the previous paper. The aim of surgical treatment was to empty the uterus. Dr. Grandin impressed the point that one should give attention to the daily secretion of urine, the relative proportion of solids, even though albumin were absent. It was toxæmia which we should endeavor to forestall.

When the patient had shown any of the classical symptoms of eclampsia, the uterus should be emptied. If already in the throes of eclampsia when seen, measures of the most active type should be employed for emptying the uterus. Fortunately cases were seldom so urgent as to preclude sufficient preparatory measures, for in emptying the uterus it should always be done with the care of a major surgical operation.

The only method which he would resort to in non-urgent cases, because he considered it safe, effective, and aseptic, was the following: The external genitalia and vagina having been rendered aseptic, the cervix was dilated sufficiently with steel dilators to permit of being packed with gauze up to the internal os. The upper vagina was filled firmly with gauze. After twenty-four or thirty-six hours the gauze was removed. Prior to the sixth month he found it preferable to introduce a second packing under absolute asepsis, for rarely after the first one was the cervix sufficiently softened to enable the finger to be utilized in conjunction with the dull curette in bringing out the fœtus. Under the third month, at the end of twenty-four hours, in the absence of pathological change in the cervix, under anæsthesia, the finger aided by the dull curette could now absolutely empty the uterus. He did not consider the procedure properly performed unless the finger was inserted to the fundus and the organ was completely emptied. After the third month and up to the sixth, dilatation was more difficult. The only risk was from hemorrhage, and this was forestalled by use of the uterine tamponade. Forceps above the brim should never be used unless version was contraindicated; if used, it should be axis-traction forceps. The uterus being emptied the tamponade might be employed after sufficient bleeding had taken place. Many patients were benefited by this loss of blood to an extent which we little appreciated. If infection took place, the operator or attendant was to blame.

In eclampsia, if there was no pathological obstruction, it was usually possible under surgical anæsthesia to empty the uterus by the method of manual dilatation alone within the space of forty-five minutes. In the mean time such remedies as the operator had faith in could be given hypodermically, and, if needed, venesection by the uterine route could be resorted to. The only risk which rapid dilatation subjected the woman to was sepsis. There was no danger from hemorrhage, as experience had shown. Should rupture occur it could easily be repaired.

In Dr. Grandin's experience, the symptoms abated after the uterus had been emptied, except in fulminant cases, in which neither drugs nor surgical interference availed. Here, slow preliminary dilatation could not for a moment be thought of, but such cases were extremely rare, and Dührssen's incisions could be resorted to. The criticisms upon this formerly made by him he now considered not well founded, but the indications for Dührssen's incisions, as stated, were rare.

A third group of cases was that in which there was obstruction to the parturient tract by tumors, etc. Here the only course was by Cæsarean section.

DR. CHARLES JEWETT agreed with most points contained in both papers, but said he had found veratrum valuable.

DR. HANKS referred to the significance of headache, anæmia, pulse of high tension, etc., even in the absence of urinary symptoms. He doubted whether one should wait for the action of gauze; and as to Barnes' dilators, one always had his fingers with him.

DR. J. CLIFTON EDGAR thought there were clinical indices of eclampsia which should enable us to avoid it. We ought not to pin our faith to any single symptom. Pressure on the ureters had been mentioned as a cause, but he had not been able to confirm it. He found use for veratrum viride. He felt thankful that Dr. Grandin had placed manual dilatation of the cervix in the light which he had this evening. He thought that formerly it had been spoken of too lightly, and that harm had been done the past two years in undertaking manual dilatation when it was not called for or without taking proper steps for its safe performance. He wished to repeat that manual dilatation was extremely difficult and dangerous if undertaken before the internal os had disappeared or as long as there was a cervix.

DR. R. A. MURRAY was fully in accord with Dr. Grandin's paper. He had not heard Dr. Marx's. Calomel caused the kidneys to act, and enabled us to use veratrum viride with advantage. Nitrogenous foods required to be used with care. Many cases of eclampsia seen by him had been precipitated by some impropriety of diet. Dr. Murray was opposed to the use of chloral hydrate by the rectum, as had been recommended by Playfair and others, as he thought it was liable to produce fatal narcosis after the uterus had been emptied.

DR. AUSTIN FLINT, JR., asked Dr. Marx whether he had known of a case of eclampsia due to valvular or other forms of cardiac disease. Also whether he had known of occlusion of the ureters from bending. Dr. Flint thought that veratrum viride, next to nitroglycerin, was the best drug we had in these cases. He forbade morphine.

DR. H. E. CRAMPTON thought there were cases of eclampsia which were purely neurotic in origin.

After some further remarks by Drs. GORDON and L. S. RAU, DR. MARX closed.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 13, 1896:

	Cases.	Deaths.
Tuberculosis.....	170	100
Typhoid fever.....	15	5
Scarlet fever.....	101	9
Cerebro-spinal meningitis.....	3	2
Measles.....	228	17
Diphtheria.....	262	31
Small-pox.....	0	0

Almsgiving.—Every gift that a man receives from some other man without work, without reciprocal service, is an alms, and as such is deeply immoral. The sick, the old, the weak, those who cannot work, must be supported and tended by their fellow-creatures; it is their duty and it is also their natural impulse. But to give to men capable of working is under all circum-

stances a sin and a self-deception. If men capable of work find no work, this is obviously attributable to some defect in the economical structure of society; and it is the duty of each individual to assist earnestly in removing this defect, but not to facilitate its continuance by pacifying for a while the victim of the defective circumstances by a gift. Charity has in this case merely the aim of deadening the conscience of the donor and furnishing him with an excuse why he should shirk his duty of curing recognized evils in the constitution of society. Should, however, the capable man be averse to labor, then charity spoils him completely and kills in him entirely any inclination to put his powers into action, which alone keeps the organism healthy and moral. Thus, alms extended to an able-bodied man degrades both the donor and the recipient, and operates like poison on the feelings of duty and the morality of both.—MAX NORDAU ("Degeneration," p. 156).

Bigotry.—Dr. Savage, in the *Journal of the American Medical Association*, says that "Bigotry, whether characterizing an individual or a class of individuals, in matters medical never had other than a harmful effect. It would be well if this ill-shaped monster could be forever buried, without hope of resurrection. Men who are not willing to accept facts presented by others, and will not weigh the conclusions that have been based upon them, are not the men who will make advances themselves nor will they be helpful to others who would. Destroy bigotry and there will be no 'pathies,' but in their stead would stand one grand brotherhood of physicians. A medical bigot knows not enough to know that he does not know it all, and therefore always stands ready to destroy anything that does not emanate from a source peculiarly his own. Such an one would say, 'I will not use this instrument because it was invented by a homœopath; I will not administer that drug because it was introduced by an eclectic; I will not bathe my fevered patients nor give them cooling draughts because this is the method of the hydropath; I will not listen to suggestions coming from common people.' The man who would attain to the greatest wisdom must gather grains of thought from all fields, must use his judgment in separating the good from the bad, and must be willing to feed his fellow-men from his well-filled granary. If Jenner had not listened to the stories of the milkmaids, vaccination would not have been discovered, and the era of immunization, inaugurated by Pasteur but founded on Jenner's discovery, would have been longer delayed. We should not forget that all people are God's people, and that He may use one or another in bringing into the world the good which comes alone from Him. Away with bigotry and send bigots with it!"

Numerous Names for Roentgen's Discovery.—Among the many names used to designate the discovery of Professor Roentgen are the following: "X" ray photography, shadowgraphy, radiography, cathode photography, cathography, electrography, fluorography, skiagraphy, skotography, and Roentography.—*American Medical and Surgical Bulletin*, April, 1896.

Origin of the Cocktail.—The most remarkable explanation of the origin of the word "cocktail," according to the *New York Press*, comes from an ancient print. The old doctors had a practice of treating certain diseases of the throat with a pleasant liquor, applied with the tip end of a long feather plucked from a cock's tail. They finally began to use this preparation as a gargle, and the name cocktail clung to it. The gargle gave way to an appetizer, and the appetizer to a mixture of bitters, vermouth, and liquor, that is still in occasional demand.

THE STATE OF THE GASTRIC MUCOSA IN SECRETORY DISORDERS OF THE STOMACH.¹

By MAX EINHORN, M.D.,
NEW YORK.

You all know the great strides which have of late years been made in the study of diseases of the stomach. The chief progress lies in our ability to examine the different functions of the organ, but principally that of secretion. In this latter function many deviations from the normal condition are found, and indeed these constitute the ailments of the greater number of patients with chronic digestive disturbances.

Must there always be a manifest anatomical lesion for such gastric disorders, or can they be caused and entertained by some purely nervous influences? This question has been and is still studied by the foremost clinicians of this country and Europe, and a positive answer cannot as yet be given. Leube and Ewald on the other side of the ocean and in this country Dr. Charles G. Stockton, of your city, have laid much stress upon the neurotic character of these secretory disorders. Dr. Stockton even showed that some functional gastric anomalies are occasionally of reflex origin. Hayem,² however, is of the opinion that the secretory anomalies are due to anatomical changes in the gastric tubuli, which view is also held by Boas and others.

The minute anatomical condition of the stomach can seldom be studied in autopsies, as soon after death and sometimes even during the agony the glandular layer is subject to manifold artificial changes, which more or less mar the true picture. For this reason efforts have been made to study the pathology of the stomach by means of small pieces of mucosa excised while performing major operations on the stomach (Korczynski and others). Boas, appreciating the importance of such examinations, was the first to investigate with the microscope pieces of gastric mucosa found occasionally in the wash water of the stomach after using lavage, and Cohnheim³ has recently published an extensive paper comprising his own and Boas' experience on this subject.

During the last three years I had the opportunity of examining small pieces of gastric mucosa from thirty-two patients. From several of them pieces of gastric mucosa were obtained at different periods of time, and in this way the examination could be repeated and the result compared with the first examination. It appeared to me of interest to compare the results of the microscopical examinations of the specimens found in these patients with the condition of the gastric secretion manifested by them. This may perhaps give us a clew as to the question above ventilated, namely,

whether the secretory anomalies are dependent upon anatomical changes. But before analyzing my cases permit me to say a few words with regard to the occurrence of these pieces of gastric mucosa and to their examination.

In washing out the stomach (especially in the fasting condition) occasionally a small piece of gastric mucosa may be found in the wash water. Such a piece may also be found occasionally in the gastric contents, when examining the patient after a test breakfast or test dinner. I have also observed that in some cases the occurrence of small pieces of gastric mucosa in the wash water is a constant phenomenon (erosions of the stomach). The number of these pieces varies from one to four. Such a piece looks quite red. The thickness may vary from one-half to one millimetre, while the size may vary from that of a large pin's head to that of a small bean. Sometimes they are found embedded in mucus. While the presence of glands in these small pieces may be found by examining them in the fresh condition under the microscope, a thorough examination can be made only after a sufficient preparation of these particles (hardening in alcohol, embedding in celloidin, and staining with eosin-haematoxylin, picro-carmin, methylene blue, and thionin).

In examining the microscopical picture of the different specimens the following groups can easily be distinguished:¹

1. N.—Normal: Glands and interglandular tissue exist in normal proportions.
2. C.—Connective tissue: While there is a normal proportion between glands and interglandular tissue, there is a marked proliferation of connective tissue around the glands.
3. P.—Proliferation: There is a marked proliferation of glands; they are nearer each other, and sometimes have an elongated and curved shape.
4. B.—Beginning atrophy: The glands exist in smaller numbers and are sometimes also smaller in size, the interglandular spaces being quite large and filled partly with small-cell infiltration, partly with connective-tissue formation.
5. A.—Atrophy: Complete atrophy; no glands visible; only indications of their previous existence; round-cell infiltration.
6. V.—Vacuolization: Within the glands exist vacuoles of different shape, being the result of a mucoid degeneration of some glandular cells.

Sometimes one specimen shows characteristics belonging to two of the groups mentioned.

In the following table is found a list of all the cases examined, stating diagnosis, the condition of the gastric secretory function, and the pathological structure as found in these pieces of mucosa under the microscope and characterized by the above-mentioned initials. Whenever one specimen belonged to two different groups, it was signified by the two corresponding initials, the first marking the principal feature of the specimen. In going over the table it will be advisable first to consider each secretory group apart.

¹ The illustrations have been taken from my book, "Diseases of the Stomach" (Wm. Wood & Co.), now in press.

¹ Read before the Alumni Association of the University of Buffalo, at the fiftieth anniversary, Tuesday, May 5, 1896.

	37. R. H. A.	do.	do.	A.	

There were four cases of euchlorhydria (or normal gastric juice). The anatomical state presented quite varied pictures: proliferation of glands with connective-tissue formation, beginning atrophy, and slight vacuolization.

One patient (R. H.), from whom pieces of gastric mucosa were obtained on three different days, presented varied pictures on each occasion.

Twelve cases of hyperchlorhydria showed proliferation of glands in six, while in the remaining six the gastric mucosa presented either a normal appearance or slight connective-tissue formation around the glands; only twice was slight vacuolization visible, and once atrophy of glands with connective-tissue formation.

Nine cases with hypochlorhydria presented a normal condition of the glands in three, atrophy in two, beginning atrophy in two, connective-tissue proliferation in one, and proliferation of glands in one. Of these nine cases two were examined on two different occasions; in one the microscopical pictures were pretty much alike, while in the other once atrophy and the second time proliferation of glands were found.

Seven cases of achlorhydria (principally achylia gastrica) showed a normal condition twice, complete atrophy three times, while once there was very

marked vacuolization and once slight proliferation of glands.

In none of the four different secretory conditions was there found a perfect harmony in the microscopical picture of the gastric mucosa. It, therefore, does not appear justifiable to make a positive diagnosis as to the existing disease from the examination of such small pieces of gastric mucosa.

Two facts, however, are quite apparent: proliferation of glands is frequently met with in hyperchlorhydria (in half the number of cases) and atrophy is encountered in the same proportion in achylia gastrica.

If we now return to our first question, whether anomalies of the gastric secretory function are dependent upon anatomical lesions, it seems that the results of the table speak against this assumption. For if anatomical changes are the primary factors, there ought to be more constancy in the results of these microscopical examinations.

The table, however, shows that there is some connection between hyperchlorhydria and proliferation of glands on the one hand, and between achylia and atrophy of the glandular elements on the other hand. How are we to explain these anatomical changes if we do not deem them the principal factors in these conditions?

Before answering this question I would like to

remind you of Edinger's¹ excellent paper: "A new theory of the causes of some nervous diseases, especially of neuritis and tabes," in which he explains the anatomical changes found in the nerves and the spine by a disproportion between the functional activity and the replacement of these elements. You all know that normally the increased activity of an organ leads to

The facts just mentioned show the importance of the functional activity with regard to the state of an organ: the elements which come more into play and do more work will gain supremacy, they will increase in strength and in numbers.

If now we return to the stomach there seems to be hardly any difficulty whatever in explaining why con-

FIG. 1.—A small piece of gastric mucosa (from patient, Mrs. H.) presenting a cross-section of the glands in normal appearance. $\times 80$.

FIG. 2.—A piece of gastric mucosa (from patient, Mrs. R. S.) showing beginning atrophy of the glands (small pale areas within the glands) and connective-tissue proliferation. $\times 120$.

FIG. 3.—A piece of gastric mucosa (from patient, H. R.) showing the mouths of glands; the pale spots show beginning atrophy of the glands; connective-tissue proliferation best shown in lower part of specimen. $\times 120$.

the strengthening of the same; often also to a direct increase in volume. On the other hand, inactivity of an organ leads gradually to a weaker and atrophic state of it.

According to W. Roux² there exists the following law: "Increased activity heightens the specific force of the organs, while a diminished activity causes a

ditions of hyperchlorhydria are frequently found associated with a proliferation of glands, while those of achylia occur with an atrophy of same. It would be contrary to the above-mentioned law if this were not the case.

It remains only to explain why the increased function of the glands does not always show hypertrophy of same, and, *vice versa*, their inactivity an atrophy. But this can be answered by assuming that the functional activity or inactivity has not lasted long enough to produce those changes over the entire organ.

The hypothesis which I have expounded before you is not merely of a theoretical nature, but seems to me to be of practical importance with regard to treatment.

FIG. 4.—A piece of gastric mucosa (from patient, E. H.) showing proliferation of glands. $\times 80$.

FIG. 5.—A piece of gastric mucosa (from patient, B. E., with carcinoma cordiae) showing destruction of glands by connective-tissue proliferation. $\times 60$.

FIG. 6.—A piece of gastric mucosa (from patient, R. H.); no glands visible, only some empty spaces where glands had previously existed. $\times 80$.

weaker state of the organs." Each cell, according to this writer, has to gain a living by work, and the more it works the better nourished it is and the stronger it grows.

Πόλεμος πατήρ πάντων—"Strife the cause of all"—Heraklitos once said, and the entire truth of this sentence has been appreciated since the work of the great Darwin and his followers (Haeckel, Roux, and others).

¹ Edinger: Volkmann's "Sammlung klinischer Vorträge," 1894, No. 106.

² W. Roux: "Entwicklungsmechanik der Organismen," 1895.

Referring the functional disorders of gastric secretion as due to direct anatomical changes (inflammatory processes of the organ), the treatment would have to look principally to according the organ more rest and to diminishing its work in every conceivable manner. If the above hypothesis be true, that the secretory disorders are primary, not dependent upon inflammatory processes, then the treatment will have to be directed toward improving the general (and also nerve) state of the system and also toward methodically strengthening the stomach in such a manner that the increased

function shall be balanced by increased nutrition and replacement of waste.

To recapitulate, permit me to draw the following conclusions:

1. The microscopical examination of a small piece

FIG. 7.—A small piece of gastric mucosa (from patient, D. S., with achylia gastrica) found in wash water from stomach; only few glands visible, empty spaces where glands had previously existed; general small-round-cell infiltration. $\times 80$.

of gastric mucosa found in the wash water after using lavage does not permit a positive diagnosis.

2. Although we frequently meet with anatomical

FIG. 8.—A small piece of gastric mucosa (from patient, J., with carcinoma pylori) showing mucoid degeneration of the glands with vacuolization; some connective-tissue proliferation. $\times 140$.

conditions of the gastric mucosa which correspond to functional disorders of secretion, this does not prove that these are due to the anatomical state. The latter, instead of being the cause, may be the effect.

To Prevent Rusting.—Common baking-soda put into the water in which instruments are boiled in order to sterilize them will, to a great extent, if not totally, prevent rusting.—*Medical Summary.*

A SUMMARY OF THE TREATMENT OF CHRONIC RENAL DISEASES.¹

By WILLIAM H. McENROE, M.D.,

NEW YORK.

MANY attempts at classification have been made to indicate the various conditions found in the kidneys after death, and to give to each form a definite clinical history; but as not one of these has received general acceptance the result has been to confuse the nomenclature of an already intricate subject. The various forms of chronic renal disease, while presenting considerable difference in their origin and symptoms, have general points of resemblance so positive and so numerous that they are easily recognized clinically. In many cases the kidneys present a great variety of morbid changes as regards the color, the size, the condition of surface, etc. They are sometimes small, red, hard, and nodulated; again, they may be large, white, soft, and smooth. Three varieties are generally recognized, viz.: chronic diffuse nephritis, chronic interstitial nephritis, and amyloid degeneration of the kidneys.

During the early stages of chronic diffuse nephritis, the kidneys are swollen and are red or gray in color. Later on, during the progress of the disease, they become very large in size and white in color. This has been described by writers as the large, smooth, white kidney, and generally remains as such to the end. Sometimes, however, the kidneys shrink and become granular. This form of disease is most often caused by exposure to cold and by scarlet fever. It sometimes follows repeated pregnancies and may occur in pulmonary phthisis. The onset is generally very sudden, especially if cold or scarlet fever are the exciting causes, and as a rule is accompanied by general dropsy. The urine at first is scanty in quantity, dark in color, and contains albumin, blood, and casts. Later on the urine becomes more copious, pale in color, and the quantity of albumin is diminished. An attack of acute uræmia may occur at any time during its course. Retinitis albuminurica is quite a common complication, and cardio-vascular changes are often found during the later stages of this condition.

Chronic interstitial nephritis or cirrhosis of the kidney is a very slow, insidious affection, and in a large number of cases is chronic from the start. It often remains latent for an indefinite period. It is seldom if ever seen in early life, but usually occurs in persons over thirty-five years of age. The chronic abuse of alcoholic beverages, such as whiskey, brandy, and gin, is an important factor in the production of this condition. Persons in whom the arteries have a tendency to early degeneration are more likely to develop cirrhosis. It is very often caused by dietary errors—eating too fast and too much, the excessive use of animal food, producing a condition of lithæmia by overtaxing the liver and interfering with the elaboration and excretion of poisonous materials, which by their presence in the blood produce renal irritation. Gout and chronic poisoning by lead are also factors in its production.

Amyloid degeneration or lardaceous disease of the kidneys is mainly caused by syphilis or by prolonged suppuration. The kidneys are very large, pale, and waxy-looking, their tissues giving the characteristic reaction with iodine. The urine is very copious, clear in color, and contains a large amount of albumin, as a rule. General anasarca is a very frequent symptom, but cardio-vascular changes are rarely found.

Before taking up the subject of treatment, I will proceed to name certain symptoms and effects that be-

¹ Read before the New York Medico-Surgical Society, May 31, 1896.

long in common to all the forms of diseases of the kidney.

Albumin.—This is found in a greater or less amount in every form of chronic renal disease. The urine in some cases may contain as much as five per cent., a quantity more than half as great as that found in the serum of the blood. Hyaline, granular, epithelial, and sometimes blood casts are found. The normal solids of the urine are all diminished and urea is markedly reduced. The presence of albumin in the urine is undoubtedly due to changes in the glomeruli and renal tubules.

Dropsy.—This is a constant symptom, but occurs more frequently in the acute form. It is also most often found with the smooth, large, white kidney, and usually begins in the face, about the eyelids. The effusion may pass to the feet and legs, becoming excessive and general and involving the whole body. It may disappear for a long time and then return. After the disappearance of the effusion œdema will be found underneath the eyelids, around the ankles, over the anterior surface of the tibiæ, and sometimes about the genital organs.

There is another form of dropsy occurring in chronic Bright's disease, which is almost identical in all its characters with that produced by chronic cardiac disease or by pulmonary emphysema, and is caused by obstruction in the systemic veins owing to weakness of the heart. It is always found in the most dependent portions of the body—around the ankles and in the legs. It is often accompanied with intense dyspnoea and great lividity. The skin is usually very dry, pale, and glossy, sometimes sallow and rough. There is no pain in the back in the majority of chronic cases.

Retinitis Albuminurica.—This is a very significant symptom and generally assumes a degenerative character from the start. It consists of a number of white spots arranged closely around the optic disc and sometimes assuming a fan-like streaked appearance. Hemorrhages are often associated with this condition. In some cases there is an intense optic neuritis with great swelling and œdema of the retina, completely hiding the optic disc. Notwithstanding the severity of these symptoms, it is rare that central vision is lost or complete amaurosis follows.

Secondary Inflammations.—These are sometimes the direct cause of death and are always serious complications. Secondary inflammation of the serous membranes of the pericardium, the pleuræ, and the peritoneum—are more frequent, and the tendency of such inflammatory action is to suppuration. The lungs are sometimes involved, and even meningitis is produced.

Pulmonary phthisis is a frequent complication. Very often the phthisical process is far advanced before the kidneys become involved. In other cases the renal disease precedes the pulmonary and always assumes the amyloid form of degeneration.

Cardio-Vascular Changes.—Coincident with the cirrhotic process in the tissues of the kidneys, the walls of the arteries and capillary blood-vessels become the seat of characteristic changes, consisting of chronic endarteritis with an exudation of hyaline material on the outside of the blood-vessels. The walls of the affected vessels become greatly thickened and their calibre diminished in size, and in the case of the smaller arteries the cavity is completely obliterated. This increase of connective tissue in the various organs of the body never occurs without injury to the proper cells of the part pressed upon, and as this shrinks the process goes on and uses up what is left of the proper cells of the part inflamed, until there is ultimately nothing but a mass of fibrous tissue left. This condition of arterial sclerosis is a constant companion of renal cirrhosis. It is the cause of

the hard, incompressible pulse of this disease, and gives rise to a greater or less derangement in the blood-supply of the different organs. It is a common cause of apoplexy, and the interference with the circulation in the brain gives rise to certain cerebral symptoms which are characteristic: First, impairment of memory, due to anæmia and malnutrition of the brain. Second, vertigo, especially in the morning or just after rising. Third, a persistent tendency to wake too early in the morning, sometimes with headache, which passes off soon after rising. The patient also suffers from cramps in the calves of the legs just after or before getting out of bed. Fourth, a vague sense of fear as of some impending danger; the intellect is dull and often greatly impaired.

Cerebral Symptoms.—The manner in which uræmic symptoms appear is varied and the different forms which they assume are very numerous. The most prominent symptoms of chronic renal disease are often of a cerebral character. Headache is a constant symptom; more often there is a sense of compression over the top of the head, and pain radiates to the back of the neck. These symptoms are caused by the presence in the blood of toxins or poisonous substances that are excreted by healthy kidneys. Delirium, often associated with rigidity of the leg or arm and accompanied by a tremor or trismus of the facial muscles or even the muscles of the eye, may occur. A very constant effect of uræmic poisoning is amaurosis, which usually comes on quickly, affecting both eyes, and is almost always complete. I have known complete loss of hearing to precede an attack of uræmic convulsions. Vomiting often occurs and is usually associated with diarrhœa. It is claimed that this is produced by the irritation of ammonium salts, caused by the disintegration of urea in the alkaline medium of the intestine. Following the attacks of vomiting there is a sensation of heaviness and a tendency to sleep. In other cases there are no premonitory symptoms, the patient passing into convulsions followed by profound coma. The convulsions may consist of a single paroxysm; more often there is a succession of paroxysms following each other, and they may continue for several hours between the attacks, the patient lying in a condition of profound insensibility from which he cannot be roused.

The following symptoms are characteristic of uræmic coma: The pupils will not react to light. There is a urinous odor from the surface of the body. The respirations are irregular, sometimes rapid and sometimes slow; they are always of a peculiar hissing character. The temperature is elevated at first, but later slowly falls. The pupils are as a rule irregular, and albuminuric retinitis is almost always present. The face is pale. The pulse in a large number of cases is incompressible, and rigid arteries are found. The phenomena of an epileptic attack closely simulate uræmic convulsions, and it is sometimes very difficult to distinguish between them. The convulsive movements in epilepsy are generally unilateral; both sides are equally affected in uræmia. The initial cry and great pallor of the face preceding the attack is peculiar to epilepsy. The temperature is not elevated in epilepsy and reflex sensibility continues all through the paroxysm. After an attack of uræmic convulsions the patient passes into deep coma. Following an epileptic seizure there is only a deep sleep, from which the patient can be roused. An examination of the urine will generally determine the nature of the case. In apoplexy the coma always precedes the convulsions. There is conjugate deviation of the eyes, facial paralysis, and hemiplegia. In opium poisoning the pupils are symmetrically contracted, even down to a pin point in size. The respirations are exceedingly slow, even as

few as five per minute. The pulse is strong, full, and readily compressible. The patient is not absolutely comatose, and can therefore be partially aroused. Acute alcoholic poisoning is a very common cause of coma. The respirations are hurried, and expiration quickly follows inspiration. The pulse is quick and strong and the patient can be partially aroused, but returns to a drunken consciousness. His answers are not rational, the words are not well articulated; he is irritated by interference and often uses profane language. There is another variety of coma due to concussion of the brain from blows or falls on the head, and it is of great importance to distinguish this form, as it is frequently due to criminal assault. There is something very characteristic in this form of coma, for the control of the brain over the spinal cord is withdrawn; hence the reflexes of the spinal cord are set free and every external impression leads to twitching of the muscles, sometimes great enough to produce a movement of the whole limb. Hence, whenever there is jactitation it points to some injury of this kind to the head, and is very significant.

Treatment.—This should consist of, first, measures taken to prevent further structural changes in the kidneys, to remove as quickly as possible all inflammatory products that may obstruct the smaller renal tubules, to facilitate the elimination of urea, and to remove or palliate certain symptoms, such as dropsy, anæmia, etc. The cause of the disease must be sought for and removed if possible. If the chronic abuse of alcohol is a cause, it must be stopped. Prolonged exposure to very severe weather must be avoided. It will be found in many cases of continued suppuration, caries, necrosis, chronic cystitis, and stricture of the urethra that renal degeneration has already taken place. This should be borne in mind by the surgeon, and should have great influence in deciding upon an operation.

The diet should be light and of the highest nutritive value. Milk as a rule agrees very well indeed. It is best given with equal parts of lime water. Alcoholic liquors are badly borne and should be withheld. If alcohol is absolutely required, one or two glasses of red wine may be taken during the day with food. The patient should wear flannel next to the skin, and moderate exercise in the open air should be indulged in. Many writers lay great stress on keeping up a constant flow of water through the kidneys, thus endeavoring to wash clear the renal tubules of all the cellular materials that they may contain, and using such remedies as the sweet spirit of nitre and other diuretics for this purpose. I approve of the regular administration of cathartics, and for this purpose twenty grains of the compound jalap powder given three or four times a week is very useful. It is also important that the function of the skin should be kept in action, and for this purpose the warm bath is very useful. The patient can be placed in a bath of the temperature of 100° F., and hot water may be gradually added to it until the temperature reaches 104° or 106° F. The patient is kept in the bath for about half an hour, and is then removed and wrapped in warm blankets for three or four hours, during which time great perspiration takes place. The hot-air bath is another method employed to induce diaphoresis. The patient should be stripped and placed upon a chair, under which a lighted alcoholic lamp is placed. A blanket closely pinned around the neck and reaching to the floor confines the heated air to the surface of the body. If the patient is too weak to sit up, the hot air may be introduced underneath the bedclothes, which can be elevated so as to form a tent or cradle.

In using diaphoretics as eliminatives, it must be remembered that the skin is an eliminative organ only to a small extent, and acts as such only when the

other eliminative organs fail. Therefore, whenever the skin is to be used for this purpose, it should be always prepared for this vicarious action. Any existing tension found in it must be removed; for when the skin has been dry for any length of time the epithelial layers are brought together and the mouths of the glands are closed, thus preventing the discharge of secretions. This condition is especially present in dropsy, when the skin is dry, owing to the subcutaneous effusion acting as an obstruction to the capillary circulation, thus preventing the action of the sebaceous glands by interfering with their blood supply. Diaphoresis, therefore, is greatly assisted by anointing the surface of the body with olive oil. It must be remembered that diaphoresis cannot be induced when other eliminative organs are in abnormal activity; consequently, diaphoresis should not be attempted while the bowels are under the influence of a cathartic. One of the best methods of applying moist heat is in the form of the hot pack. The surface of the body is well oiled and the patient is wrapped up in a woollen blanket that has been immersed in boiling water and wrung out as dry as possible; over this is placed a dry woollen blanket, and over all a linen sheet. Warm diaphoretics should be given internally.

Pilocarpine is undoubtedly the most powerful diaphoretic known, and were it not for certain drawbacks it would be used extensively. Its power is not increased by combination, and it is not necessary to assist or increase its action by keeping the patient warm; for pilocarpine acts at all times, and it is only necessary to keep the patient from being chilled. Owing to its depressant action on the heart, pilocarpine should be used with great care. I have given it in doses of from one-eighth to one-fourth of a grain hypodermatically for dropsy occurring in young or middle-aged persons, without fear.

Diuretics are remedies which increase the volume of urine excreted by the kidneys by increasing the general blood pressure, by causing dilatation of the renal arterioles, or by directly irritating the substance of the kidney itself. The condition of the urine should always be considered a guide for the administration of diuretics.

Urine of high specific gravity and normal quantity indicates high living with gouty tendency. Saline diuretics should be given, the diet regulated, and alcohol prohibited.

Urine of high specific gravity but diminished in quantity, unless due to excessive perspiration, calls for the administration of saline diuretics. The acetate or citrate of potassium may be given in twenty to thirty grain doses.

Urine with uric acid deposits indicates a tendency to formation of stone. Plenty of pure water should be taken; liquor potassæ in half-drachm doses largely diluted and sometimes the carbonate or citrate of potassium in twenty-grain doses should be given.

If bile is present in the urine, promote vicarious action by the skin and bowels; also use remedies to act on the liver.

Deficiency of solids and quantity due to renal congestion occurs in scarlatinal and acute nephritis. The object is to re-establish the normal secretion of urine. Digitalis and the saline diuretics are useful.

Deficiency in the quantity of urine in dropsy is very often caused by fluid in the abdomen. This mechanical obstruction must be got rid of, or else diuretics will not always act.

The turpentine class of diuretics are active renal stimulants, and are very useful in pyelitis, chronic cystitis, and chronic inflammation of the urinary tract. I have great faith in digitalis as a diuretic, especially if combined with calomel or corrosive sublimate. Digitalis produces a free flow of pale urine of low

specific gravity, and its action when once secured is often continued for four or five days, producing considerable depression of the system. When calomel is combined with digitalis so as to direct its action to the kidney, it becomes one of the best remedies for chronic Bright's disease, as it liquefies and absorbs the hyaline material which surrounds the arteries, hardening and contracting them, and setting up a slow inflammatory process, which destroys the glandular structure. In the treatment of chronic renal diseases the specific gravity of the urine is the guide. At first the specific gravity falls to about 1.010, and remains there for a long time, but falls again at the close of the disease. When it falls to 1.006 there is great danger. Calomel increases the watery flow of the urine, but not its solid constituents. One grain of calomel, one grain of squill, and one grain of pulverized digitalis make an excellent diuretic pill. If the pulse becomes intermittent the digitalis must be left out. Digitalis is especially indicated in acute nephritis; the stimulant diuretics cannot be given, as they intensify the renal congestion.

For the prolonged treatment of chronic renal diseases I prefer a pill containing one-twenty-fourth of a grain of corrosive sublimate, one grain of digitalis, one grain of squill, and one grain of quinine sulphate; one of these to be taken three times a day. Very often in this condition the arteries are hard and rigid, and there is great danger from the rupture of a blood-vessel owing to the increased arterial tension produced by digitalis. To overcome the bad effects of digitalis upon the arteries, nitroglycerin in the form of tablets of one-one-hundredth grain each should be given. It may be necessary to increase the dose up to one-fiftieth or to one-twentieth grain, or even to one-tenth grain. Therefore, for the hard incompressible pulse of arterial sclerosis with renal cirrhosis and the cerebral symptoms already described, no remedy equals corrosive sublimate, and if anæmia is very pronounced it can be given with the sweet spirit of nitre and the muriated tincture of iron. No remedy is so decidedly effective as corrosive sublimate against this common cause of declining health, producing premature old age. The bromide of lithium has been employed recently in these cases with some success. It is best given in doses of five grains three times per day. It can be combined with the benzoate of sodium in the same doses.

It is a well-known clinical fact that structural degeneration of the kidneys comes on very slowly, and is always the result of renal irritation, continuing sometimes for years by imperfect intestinal digestion. We know there are constantly forming in the intestines by normal processes of fermentation soluble alkaloidal poisons, which are taken up by the portal circulation and conveyed to the liver, whose function it is to destroy them. Now, if the liver is out of order and cannot kill these poisonous products, they enter the general circulation and produce most serious results. A large number of these poisons have been isolated, some of them resembling atropine, curare, and other powerful poisons. Healthy urine, which contains several of these, is more poisonous than the urine of diseased kidneys. It is now known that urea is not the cause of uræmia, for we often find no diminution in the amount of urea in the cases of many persons who show uræmic symptoms. It has been satisfactorily demonstrated that uræmia is entirely due to the presence of these alkaloidal toxins in the blood. Therefore, in every case of chronic nephritis intestinal antiseptics should be used. Five grains of salol and five grains of the subcarbonate of bismuth are very useful for this purpose. A course of mineral waters is a very useful adjunct to this treatment, especially if begun in the early stages of the disease.

When there is obstruction to the general circulation, caused by spasm of the arteries, the heart beat being rapid, strong, and vigorous and accompanied by an incompressible pulse, it means extreme danger. This condition is present in uræmic convulsions and puerperal eclampsia, where the pulse may run up to 130 or 140 per minute. In ordinary cases of fever a rapid pulse is not necessarily dangerous, but when the rapid action is accompanied with an incompressible pulse it becomes extremely serious. This condition is also found in acute alcoholic coma. General blood letting is imperative. If this cannot be done, large doses of the tincture of veratrum viride should be given. It will moderate the pulse, cause the heart to beat less strongly, open the contracted arteries, and make the pulse compressible. I have given twenty minims every twenty minutes for one hour and a half before the convulsions ceased.

Hypodermatic injections of morphine sulphate are sometimes very useful in uræmic convulsions. The dose should be increased from one-fourth grain up to one-half grain, and be repeated every two hours until the convulsions are controlled.

SEVERE POST-DIPHTHERITIC PARALYSIS IN AN ADULT TREATED BY ANTITOXIN.

By GEORGE THEO. MUNDORFF, M.D.,

HOUSE PHYSICIAN, ST. FRANCIS HOSPITAL, NEW YORK CITY.

JOHN M—, aged twenty years, single, born in Ireland, by occupation a hotel porter, was admitted to St. Francis Hospital, service of Dr. August Seibert, March 2, 1896, complaining of general weakness and partial paralysis of the limbs. Family and previous personal histories were negative.

History of present illness: On December 25, 1895, the patient took sick with a severe attack of diphtheria, which kept him confined to his bed for ten days. He received internal medication, but no injections of antidiphtheritic serum. A few weeks after his apparent convalescence he noticed his articulation of words becoming indistinct, deglutition becoming embarrassed, the swallowed drinks regurgitating through the nares, and his voice acquiring somewhat of a nasal character. In addition, he suffered from double vision, scanty urination, and constipation. Subsequent to this walking became difficult, and finally his arms became powerless. Conscious of growing steadily worse, he decided to enter a hospital.

The patient was over six feet in height and weighed about one hundred and fifty pounds. He was anæmic and emaciated. The muscles of the trunk and of the four extremities were visibly atrophic, particularly noticeable in the pectorals, the deltoids, and the biceps. Patellary reflexes were entirely absent. The pupils were widely dilated and the vision was slightly impaired; there was no strabismus. The voice was hoarse, speech indistinct, and the pronunciation of the gutturals somewhat difficult. Examination of mouth: the velum palati was partially insensible to touch and absolutely motionless. The isthmus of the fauces and walls of the pharynx were slightly anæsthetic. The uvula was motionless and atrophied. There was difficulty in rising. The patient was barely able to support himself on his legs. The feet were cold. Application of electricity to various muscles elicited very weak response.

Diagnosis: Post-diphtheritic paralysis.

Treatment: Following Dr. Seibert's suggestion, an injection of the antitoxin of diphtheria (seven hundred and fifty units) was given above the right rectus abdominalis on March 4, 1896. There was no appreciable rise of temperature following this injection.

The patient was permitted to sit up the next day. Noticing the gradual improvement in the patient, we decided to give him another injection. This was done on March 13th, and at this time a strength of one thousand units was given. From this day until the present time there has been a marked improvement in the patient and a gradual disappearance of his former unpleasant symptoms. He has no more difficulty in articulation or deglutition. He is able to employ his arms and to walk about the wards.

This is the second case of severe post-diphtheritic paralysis within six months in an adult in Dr. Seibert's service, and in neither patient was any antidiphtheritic serum used. Whether or not the improvement of the paralysis in this case is due to a possible action of the antitoxin must necessarily remain doubtful until the complete action of the remedy has been fully analyzed.

March 30, 1896.

Progress of Medical Science.

Pylephlebitis and Abscess of the Liver Following Typhoid.—Dr. Lannois has recently described pylephlebitis and abscess of the liver following typhoid, in which the bacillus of Eberth was present in the pus from the abscess, though not in pure culture. He states that liver abscess following typhoid is very rare, occurring, according to Schultz, of Hamburg, once in thirty-six thousand and eighty cases. Lannois divides abscess of the liver following typhoid into three classes: (a) Metastatic abscesses having an external suppurative focus as a point of origin. (b) Abscesses from typhoid ulceration of the biliary passages. (c) Abscesses due to pylephlebitis. He places his case in the last class. The case occurred in a man of twenty-eight years of age and came on at the end of the attack, the patient having been afebrile for three days. At the end of this time he was taken with a violent chill with fever, and the signs of pleural involvement at both bases. This was followed by swelling of the abdomen and great pain in the right hypochondrium. There were no positive physical signs in the abdomen, and the case was regarded as one of tuberculous peritonitis on account of the pleural involvement and the swelling of the abdomen. The patient died three days after admission; the autopsy showing healed ulcers in the ileum, and also partly healed ones, both in this part of the intestine and in the appendix. The vena portæ, the inferior mesenteric vein, and the splenic vein all contained adherent ante-mortem clots. In the liver a number of abscesses were found containing creamy yellowish pus. A number of organisms were present in the pus, and one was isolated which resembled the typhoid bacillus in every way, except that it slightly liquefied gelatin. The author ascribes the liquefaction to impure culture, and states that this is the only case recorded where a satisfactory bacteriological examination has been made.—*Revue de Médecine*.

Is Surgical Intervention Warranted in Primary Renal Tuberculosis?—This question was the subject of an address delivered recently by Dr. Pousson. He first described the different methods of invasion in primary and secondary infection, as the bacilli locate in the vascular zone of the organ in the former case, and produce the phenomena of congestion, pains, and hæmaturia. Secondary infection attacks the zone of the pyramids and is a mixed process starting in the bladder, and revealing its presence chiefly by suppurative lesions, or pyuria. The hæmaturia is often the only symptom of infection for quite a while, and he cites many cases where it persisted alone for months. Here he thinks surgical intervention entirely uncalled

for, as this form is not exposed to complications from other infections, owing to the isolated position of the organ. Only when it is accompanied by severe pains preventing rest, or excessive, weakening hæmaturia, which forces the hand of the surgeon, as it were, is a surgical operation legitimate and nephrectomy indicated. In all cases in which the other organs seem to be exempt, he agrees with the majority of French physicians, that local attempts to exterminate these bacilli from the system are apt to be fruitless and followed by their reappearance there or elsewhere.—*Archives de Bordeaux*.

Fistula in Ano.—Dr. B. B. Porter (*Journal of Medical Science*) offers the following hints: 1. Remember to operate upon all cases of fistula where there is sufficient vitality or nutrition to heal the wound. Always divide the fibrous membrane at the bottom of the tract and pack the wound at the bottom for the purpose of healing by granulation. 2. Remember always to open abscesses early to prevent fistula in ano. 3. Remember, if you operate on a fistula in a tuberculous patient, to give him the benefit of the doubt. 4. Remember that you should never fail to examine your patients thoroughly for small arms leading out from the main tract, and examine for an associate stricture, which may be the cause of the fistulous tract. 5. Remember that you are never to cut the sphincter but once in any operation, and be careful and warn your patient of the danger of incontinence. 6. Remember that you are to confine your patient in bed, not trusting to care of the nurse exclusively. Tuberculous cases should be an exception to the rule; give them moderate exercise and fresh air. 7. Remember that physiological rest is the first principle in the cure of all diseases. 8. Remember that in all operations involving the rectum, it is good surgery to dilate the sphincter. 9. Remember that all cases of fistula in ano should be operated upon, and best by the knife, except in cases of Bright's disease, cancer, cardiac and hepatic affections.

On the Line of Action to be Adopted in the Case of a Woman Who is About to Die while yet Undelivered.—Remy advises under such circumstances as these that an effort be made to save the life of the child, and as a means of accomplishing this three plans have been suggested. They are: (1) To wait for the mother's death and then immediately to extract the child; (2) to do Cæsarean section while the mother is yet alive; (3) to employ means to expedite labor and to extract the child by the natural passages as speedily as possible. Remy then proceeds to discuss the relative advantages of these different modes of action. Prunshuber's statistics show that when the mother is allowed to die before the child is extracted by abdominal section, only about five per cent. of the children survive. Puech's statistics are somewhat more favorable; but there can be no doubt that the chance of obtaining a living child under these circumstances is very small. The performance of Cæsarean section upon a dying woman who is unable to give her consent to the operation is undoubtedly open to sentimental objections. Gusserow and Manasse consider that the operation is justifiable under the following conditions: (1) When it is clearly proved that the mother is about to die, and (2) that the child is alive. Remy favors the plan of rapid dilatation of the cervical canal and extraction of the child per vaginam. Violent measures should be avoided, and the dilatation should be proceeded with as slowly as the condition of the mother will permit. The cervix may be dilated by means of Champetier de Ribes' bag or by the hand alone. If traction is made upon the bag, dilatation may be produced in less than half an hour.—*Practitioner*.

THE PAINS OF HEART DISEASE.

PAIN associated with diseases of the heart is one of the most alarming and distressing of symptoms. Nothing frightens even the bravest more than a feeling of pain in this region, with the sinking and feeling of helplessness that often accompany it. The prevalent idea that people who have heart disease are liable to die at any moment and the frequent reports of death from heart failure make symptoms of this kind particularly terrorizing.

Dr. James McKenzie, of Edinburgh, has published an article upon pains and other sensory symptoms that are associated with heart failure. Dr. McKenzie's article is devoted to the presentation of evidence showing the special kinds of pain, hyperæsthesia, and nervous disturbances that are produced by heart disease and heart weakness. He shows, also, the distribution and character of these pains and other sensations. He finds that the common seat of pain, in cases of heart weakness and in attacks of heart failure, is that which is familiar to all, namely, the region of the left breast and the left arm, especially the inner and ulnar side of it. He reports several cases of patients who had attacks of pain in this region, and in whom careful and repeated physical examination showed no heart disease. These patients all died suddenly, however, from acute heart failure. Dr. McKenzie finds that in persons who are liable to these attacks there is a cutaneous hyperæsthesia over the area where the pain is felt—a hyperæsthesia that is easily mapped out by slightly pinching the skin or pressing it with a pin-head. In most cases, he says, the pain starts in the chest and radiates into the arm. In rare cases the pain starts in the arm and radiates to the chest—a fact which has been noted by Walsh. There is sometimes, he finds, irregularity in the distribution of the pain; just as there are persons whose spinal nerves are distributed in a peculiar way. Thus, he gives an account of a man, fifty-two years old, whose chief complaint was pain induced by exertion. This pain began in the left chest, extending to the armpit, down the inside of the arm, thence across the palm to the thumb, causing great aching in the thumb. This man had no detectable heart disease, but he died rather suddenly, and the cardiac muscle was found to be fatty and degenerated.

Other cases are cited in which the pain was confined to the left chest under the nipple, and other cases in which it is limited to the ulnar border of the left

arm. These pains were generally brought on by some exertion, associated with some cardiac distress. At times the pain extends over to the right side and right arm, and one case is given in which the patient, with a very damaged heart, used to suffer from great pain over the right scapula and the inner part of the right elbow-joint. The bilateral distribution of the pain in heart disease is not equal, it being more marked upon the left side than upon the right.

Besides the hyperæsthesia and pain, which are described as occurring in the left chest and arm and sometimes the right chest and arm, Dr. McKenzie finds at times an abnormal sensitiveness over the neck, in the region of the sterno-mastoid and trapezius muscles. The pain of heart disease in some cases, starting in the left side of the chest, runs up into the neck and behind the ears, and in these cases hyperæsthesia is present here. Sometimes the pain and tenderness affect the whole of the left side of the face and may extend down, involving in this case the shoulder and outer side of the arm, instead of the inner side, as is the rule.

These phenomena of transferred pain are due, of course, to the irritation from the diseased organ passing up to the spinal cord, and thus referred down along the cervical nerves. This tendency to transference of pains has been often studied, and is one of the curious and at the same time important phenomena observed in one's clinical studies.

ICE CREAM.

THE British Institute of Preventive Medicine has dealt a deadly blow to ice cream. A very exhaustive inquiry regarding the nature and adulterations of this toothsome substance has just been completed by Dr. MacFadyen and Mr. Collyer, F.I.C. These gentlemen tell us that ice-cream has only 26.5 per cent. of solids, the rest being water; that the solids consist of fats, four per cent.; sugar, twelve per cent.; starch, six per cent.; albuminoids, four per cent.; and mineral matter, one-half per cent. This all sounds well enough, and would lead the unwary reader to think that ice cream was all right, but the denouement comes in the results of microscopical research. The microscope shows the presence, in London ice cream at least, of bedbugs, bugs' legs, fleas, straw, hair, coal dust, woollen and linen fibre, tobacco, epithelial scales, and muscular tissue. Even the microscopical examination, however, is delectable compared with the results of bacteriological studies. These reveal in street-barrow ice cream, a maximum number of seven million microbes per cubic centimetre, while the ice cream of the shops has only one million per cubic centimetre. The character of the micro-organisms is extremely mixed. There are the bacteria coli commune, besides spirillæ and putrefactive microbes of various kinds. We find no account of a chemical analysis, which would perhaps add the final touch to the pathological picture of the ice cream of the shops. In this country it is known that ice creams chemically contain a poison known as tyrotoxin. But in London

it seems, what with the bugs and the microbes and the filth generally, there is no particular need of further research to prove that the ice creams of the peddlers and the streets are not good things to eat. It would be a manifest injustice to the ice-cream industry, however, to suppose that the supply which is furnished to the American public is at all comparable to that which has been investigated by the English authorities.

News of the Week.

Royal College of Surgeons in Ireland.—At the election of officers of this body, held on June 1st, Mr. Thomson was chosen *President*, Mr. Kendal Franks *Vice-President*, and Sir Charles Cameron *Secretary*.

Section on Alcoholism at the Moscow Congress.—The organizing committee of the Twelfth International Medical Congress has, at the request of Dr. Ignatiev, decided to establish a section for the discussion of the alcohol question. This is the first time there has ever been a special section for alcoholism at an international congress.

The Plague in Hong-Kong.—Eighty-one cases of bubonic plague were reported in Hong-Kong during the week ending June 1st, the deaths during the same period numbering seventy-three.

An Epidemic of Hysteria visited several of the public schools in this city last week. It began with a statement by one of the little girls that she had seen the devil, and during that and the following days many of the other girls, frightened by each other's stories, were seized with hysterical convulsions and delusions of visions of evil spirits.

Appropriation of a Name.—Harvard University, on behalf of its medical school, has filed a bill in the United States Court in Chicago, against the Harvard Medical College of Chicago, seeking to enjoin the latter from the use of the name "Harvard," as being a fraud upon the university and the public. Suit was begun June 13th in the United States Court, Northern District of Illinois, in equity. The title of the case is "The President and Fellows of Harvard College vs. The Harvard Medical College of Chicago."

The Mississippi Valley Medical Association.—A meeting of the executive committee of the Mississippi Valley Medical Association was held at Atlanta, on May 6th, and the following gentlemen were appointed to deliver addresses: Dr. H. N. Moyer, Chicago, address on "Medicine"; Dr. Horace H. Grant, Louisville, address on "Surgery."

The New York Polyclinic.—Dr. W. W. Van Valzah has been elected professor and Dr. J. Douglas Nisbet adjunct-professor in the department of general medicine at the New York Polyclinic Medical School and Hospital.

A Jenner Memorial Medal.—At the annual meeting of the Epidemiological Society of London, on May 15th, it was unanimously resolved, having regard to

the historical connection of the society with vaccination and other preventive measures, to found a medal in memory of Edward Jenner. It is proposed that the medal shall be founded with a view to the promotion of epidemiological research, and that it shall be bestowed from time to time by the society on persons who shall have contributed to the knowledge of preventive medicine.

Obituary Notes.—DR. WILLIAM ANDERSON died at Indiana, Pa., March 29, 1896, aged seventy years. He graduated at Jefferson Medical College in 1852, locating at Indiana, Pa., where he continued in the practice of his profession until the time of his death. He was one of the founders and for many years secretary of the Indiana County (Pa.) Medical Society, and in 1865 president of the Medical Society of the State of Pennsylvania.—DR. THOMAS HUN, of Albany, died at his home in that city on June 22d. He was born in 1808, and attended Union College, from which he was graduated in 1825. He received his degree in medicine from the University of Pennsylvania in 1830, and afterward studied for a time in Paris. He was for many years dean of the Albany Medical College.—DR. MORGAN L. FILKINS, an eclectic physician of Rochester, died at his home in that city on June 13th, at the age of seventy years.—DR. CARL FINKELNBURG, professor of hygiene at the University of Bonn, is dead. He was born in Maria-linden, June 16, 1832.

The French Congress of Ophthalmology, which was held last month, was presided over at its closing session by Dr. Lucien Howe, of Buffalo, N. Y. The prevention of blindness, which was one of the questions receiving especial attention, was brought up by Dr. Howe, who stated that in America laws have been passed in several States to punish midwives by imprisonment and fine if they do not give prompt notice to the medical authorities of the occurrence of ophthalmia in new-born children.

St. John's General Hospital at Pittsburg, Pa., was formally opened on May 12th. The hospital will be in charge of a superintendent and an assistant superintendent, who are deaconesses from the Drexel Home at Philadelphia.

The First Scandinavian Congress for Internal Medicine will be held in Göteborg on August 27th, 28th, and 29th of the present year. Dr. H. Köster, of Göteborg, is the provisional secretary.

Dr. James Hamill, a veterinary surgeon of Brooklyn, died a few days ago in the witness chair in court, while giving his testimony in a suit over the sale of a horse.

American Association of Genito-Urinary Surgeons.—At the meeting of the American Association of Genito-Urinary Surgeons, held at the Hotel Brighton, Atlantic City, N. J., June 2d and 3d, the following officers were elected for the ensuing year: *President*, Dr. Francis S. Watson, of Boston; *Vice-President*, Dr. J. William White, of Philadelphia; *Secretary*, Dr. W. K. Otis, of New York.

Dr. R. A. Blood, of Charlestown, has been appointed by the governor surgeon-general of the Massachusetts Volunteer Militia to fill the vacancy caused by the death of the late Dr. Edward J. Forster.

The American Association for the Advancement of Science will hold its forty-fifth annual meeting at Buffalo, August 22d-29th.

Washington State Medical Society.—At the annual meeting of this society, held at Tacoma on May 19th and 20th, Dr. R. L. Thomson, of Spokane, was elected *President*, and Dr. J. M. Semple, of Medical Lake, *Secretary*. The next meeting will be held in Spokane in May, 1897.

The Woman's Medical College of Baltimore has lengthened its annual course to eight months, from October to May inclusive. The following appointments in the faculty have been made: Dr. R. T. Taylor, orthopædics; Dr. T. C. Gilchrist, dermatology; Dr. H. P. Hynson, pharmacy; Dr. G. M. Linthicum, physiology; Dr. K. B. Batchelor, associate professor of obstetrics. A chair of mental diseases has been added and also departments of bacteriology and embryology.

Famine in China.—There is a famine in Kwangsi province, China, and it is reported that the people have been driven to the killing of children for food.

Cholera in Egypt.—The official statistics show that during the first ten days of June there were in Egypt 761 new cases of cholera and 631 deaths. Of these, 249 new cases and 230 deaths were in Cairo.

Garbage Disposal.—It is proposed to organize a private company in Plainfield to dispose of garbage. The system will, however, be under the supervision of the board of health. The company will furnish each house with an air-tight can and have a set of cans numbered in duplicate. The gatherer when he leaves the plant will have the same number of cans on his wagon as he will bring back, and at each house where he removes a can he will leave the duplicate. As soon as the cans are emptied they will be disinfected with steam. All the garbage will be burned in a crematory.

Sailors Killed by Sunstroke.—On a recent voyage of the British cruiser *Bonaventure*, the flagship of the East India squadron, from Colombo to Pondicherry, seventy men were lost by heatstroke.

A Gift to the Public Library.—Mr. J. S. Kennedy has presented to the New York Public Library on the Tilden, Lenox, and Astor foundations, the American historical collection of Dr. Thomas Addis Emmet. The collection will be known as the Emmet Library.

Andrea Verga.—A bust to the memory of Prof. Andrea Verga, the Italian alienist, whose death occurred last year, was unveiled in Milan on May 15th. The bust was placed in the hall of the Society for the Protection of the Insane Poor, of which he was the founder.

Anti-Vivisectionists and Hospitals.—An anti-vivisection society in England has issued a manifesto

advising the withholding of Hospital Sunday contributions from hospitals to which laboratories are attached. How the post-mortem examination of human tissues in hospital laboratories can hurt the feelings of dogs and horses is not explained.

Medical Examinations in England have become multiplied to such a degree as to be a burden, and the General Medical Council is considering how far the unessentials may be cut out from the list of requirements.

Degeneration of the British Army Medical Service.—Owing to the low social standing to which medical officers in the British army are condemned, there has been an unusual lack of candidates at recent examinations. Instead of removing the difficulty by recognizing the doctors as gentlemen and soldiers, it is proposed to tempt more candidates by lowering the standard of requirements.

The Anti-Vivisection Bill.—Dr. Atkinson writes to the *Journal of the American Medical Association* that he has received letters from Senator M. S. Quay, Congressman Robert Adams, Jr., Senator McMillan, and from the commissioners of the District of Columbia, all of whom appear to be impressed with the justice of the protests against the obnoxious anti-vivisection bill, and will aid to defeat it.

Dr. Renvers, fleet-surgeon to the German Asiatic squadron, died of accidental poisoning on board the flag-ship *Kaiser*, in Yokohama harbor, on April 11th. In the early hours of that morning Dr. Renvers wished to take a dose of medicine, but inadvertently poured into the glass a solution of bichloride of mercury and drank it off. He at once discovered the mistake, and the stomach was emptied without delay, but without avail, as death speedily followed.

The Population of London, according to the census taken last March, is 4,411,271. In 1891 it was 4,211,743, an increase of nearly 200,000 in five years.

Dr. Arthur Stradling died recently in Ceylon from a snake bite. He had for many years been studying the venom of snakes in India and Ceylon with a view to the discovery of an antidote. He believed that he had succeeded in this and that he was immune against snake bites, but his belief was ill-founded, for he died within a few hours after being bitten.

Lead Poisoning is doubtless of much more frequent occurrence than is generally supposed. In England the law now compels the report of all cases of plumbism to the Faculty Department. For the month of February fifty-three cases were reported, and in March sixty-five. Of the latter thirty-eight were men, twenty-one women, and six children—four boys and two girls.

A Berlin Society of American Dentists.—The dentists of Berlin who are graduates of American dental colleges, at a meeting recently held, decided to form an organization.

Prophylactic Injections before Operations on Diabetics.—M. Boucheron, at a recent meeting of the

Biological Society, read a paper on the importance of injecting streptococic serum previous to operating on diabetic patients. He especially recommends this treatment in operating for cataract.

Tillmanns on Lister.—A recent number of *Nature* contains an appreciative biographical sketch of Sir Joseph Lister from the pen of Prof. R. H. Tillmanns, of Leipsic. "As long as there is an earthly immortality it must be his, for as long as ever surgery is scientifically discussed his name cannot fail to be mentioned," are the closing words of the article.

Stricken Cuba.—Reports from Cuba to the newspapers and press associations continue to bring notice of epidemics in many parts of the island. At Cienfuegos small-pox is epidemic, forty deaths from the disease having occurred during the second week in June, and yellow fever, dysentery, and pernicious malarial fever prevail to a constantly increasing extent. Yet no attempt is made to improve the sanitary condition of the place, the Spanish officials' indifference in such matters being illustrated by the fact, as reported by the Associated Press, that there was a large heap of dead horses decomposing in the steaming heat near the railway station, and not the first step had been taken to bury them. In Havana measles and dysentery are epidemic, small-pox and yellow fever are steadily increasing, although the latter is confined chiefly to the Spanish troops, and the usual malarial fevers of the rainy season are rife. The sanitary condition of the city is very bad, the water supply is poor and in danger of being cut off entirely by the revolutionists, and milk is scarce and of bad quality. From Santiago the United States Marine Hospital inspector reports that small-pox is raging epidemically and is constantly increasing, as no attempt at isolation of the sick is made, pernicious malarial fever is very common, and many deaths occur from dysentery among adults and from gastro-enteritis among children. From Sagua la Grande the American consul reports that the number of deaths from yellow fever in the army of occupation is steadily increasing.

Chiropodists, Too.—Our esteemed contemporary, *The Medical Press*, takes umbrage at the striving after higher things of our opticians, giving vent to scorn in the following: "The vendors of spectacles propose to follow the example of the plumbers, nurses, midwives, and, perhaps, the chimney sweeps and pork butchers, and to get themselves recognized and registered by law. At least, a bill with that object has been introduced into the New York legislature, which provides for a State board composed of spectacle sellers, with a corps of examiners, and all sorts of penalties for any one who sells a pair of goggles without a license." Our contemporary forgets the chiropodists and their society. But why shouldn't all be registered whose trade or profession demands the exercise of special skill, through lack of which injury may be inflicted upon innocent persons?

The Teaching of Science in Elementary Schools is said by the Bishop of London to be a very great evil, and he urges that it be got rid of. We wonder

what he would think of wasting several hours a week in trying to teach six-year-olds the chemistry of alcohol.

To Prevent the Spread of Contagious Diseases.—Secretary Carlisle has issued an order designed to prevent the spreading of contagious disease by immigrants in other places than the port of entry. It provides that after arrival at a quarantine station of a vessel upon which there appears, or has appeared during the last voyage, a case of cholera, small-pox, typhus fever, or plague, and after quarantine measures provided by regulations of the treasury department have been enforced and the vessel given free pratique, it is ordered that notification of the above-mentioned facts be transmitted by the quarantine officer to the commissioner of immigration at the port of arrival, whose duty it shall then be to transmit by mail or telegraph to the State health authorities of the several States to which immigrants from said vessel are destined, the date of departure, route, number of immigrants, and the point of destination in the respective States of the immigrants from said vessel, together with the statement that said immigrants are from a vessel which has been subject to quarantine by reason of infectious disease, naming the disease. This information is furnished to State health officers for the purpose of enabling them to maintain such surveillance over the arriving immigrants as they may deem necessary.—*Boston Medical and Surgical Journal*.

A Wasted Life.—Dr. J. R. Fabricius, of New York, writes: "Reading your article, 'A Physician's Heroism,' in a recent issue of your paper, recalls to my mind the case of Dr. Maier, who during his service as assistant physician in the Julius-Spital, Würzburg, in 1894, received an alcoholic suffering from diphtheria. After tracheotomy had been performed, the doctor thought it necessary to remove some obstructing membrane from the air tract, for which purpose he inserted a catheter, sucking up the material. The result of this was that Dr. Maier contracted a malignant type of the disease, which rapidly proved fatal, while the patient recovered."

The British Medical Association is to be invited to hold its annual meeting for 1897 in Montreal.

Turning the Tables.—A physician complains in *The Lancet* that he recently went to the New Hospital for Women in London, and asked to be allowed to be present at the dispensary hour. The superintendent informed him, however, that the hospital was conducted by female practitioners only, and no medical man could be admitted, as the patients would not like it. Our contemporary comforts the indignant correspondent by informing him that the Pathological Society of London has recently refused by a large majority to admit women members.

Shorthand for Medical Students.—A petition, signed by the members of the Society of Medical Phonographers and others, has been presented to the General Medical Council of Great Britain, praying that shorthand shall be an extra optional subject for the preliminary examination required by the council.

Vaccination in the Philadelphia Schools.—The Philadelphia board of health is endeavoring to enforce strictly a law enacted a year ago, which makes it obligatory on the heads of Sunday, parochial, and private schools to see to it that no child is allowed to remain in the school who cannot present a certificate of successful vaccination or of having had small-pox. It is merely the application to Sunday schools, parochial schools, and private schools of the same conditions which in the past have been imposed in the public schools.

Foreign Students in France.—The medical students of Paris are still exercising themselves concerning the question of competition by foreigners. A petition, signed by most of the hospital internes, has been presented to the government, praying that every foreigner may be allowed to be registered as a medical student, but that the doctor's degree shall not give foreigners the right to practise in France. This right should be exercised only by those who are graduates in arts of a French university and naturalized French subjects. In other words, foreigners may be allowed to imbibe knowledge and pay out good gold in exchange, but shall not be allowed to utilize the knowledge so acquired or get back any of the money so expended from French subjects.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the U. S. Navy for the week ending June 13, 1896. June 6th.—Passed Assistant Surgeon P. H. Bryant ordered to Naval Station, Newport, R. I. Assistant Surgeon C. M. De Valin detached from the Chelsea (Mass.) Hospital and ordered to the *Blake*. June 13th.—Passed Assistant Surgeon E. R. Stitt, detached from the *Bache* and ordered to the *Vermont*. June 15th.

Changes in the Medical Corps of the U. S. Navy for the week ending June 20, 1896. June 12th.—Surgeon R. Whiting detached from the *Monterey*, ordered home, and granted three months' leave. Surgeon C. T. Hibbett, detached from the *Bennington* and ordered to the *Independence*. Surgeon H. T. Percy, detached from Board of Examiners, Washington, D. C., July 1st, and ordered to the *Monterey*. Surgeon W. A. McClurg, ordered as member of Medical Examining Board, Washington, D. C. Passed Assistant Surgeon J. W. Baker detached from Board of Examiners, New York, June 22d, and ordered to the *Bennington*. Passed Assistant Surgeon C. F. Stokes ordered as recorder of the Medical Examining Board, New York, June 22d. June 13th.—Surgeon A. C. Russell detached from the Board of Medical Examiners, New York, July 5th, and granted leave until August 7th, with permission to go abroad. Assistant Surgeon M. K. Johnson detached from the *Franklin* and ordered to the *New York*. Assistant Surgeon F. C. Cook detached from the *New York* and ordered to treatment at Naval Hospital, New York. June 15th.—Assistant Surgeons W. N. Wheeler and R. S. Blakeman ordered to instruction at Naval Laboratory, New York. Passed Assistant Surgeon J. W. Baker ordered to delay reporting until July 18th.

Obituary.

THOMAS F. COCK, M.D., LL.D.,

NEW YORK.

THE death of the veteran physician, DR. THOMAS F. COCK, closes an eventful life history intimately associated with the medical progress of the past half-century. It is so seldom vouchsafed to a medical man to compass such an extended sphere of usefulness that his final taking off carries with it a satisfaction of unusual privileges well improved and valuable services modestly and consistently fulfilled. His entire career was marked with such an earnestness of purpose and sincerity of endeavor that he was a shining example to all the numerous medical friends with whom his onerous and responsible duties brought him in professional and social contact. From the commencement of his career he took a leading place and proved how much could be accomplished by faithful work, untiring ardor, and loftiness of purpose. His large family practice, which grew with his years and strengthened with his rapidly extending associations, was, in the fulness of his prime, the substantial evidence of properly estimated and widely appreciated worth. The soul of gentleness shone in all the phases of his varied duties and made him to his patients not only the calm and self-reliant physician but the ever helpful friend in most trying emergencies. Eminently practical in his instincts, he enjoyed to the fullest measure every opportunity for those broader and more varied experiences which make the life work of the general practitioner so interesting and so fraught with well-requited labor. Thus he worked, quietly, modestly, and earnestly, leaving behind an unblemished life and the highest exemplification of a consistently earnest Christian character. Better than this can be said of no man whose every effort was directed to the saving of the life of others, and none can better merit the divine benediction of "Well done, thou good and faithful servant."

He was born in this city in 1819, and after a preliminary training entered Columbia College in 1832 and subsequently Haverford College (Pennsylvania), in 1834, from which latter institution he graduated in 1836. He then commenced the study of medicine in 1836 in the office of Dr. Alexander H. Stevens, of New York. In 1838 he went to Philadelphia to attend lectures in the University of Pennsylvania, and was graduated there in 1839. During his stay in that city he was a private pupil in the office of Dr. George B. Wood. In 1840 he entered Bellevue Hospital as interne and commenced practice in New York in 1841. He was elected visiting physician to Bellevue Hospital in 1849 and served there until 1855, when he resigned. He was then elected visiting physician in 1855 to the New York Hospital and continued in service until that institution was removed to Fifteenth Street in 1868, when he resigned and was appointed on the consulting staff, which office he held until his death. He was also consulting physician to the Woman's Hospital, Woman's Infirmary, and New York Lying-in Asylum, to which he was attached since 1841. He was also a member of the Medical Society of the State of New York, of the County Medical Society, of the American Medical Association, of the Society of Widows and Orphans of Medical Men, honorary member of the Medical and Surgical Society, and an original member of the New York Academy of Medicine and New York Pathological Society. The degree of LL.D. from Haverford College (the first one granted by it) was conferred on him in 1883.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL MEETINGS AND MANAGEMENT—MEDICAL SOCIETY'S CONVERSAZIONE—THE BREAKING-STRAIN—POST-OFFICE MEDICAL ASSOCIATION—WOMEN AND THE PATHOLOGICAL SOCIETY—A FEMALE EXAMINER—A JENNER MEDAL—JENNER SOCIETY—HIS STATUE—THE GLOUCESTER EPIDEMIC—THE VACCINATION COMMISSION—CLINICAL SOCIETY.

LONDON, June 6, 1896.

HOSPITAL meetings are very thinly attended unless some dispute is on hand. Governors who subscribe handsomely can seldom be induced to attend, and officials are often obliged to canvass to secure a quorum for the transaction of the formal business. It is not altogether indifference, as the handsome subscriptions often attest; but to many men it is easier to give money than time, especially during business hours. And then, "after office hours" most people have engagements of some kind, absolute leisure being almost unknown in their lives. Family claims are more urgent than those of charity, and it is assumed that the latter is well covered by subscriptions so long as confidence is felt in the management. The misfortune of this is that the average governor is profoundly ignorant of the elements of hospital management, and when some excitement or scandal threatens is unable to form a reliable judgment on the case. At Wolverhampton lately the annual meeting was followed by a good concert, and in other towns some such inducement has been successful in attracting attendance. The dinners so often held are seldom the occasion of transacting any business. Indeed, they are almost invariably nothing more than efforts to raise money, and an invitation to a festival dinner is regarded only as a begging letter.

The apathy of subscribers as to the management of their charities accounts to some extent for the way in which the officials and a few officious persons are able to rule these institutions and for not a few of the scandals that occur. These officious persons attain to such importance in their own eyes that they cannot bear to have their opinions or plans discussed. Some treat their medical officers in a way that menial servants would resent, and when the staff decline to be domineered over are quite incapable of appreciating the position. The newspaper correspondence on the Liverpool case illustrates this. One of the board actually has written in the local papers that the doctors had claimed to decide whether a case is theirs or may be trusted to the midwife, and adds that this would give the doctors too much control, so the board was bound to resist. The best thing a board so prejudiced could do would be to resign their offices, and so make way for a new set of managers who would not be so blind as to prefer the control of the matron midwife.

The *conversazione* of the Medical Society was a sufficiently successful function, and amid light refreshments and smoking afforded opportunity for chit-chat and renewed intercourse with professional friends. The annual oration was a sufficiently serious make-weight. It was delivered by Dr. Allchin, who took for his subject "The Breaking Strain," or the exact conditions of death. How living protoplasm passes into the state of dead matter he regards as a proper subject of scientific research, and as quite distinct from the necessarily insoluble Why. He pointed out that death is not inevitable to every living creature, unicellular organisms merely dividing and so having a kind of immortality; but the power of self-division

is lost by cells which have advanced in differentiation, and propagation is then confined to certain elements, the individual dying. The life of the soma is identified with its nutrition and closely related to its reproductive power, the failure of the last being associated with senescence. Perhaps, then, the necessary stimulus to vitality may reside in the sexual elements—a ferment, perhaps, or internal secretion. This is surely material enough for any one. The hypothesis is certainly no more unreasonable than its opposite—the development of an antitoxin.

The annual meeting of the Association of Post-Office Medical Officers was held last week, when a report was submitted, prepared at the request of Lord Tweedmouth, on the sanitary state of the post offices of the country. At the dinner in the evening Sir Walter Foster was among the guests, and, replying to the toast of the Houses of Parliament, commended the officers as having wisely and well organized themselves, and expressed his desire to see life peerages occupied by medical men in recognition of their self-sacrifice for the good of humanity. None are more worthy of seats among the Lords.

The *Press and Circular* is excessively angry with the Pathological Society for declining to admit women, and declares that all the arguments were with the innovators but the votes with the conservatives. The arguments of the latter are termed by the *Press* "tiresome old platitudes" and "diatribes against the impious trespass of women." This is pretty strong, but your contemporary goes on to declare that there is "pruriency in the very suggestion" of feeling it "indelicate to discuss certain subjects before a fellow practitioner, female though she be," and that it is "mere professional jealousy and petty rivalry." After this, it was hardly necessary to call names, such as "sexual hyperaesthetics," or sneer at "superannuated fellows" defending their society from "moral contamination." If these angry phrases represent "the arguments of the innovators," it is scarcely to be wondered at that the "votes of the conservatives" went against them. After such a display of feminine anger I hope your contemporary feels relieved.

A different phase of the woman question has been reached in Dublin. There the students are excited because the College of Surgeons has appointed Miss Dr. Dickson examiner in obstetrics. This is only the corollary of admitting ladies to the profession, and, as Miss Dickson is a most distinguished Dublin student, I cannot see why her fellow-students should object to her becoming an examiner. Perhaps it is only Pat's love of excitement that makes him threaten. Irish students could not be destitute of the national humor.

The Epidemiological Society proposes to found a memorial Jenner medal, to be bestowed from time to time on persons who shall have contributed to the knowledge of preventive medicine.

A Jenner society has been formed at Gloucester, of which the zealous medical officer of health, Dr. Bond, is secretary. The first work of the society will be to circulate truthful literature on vaccination and otherwise check the false statements of the misguided "antis," or, as Jenner called them, "anti-vaccs," for he met with the usual opposition of ignorance and self-conceit.

The colossal bronze statue of Jenner in Kensington Gardens is the work of Mr. Calder Marshall, R.A., and is dated 1858. There was at first no little discussion as to the site it should occupy. It was first placed in Trafalgar Square, but some argued that Jenner would be out of place among soldiers and sailors, and some cynically pretended that no place could be found for one who only saved lives instead of destroying them. Mr. Punch had some lines addressed to England by

the ghost of Jenner, in which occurred the cutting couplet:

"I saved you many a million spots,
And yet you grudge one spot for me."

A spot was eventually found, and the statue removed from Trafalgar Square to Kensington Gardens.

The epidemic at Gloucester is abating somewhat, but is still a terrible object lesson. Four per cent. of the population has been attacked. During the last three weeks only two hundred cases were notified, bringing the total of the epidemic up to more than eighteen hundred.

On May 29, 1889, the vaccination commission was ordered to "report with as little delay as possible." During these seven years, at a cost of nearly £20,000, the inquiry has dragged its slow length along, but no report has yet seen the light and the laws on vaccination have been in many places left in abeyance pending the expected report.

At the meeting of the Clinical Society of London, on Friday, Dr. A. H. Weiss Clemon read notes of a case of typhoid fever with hyperpyrexia, in which acute cardiac dilatation occurred, treated by venesection and resulting in recovery. Mr. A—, aged twenty-five, became ill on November 13, 1895. His condition was, on the 26th, satisfactory; pulse 90, tongue moist and not excessively furred, and no abdominal distention. At 10 and 11:45 P.M. epistaxis occurred. Temperature at midnight, 103.4° F. Two hours later there was a severe rigor, he became wildly delirious, and the axillary temperature rose to 106.7° F. Vigorous iced sponging reduced this to 103° F., and he became quiet, though he continued unconscious. At 7 A.M. his temperature was normal, but at 7:30 there was another rigor with delirium, and the axillary temperature rose to 107° F. Iced sponging again lowered the temperature and quieted the delirium. Between 11 and 11:30 A.M. a rapid change for the worse occurred. The patient was apparently *in articulo mortis*, the face deeply cyanosed, the jaw dropped, conjunctival reflex absent, and respiration consisting of almost futile inspiratory efforts. Examination of the heart revealed a very considerable distention of the right side of acute onset. He was at once bled eight ounces, and subcutaneous injections of digitalin (one-one-hundredth grain) and strychnine (one-thirtieth grain) and brandy administered. The cyanosis then gradually diminished: the pulse, although very feeble and irregular for a few minutes, became fuller and less rapid; and shortly the respiratory movements improved, air entering the chest more readily. An hour later, and subsequently every three hours for the next twenty-four hours, the injection of digitalin and strychnine was repeated, supplemented by enemata of peptonized milk, beef tea, and brandy. About five o'clock he regained consciousness and was able to take some nourishment. The next day considerable hypostatic congestion of the lungs manifested itself, but passed off under appropriate treatment. During the remainder of his illness rigors threatened on two or three occasions, the temperature rising to 103° or 104° F., but the patient ultimately made a complete recovery.

Dr. Chapman noticed that the venesection was successful in reducing the temperature after the usual antipyretics had failed.

Dr. F. L. Benham said it was an open question how far this reduction in the temperature was due to the venesection. In a case of rheumatic hyperpyrexia which resisted antipyretic measures he employed venesection as a last resort, but without any benefit.

Dr. S. West pointed out that rigors not unfrequently follow hyperpyrexia. Bleeding, he said, is a great relief to the overdistended right ventricle, acting in a mechanical way, but will not of itself reduce pyrexia.

Dr. H. D. Rolleston and Mr. Warrington Howard related a case of chronic dilatation of the colon in a boy aged twelve. During the three months that he was under observation his condition varied, often very suddenly. He would improve for a time, the bowels acting daily and the abdomen becoming soft. Then suddenly constipation and vomiting would come on without manifest cause. These attacks usually subsided in a day or two, but in one of them he died. There was never any obstruction, the bowels acting nearly every day. Treatment was varied, but, with the exception of calomel, nothing seemed to do any material good.

Post-mortem: Great dilatation of the colon was found; the ascending colon passed up to the hepatic flexure, from which point the transverse colon descended to the neighborhood of the cæcum; the descending colon occupied the greater part of the right half and upper portion of the abdomen; it passed out of sight in the left lumbar region, and then joined the dilated sigmoid flexure. No stricture or cause for obstruction could be found anywhere. There were numerous ulcers in the colon, due presumably to distention. The muscular coats were hypertrophied.

Mr. Baldwin related a case of central sarcoma of the femur with early dissemination, in a man aged thirty-five, who died two days after admission. A post-mortem examination was made, and widely disseminated growths were found.

OUR BERLIN LETTER.

THE TWENTY-FIFTH (JUBILEE) CONGRESS OF THE
GERMAN SURGICAL SOCIETY.

(From our Special Correspondent.)

THE German Surgical Society, which was founded in 1872 by Langenbeck, Volkmann, Simon, Bardeleben, v. Bruns, Gurlt, and Billroth, held its twenty-fifth meeting here during Whitsun week. There was a large attendance of surgeons from all parts of Germany, and many foreign guests were present. Among the latter were Sir Spencer Wells, Reginald Harrison, and John Langton from England; Halsted, of Baltimore, and Lange, of New York; Ollier and Guyon, from France; d'Antona and Bottini, from Italy; and Sklifosovski, from Russia. The meeting was opened by v. Bergmann, who gave a sketch of the foundation and work of the society and spoke of the many great surgeons who had taken part in its deliberations. The cultus-minister welcomed the members on the part of the State.

The first paper was one of an historical nature, by v. Esmarch, of Kiel, in which he reviewed the history and development of his method of bloodless operation. When the speaker was a student, the main objections to many operations were the pain, the danger of infection, and the hemorrhage. It had been his fortune, after the first two of these obstacles had been overcome, to discover by accident the way to remove the third.

Bruns, of Tübingen, then delivered an address upon the development of the modern treatment of goitre. The earlier treatment by injection of iodine and other medication had been superseded by extirpation of the gland, for it was thought that the thyroid was of no special importance in the economy. The symptoms following this operation had, however, demonstrated the physiological significance of the gland, and now the extirpation was only a partial one. The most recent treatment is with thyroid extract, by means of which a rapid and extensive improvement in the symptoms, if not an absolute cure, is obtained. König followed Bruns with a paper on the development of

our knowledge of local tuberculosis, particularly of the bones and joints, in the past twenty-five years. He said that surgeons were now more conservative than formerly in their treatment of these affections, injections of appropriate remedies and orthopædic measures being now approved. The results were more satisfactory than those of the more energetic modes of treatment. Wölfler, of Prague, then presented a communication on gastro-intestinal surgery, and Sonnenburg, of Berlin, one on the surgical treatment of appendicitis. The latter said that every case must be treated by itself, according to the special indications. In simple catarrhal inflammation, an expectant treatment is indicated, but in cases of frequent relapses or when suppuration has set in, an operation is necessary. When septic infection has occurred the operation is too late. The best results are obtained in uncomplicated cases in which the appendix is removed. Langenbuch, of Berlin, closed this series of addresses by an historical review of surgery of the gall bladder.

Anger, of Munich, then read a paper on the results of Thiersch's neurexeresis, which consists in seizing the diseased nerve with forceps and gradually twisting the latter. In this way from twenty to twenty-five centimetres of the affected nerve may be removed. The speaker regarded this as an excellent method, and one which guarded more surely against relapses, and which was free from the dangers of some other operations.

Credé, of Dresden, spoke of the advantages of silver as an antiseptic. It was found that a bacteria-free zone was always present about a piece of metallic silver introduced into a culture. Chemical investigation had shown that a lactate of silver was here formed, but of all the salts of silver the carbonate was the best for antiseptic purposes. A silver solution destroys pathogenic germs when it is of the strength only of 1 to 8,000, whereas the required strength of a sublimate solution was 1 to 2,000. In practice Credé used silver powder and silver gauze, which he said gave excellent results in the case of small wounds.

Petersen, of Heidelberg, spoke on the bacteriotherapy of malignant tumors. His experience had demonstrated that sarcomata could be cured by the action of toxins, but carcinomata had hitherto proved refractory to such treatment. Riedel, of Jena, remarked that the microscopical diagnosis of sarcoma could not be made with absolute certainty, and it was quite possible that the supposed sarcomata in these cases were pseudoleukæmic tumors which were also curable with arsenic.

The recognition of bone lesions by the "X" rays was the subject of two communications by Kümmel, of Hamburg, and Geissler, of Berlin. The presence of diseased bone was shown in the skiagraph by a wavy blurring of the sharp contour of the bone. Kümmel had obtained pictures with an exposure of only twenty to thirty seconds. He passed around pictures showing disease of the elbow, the knee, the shoulder, swelling of the phalanges of the fingers, sarcoma, foreign bodies, etc. The apparatus with which these clear pictures were taken in so short a time was very expensive, costing about \$250. Feilchenfeld said that long exposures were not without their inconveniences, for he had seen an eczema solare produced in the case of a girl by an exposure of a half-hour's duration to the Roentgen rays.

Lexer, of Berlin, read a paper on experimental osteomyelitis. He had found that osteomyelitis in animals ran a much shorter and milder course after injections of attenuated cultures of streptococcus. v. Zolge, of Dorpat, showed the skeleton of a sixteen-year-old boy who had died of myositis ossificans. The bony outgrowths corresponded to the former muscles.

Olshausen read a paper on vaginal extirpation of the cancerous uterus. The cases for operation should be selected with the greatest care, for when the lymphatics of the uterus are already involved the operation should not be undertaken, or, if already begun, should be discontinued. In one hundred cases of vaginal extirpation he had had but one death. He believed that this operation formed one of the greatest advances of modern times, more patients being saved from certain death by this means than by any other. After Dührssen, of Berlin, had described a method intended to replace Cæsarean section, and Schuchart, of Stettin, an operation devised by himself for treatment of advanced stages of carcinoma of the uterus, Baumgärtner, of Jena, read a paper on the surgical treatment of hemorrhoids. The speaker was not in favor of the thermo-cautery or of ligation of the tumors, since by these methods too much normal tissue is destroyed. His method is to dissect out the individual tumors and tie them off, suturing the incised mucous membrane. The loss of blood is very slight, and the superficial incisions are quickly healed.

A paper by Lorenz, of Vienna, on the bloodless surgical treatment of congenital dislocation of the hip, excited quite a lively discussion. He drags the head of the femur down and presses it into the rudimentary acetabulum; the limb is then so fixed by an ingenious arrangement of bandages that the weight of the body presses the head of the femur firmly into the cotyloid cavity. This method does not necessitate confinement, for the more the child walks the more the head is pressed into the acetabulum, although walking is somewhat difficult at first. The speaker had treated forty-three children in this manner and had obtained a permanent reposition in all. He showed among other cases the three-year-old child of a physician, who had been cured in three months. Most of his cases had already been treated for long periods with plaster-of-Paris without result. He expressed the conviction that every case of unilateral dislocation up to the age of six years, and every one of double dislocation up to the age of five years, could be cured. Dolega, of Leipsic, Mikulicz, of Breslau, and Hoffa, of Würzburg, also described bloodless methods of treatment.

Riedel, of Jena, drew attention to the dangers to which workers in match factories are exposed, especially since the yellow poisonous phosphorus has come again to be used. The speaker had observed especially a fragility of the bones, one workman having had thirteen fractures in eight years. In the discussion it was suggested that the government should interfere and establish rules for the prevention of phosphorus poisoning. Küster, of Marburg, reported a case of malignant tumor of the bladder in which he had separated the ureter, and, after the removal of the growth, had fastened it into a healthy portion of the bladder.

Jürgens, of Berlin, presented a communication on the etiology of sarcoma. He had succeeded in inoculating animals with sarcoma. He held that certain forms at least of sarcoma were without any doubt caused by micro-organisms, by coccidia about the size of a cell nucleus, which probably have amœboid movements and in this way penetrate the cells and destroy them. In the course of his experiments the speaker had inoculated himself, and had a tumor of the finger which disappeared only after energetic treatment with sublimate for six or eight weeks. As the cause of this growth he found a form of gregarina which is always present in epithelioma contagiosum of chickens. The speaker also succeeded in inoculating animals with melanotic sarcoma.

The Murphy button was then discussed by Czerny, Kümmel, and Braun, the general opinion being in

favor of this ingenious apparatus, although cases were mentioned in which the button was retained in the bowel, causing pressure gangrene and necessitating a second operation. Stelzner exhibited a hair tumor weighing one hundred and eight grams which he had found in the stomach of a girl seventeen years old. The child had been in the habit of biting off hairs and swallowing them. Rhen, of Frankfort, then read an interesting paper on wounds of the stomach caused by non-penetrating blows. The subcutaneous injury may consist in tears varying in kind and depth, in separations of the mucous membrane, hæmatoma, abscesses of the stomach wall, and cysts. Among the causes of these injuries the speaker mentioned kicks, trampling, crushing between buffers, etc. In one case the mucous membrane was torn into strips. The nature of the lesion depends much upon whether the stomach was full or empty at the time the injury was received, for a full stomach is more easily injured by a force direct from in front toward the spinal column. Rupture often occurs from increased internal pressure when the force acts so as to compress one portion of the full stomach. Most cases of this sort terminate fatally in spite of operation, although the speaker reported some cases of recovery.

Several communications were presented by Bürgner, of Hanan, Cramer, of Cologne, Riedel, of Jena, Schnitzler, of Vienna, and Hasse, of Nordhausen. The latter described the alcohol treatment of carcinoma, and reported four cases of cancer of the uterus which were treated with alcohol injections twenty-three years ago, the patients being still alive. Mammary cancer was treated in the same way. In several cases the tumor had been removed by operation, but the carcinoma returned. These recurrent growths were treated by injections of alcohol encircling them, and their spread was thereby checked. Those who listened to this paper seemed little inclined to credit alcohol with any cancer-destroying properties.

In connection with the congress there was an exhibition of surgical apparatus and instruments, and also of Dr. Berliner's colored plastic representations of surgical and pathological specimens. Besides the purely scientific work of the congress, the members took part in a number of entertainments. The first day's session was closed by a dinner at the Kaiserhof, at which there were three hundred and sixty covers. The cultus-minister, Dr. Bosse, presided, and on his right was Sir Spencer Wells, on his left the president of the congress, Professor v. Bergmann, and next to the latter Dr. Ollier, of Lyons. Among the speakers were English, French, German, and Russian surgeons. On the evening of the second day the members of the congress were entertained by the Freie Vereinigung der Chirurgen Berlins in Kroll's Theatre. The Emperor and Empress were also present. The entertainment consisted of nine tableaux which symbolized the history of surgery. The first represented the battle of Teutoburger-Wald, showing how the place looked where the soldiers' wounds were dressed on the battlefield. The others showed the monk, the quack, and the barber as healers, and so followed the progress of surgery down to the present day, the final picture being in honor of the Red Cross. After this the guests with their ladies adjourned to the Königssäle, where there was a splendid supper spread on long rows of tables.

The subject of an international surgical congress was discussed, and it was determined to hold the first in London in 1900. Successive congresses will be held in France, Germany, and America. Each congress will be governed by a committee of the country in which it is held.

Prof. Paul Bruns, of Tübingen, was chosen president for the ensuing year. v. Bergmann announced

the closure of the twenty-fifth session with the remark that after a meeting so fruitful and so rich in scientific labors, the society entered under most favorable auspices upon its second quarter of a century. Bruns proposed a "Hoch" for the retiring president, and Riedel expressed the thanks of the society to the Free Society of the Surgeons of Berlin for the entertainment at Kroll's Theatre.

The number of members present at the congress was five hundred and nineteen.

OUR PARIS LETTER.

(From our Special Correspondent.)

WASHING THE BLOOD—ARTIFICIAL SERUM—TREATMENT OF ANÆMIA, TYPHOID FEVER, AND PERITONEAL INFECTION WITH SERUM—METHOD OF APPLICATION—NO CHOLERA AT MARSEILLES OR TOULON, THE PORTES D'ENTRÉE OF FRANCE—TRAFFIC IN STREPTOCOCCIC SERUM—RESIGNATION OF DR. ROGER IN CONSEQUENCE.

PARIS, June 10, 1896.

THE expression "washing the blood," although a technical one, well defines treating the blood-vessels as well as the liquor sanguinis itself by means of introduction into the circulatory system of artificial serum. This method is entirely different from and not to be confounded with "seropathie," which has received several terrible blows lately, one case having resulted in death within an hour after the injection.

Physiologists have known for some time past by repeated experiments in the laboratory that a frog may be bled until the arteries and veins are empty, and these may be to a greater or less extent recharged, not with the blood of another frog, but with artificial serum or simply salt and water, without the frog ceasing to live and to move freely. The presence alone of artificial serum in its veins is sufficient to furnish that stimulation or nutrition to the nerve centres that supports life.

It was these facts that led Professor Dastre, in 1889, to inject large quantities of artificial serum into the veins of animals that had first been anæmiated or intoxicated. It was some time after that Professor Hayem, the eminent therapist of the Faculty of Medicine, applied this method in the treatment of cholera, as did also Dr. Sahli, of Berne, in the treatment of typhoid fever and uræmia. Both obtained results that are extremely encouraging. There was a lull then, and not much was said on the subject in the meetings of the scientific societies until quite suddenly and recently three very important communications, one after the other, have been made—one by Dr. Duret, another by Dr. Lejars, and a third by Dr. Tuffier, at the Société de Biologie, which place the question of washing the blood among the most interesting of the moment. This blood washing, which may be more properly so designated when applied to the human subject, is, in the case of animals bled dry, really a substitution of the saline fluid for the blood itself; that is, the blood which contains a certain proportion of serum is transformed entirely into serum, and it would thus seem that the serum is that which nourishes the nerve centres, as well as the whole nervous system, and that which sets in motion the physiological mechanism—in other words, life.

It is in uræmia that this treatment has thus far been mostly employed, and it is in these cases that the "washing" is most evident, for we have here a blood thick with the uric poisons that the kidneys have been unable to eliminate; there is renal insufficiency, and unless prompt relief is given death will quickly result. If, now, eight hundred grams, one thousand grams, fif-

teen hundred grams, even two thousand grams of a saline solution of 10 to 1,000 be injected into a vein, under the most minute precautions as regards antiseptics and sterilization, the patient may be saved. Within from twenty minutes to an hour at the longest after the injection is practised, the comatose condition disappears, the tongue becomes humid again, the conjunctiva and cornea retake their transparency, the skin is moist with a profuse perspiration, the kidneys act freely as well as the other glands of the body, the intestines move, and there is a general return to life. The saline water taken into the circulation by the vein goes out by all the emunctories, carrying with it the toxins causing the uræmic symptoms; literally washing the blood of them. Dr. Lejars, of the Beaujon Hospital, and Dr. Tuffier report cases of tetanus, of peritoneal infection, severe hemorrhages, and operatory shock, cured by means of injection of artificial serum. Only in two or three cases did the patients succumb in spite of all, several hours after the injection. In addition to the cases reported at the Société de Biologie and at the Academy of Medicine, those reported by Drs. Segond, Delbet, and Pinard are equally important, as proving incontestably the efficacy of injections of artificial serum in uræmia, typhoid fever, cholera, tetanus, severe hemorrhage, intoxications, and nervous exhaustion, whether following an operation or idiopathic. Dr. Cheron's method of employing artificial serum is to use it in small quantity and oft repeated injections, thus producing an alterative and nutrient effect, which is doubtless more efficacious in those cases in which such treatment is indicated than would be the method of Professor Dastre, which is destined to supersede entirely transfusion of the blood.

The recent epidemic of cholera in Alexandria, Egypt, seems to be on the wane; nevertheless, it has inspired fears, which, we are happy to say, are absolutely groundless, that the disease, which is evidently Asiatic in character, may be or has been brought into France. It has already been reported as existing at Marseilles, that and Toulon being the usual *portes d'entrée*. These rumors are utterly false, the truth being that all ships coming from Egyptian ports are submitted to most rigorous quarantine and other sanitary measures. The last official bulletins from Marseilles and Toulon show the health of these towns to be in a very satisfactory condition. The mortality is low and the cases of cholera sometimes observed in them at this season of the year are wanting. The same may be said of Paris, the mortality rate of which is just now considerably below the average. Moreover, Paris and Marseilles are two of the best-watered cities in Europe. Marseilles has the Durance to depend upon, which carries fifty cubic metres of water a second, so that it has been and is possible to give to all the canals, and especially to the Marseilles canal, their normal quantity of water, and hygienists know how much that means in times of drought, which always favor and foster outbreaks of epidemic cholera.

An incident has just occurred that is making quite a stir in the medical and pharmaceutical world, and which has resulted in the resignation of one of our most distinguished *chefs de laboratoire*, as it has in the dismissal of his aid, or *garçon de laboratoire*.

The facts are briefly as follows: Dr. Bouchard, professor of general pathology at the Faculty of Medicine, has for one of his favorite pupils Dr. Roger, professor agrégé and médecin des hôpitaux, editing at the same time with Professor Bouchard his great work, "Traité de Pathologie Générale." Dr. Roger's best-known contribution to science is his discovery of the antistreptococcic serum, a serum entirely different from that of Marmorek.

It seems that the pharmaceutical house of Chaix &

Rémy undertook the sale and advertisement of Dr. Roger's serum, and as the discovery became public property the inventor remained entirely out of the case. Unfortunately, the aid or *garçon*, who understood perfectly the handling of toxins and how to use them, earning but a slender one hundred francs a month, yielded to the tempting offers of Messrs. Chaix & Rémy, and began to give more attention to the manufacture of serums than to his regular laboratory duties. When Dr. Roger was informed of this he did nothing to prevent it, and the matter was referred to Professor Brouardel, dean of the faculty. The resignation and dismissal above noted were the consequence.

No blame is attached to Dr. Roger, who certainly made a mistake in not bringing the matter to light at once. He evidently acted from motives of kindness. The serum is used chiefly in the treatment of erysipelas and puerperal fever, in both of which diseases the streptococcus is characteristic.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 20, 1896:

	Cases.	Deaths.
Tuberculosis.....	258	115
Typhoid fever.....	11	1
Scarlet fever.....	91	6
Cerebro-spinal meningitis.....	3	6
Measles.....	204	16
Diphtheria.....	239	35
Small-pox.....	0	0

Surgical Morals.—According to Dr. David W. Cheever in the present feverish condition of operative surgery it may be prudent to ask ourselves what is the object of an operation and how should we regulate our conduct in unforeseen contingencies (*Boston Medical and Surgical Journal*). The problem may be condensed into the following questions: 1. When to operate. 2. When not to operate. 3. When to stop. 4. When not to stop. In regard to the first question, says the author, if we confine our selection of cases to those which clearly come under the cardinal rule for operation—namely, to relieve suffering, to prolong life, or both—there will be very little difficulty in the choice. We must consider whether life is imperilled and whether the suffering can probably be relieved. If we are asked to operate, he says, shall we accept only good risks, and decline the doubtful or hopeless cases? The second question is a difficult one to decide. Operations should not be undertaken without the full consent of the patient and his family, if it is possible to obtain it, and there should be some responsible person who undertands the nature of the operation to be done and what may be reasonably expected from it. No operation should be done when the patient is in a state of shock, unless hemorrhage, apnœa, or obstruction of the bowels is present, as in hernia, for example. If there is time the systemic condition of the patient should be fully considered—for example, as to the integrity of the heart, the arteries, and the kidneys. In a case of no emergency the age and the prospect of life of the patient should be taken into account. In cases of glandular infiltrations which are so extensive as to preclude perfect removal, he says an operation should not be done; for instance, in a tuberculous organ, or in a sarcoma of the antrum where the

sphenoid cells cannot be extirpated. There are two important exceptions to this rule, however: 1. To relieve agonizing pain an operation should be done on any slight chance, for, unless the suffering can be palliated, the patient had better die than live. 2. In a forlorn hope, so to speak, after the risk has been fairly stated, the patient is entitled to an operation, if he wishes it, and if he takes the responsibility; here, however, the limit must be those cases in which there are one or more chances of success. Must we stop when the patient fails? Not always, for the failure may be due to the anæsthetic or even to simple nausea. In this case the surgeon should stimulate the patient and consider carefully before giving up the operation. Stopping, he says, is indicated when we come to the end of all that can be taken out—for instance, in a case of malignant tumor; in an operation in the abdominal cavity, when a glance or a touch reveals that the tumor is not removable and that it has grown into vital parts; in an operation on the surface of the body when stopping will not imperil life so much as going on; in syncope with a pulse at 108; with sighing respiration, and with a colliquative sweat. Concerning the fourth question, says the author, When not to stop, keep on as long as the patient breathes; it is his only chance. The contingencies are: An operation which has so far displaced and broken up a soft internal tumor as to render death from bleeding or from sepsis certain if any is left; an oozing hemorrhage; a difficult tracheotomy; a crushed skull with a pulse of 40 and Cheyne-Stokes respiration (having trephined, he says, we cannot stop until compression is removed and the bleeding checked; extravasation of urine, and a bladder to be drained; if the patient dies in the process, we must drain the bladder. If we do not do all these things, the patient dies; his only chance lies in their being done. Surrounded with these terrible chances the surgeon, like the executioner, raises or depresses his thumb, and the patient lives or dies. There is no responsibility like this. All this should teach us, first, to be over-careful about getting in so deep that we cannot withdraw, or about meddling with what had better be left alone. Second, not to imperil life to cover our mistakes, for we all make them. Third, in self-defence to withdraw from an operation or from a case at once if our advice is not followed. To bear the responsibility, we must be absolute masters.

Medical Practice in Spain.—Medical organization is greatly wanted in Spain. Every week the medical journals report lists of vacancies for district medical officers for the poor, appointments of a kind similar to dispensaries in this country; but the appointment is made for a term of years; when no term is fixed the doctor is liable to dismissal at any moment (*The Medical Press*). The payment is, as a rule, very small, as the following will show: District C, population 1,021, salary, 995 pesetas (£39 17s. 6d.). But the advertisement naively states that the doctor shall be at liberty to attend wealthy families in the neighborhood. For the district of P, population 5,411, the salary is 875 pesetas, and there is no mention of any wealthy families being in the neighborhood. District V, population 593, salary 150 pesetas, for attendance on seventeen poor families, and liberty granted to attend the 156 wealthy ones in the neighborhood—the contract to be for a term of four years. By the termination of contract the district of A, which includes three towns, offers 3,000 pesetas (£120), the contract to be for four years. The advertisement states that there is a good road connecting the towns, and that the country is very beautiful. In all cases the application is to be made to the alcalde. Such conditions are not likely to advance medicine, and they have undoubtedly been injurious to the people. Under the startling heading

“Dinamiteros,” *El Siglo Médico* has published a series of long articles on the present condition of Spanish society, which that journal states is being undermined by drunkenness and clandestine prostitution, and appeals urgently for a better system of education, which it looks to as a remedy capable of raising Spanish women to a sense of the worth of purity.

Pathological Society of Philadelphia.—At the stated meeting of the Pathological Society of Philadelphia, held on May 14th, Dr. Joseph Sailer presented a specimen of carcinoma of the cardia with contiguous involvement of the liver, and also five specimens of right-sided endocarditis. Dr. A. E. Taylor read on behalf of himself and Dr. Sailer a valuable communication entitled “The State of the Blood in the Carcinomatous Cachexia,” detailing nineteen cases in which careful differential estimations of the blood corpuscles were made. They found myelocytes in but four of the cases, while in the large majority the mononuclear leucocytes and the transitional forms were increased in number. As a rule the eosinophilous cells were few in number. Dr. F. A. Packard presented “Multiple Tuberculomata of the Brain and Tuberculous Adrenals” attended with epileptiform convulsions and cutaneous pigmentation. Dr. M. H. Fussell presented a number of gall stones from a case in which death had resulted in consequence of peritonitis in the absence of perforation. Dr. J. Dutton Steele exhibited a greatly dilated stomach whose capacity was easily three quarts; a liver presenting an extreme degree of cirrhosis, with peculiar and extensive adhesions to adjacent structures; and the cæcum and vermiform appendix from an infant, twenty days old, in whom these parts had entered the internal ring of the inguinal canal, and the appendix had apparently been constricted. Dr. H. W. Cattell exhibited the stomach from a case of arsenical poisoning due to the ingestion of “Rough on Rats” taken with suicidal intent. Dr. M. V. Ball exhibited an anencephalic monster. Dr. A. E. Taylor exhibited a carcinoma of the posterior wall of the stomach close to the cardia, characterized during life by intense cachexia and copious hemorrhage, and also surgical kidneys and bladder due to hypertrophy of the prostate in a man thirty years old.

Philadelphia County Medical Society.—At a stated meeting of the Philadelphia County Medical Society, on May 27th, Dr. Lawrence F. Flick read a paper entitled “Calomel as a Specific in Diphtheria.” Dr. G. Erety Shoemaker reported “Cases Illustrating Three Methods of Hysterectomy for Different Indications.” Dr. T. S. K. Morton read a paper upon “Saline Infusion for Hemorrhage, with Reports of a Case of Extra-Uterine Pregnancy and a Case of Stab Wound of the Thorax Apparently Saved by its Employment.” Dr. John S. Miller reported a case of hæmothorax from a stab wound of an intercostal artery, in which the hemorrhage was controlled by packing the wound with gauze.

The Poor in London Hospitals.—The following announcement appeared in the society column of the *Standard* a few days ago: “Upon inquiry at St. George’s Hospital last evening, it was ascertained that Mr. Philip Richard Morris, A.R.A., who three weeks since underwent an operation, was progressing satisfactorily toward recovery.” In a few weeks the collection boxes will be sent around London factories and workshops to receive the pence contributed by working men and boys in aid of St. George’s and other hospitals. The question arises whether these sons of toil know that their charity is being made use of to relieve gentlemen in the position of Mr. Morris, A.R.A.—*The Medical Times*.

The Significance of Pain.—In a recent lecture Professor Potain spoke of the value of pain in the diagnosis of disease, and stated that its absence usually made the prognosis more sombre, latent affections being grave because they develop freely without any warning to the patient (*New York Medical Times*). It is because of the absence of pain that many affections have remained so long obscure and have caused great ravages, such as endocarditis, chronic nephritis, and aortitis. Certain diseases, usually painful, may sometimes exist without this symptom; in waking typhoid fever the pain is so slight that the patient can carry on his ordinary vocation until intestinal perforation occurs, causing rapid death. In pleurisy the pain, sometimes so great, may be absent, but the disease is none the less serious on that account. Cases of angina pectoris in which there is no pain are the most dangerous. Certain diseases consist only of pain, such as gastralgia and enteralgia; in others pain is the predominant symptom. It should, therefore, be studied with the greatest care, and its characteristics fully determined. Its intensity is what naturally strikes the patient, but this is not at all proportionate to its cause, and depends upon individual conditions. It is well known that certain races are but slightly sensitive to pain and that education plays a great part in this sensitiveness. A reliable physician states that there is at Chantilly a colony of English jockeys who, accustomed to horseback riding, are liable to numerous fractures, but seem to feel only slightly the pain caused by them; while their wives, with but rare exceptions, never utter a cry during delivery. The intensity of pain is of value to the physician only when it is excessive; for instance, an intensely painful spot in the side may indicate gangrenous pleurisy; the appearance of peritoneal pain in typhoid fever may indicate perforation of the intestine. The seat of the pain has but little relation to the disease; thus the painful point in pleurisy is nearly always the same, no matter what may be the precise location of the inflammation. The only exception to this is the pleuritic pain of tuberculosis. Dorsal and substernal pain ordinarily indicates an affection of the œsophagus, but to make an exact diagnosis it is necessary to use the sound. Gastric pain indicates the location of the disease, as a general rule, and the patients are not deceived when they complain of pain in the stomach. Disturbance of the biliary passages is generally marked by pain in the right hypochondrium to the other. Nephritic colic causes pain along the corresponding ureter. Vesical pain is easily recognized because of the tenesmus which accompanies it. There are pains, the seat of which is pathognomonic, such as angina pectoris, in which it is prethoracic and radiates into the left arm, and sometimes into both arms. To this rule, however, there are many exceptions. Hepatic colic may cause pain only in the epigastrium and simulate gastralgia, while epigastric pain is often related to alterations of the solar plexus, such as that due to aneurism of the abdominal aorta. Reflex pain is also an important aid in diagnosis. It is necessary to bear in mind, in this connection, the dorsal pain in gastric affections; the scapulalgia of hepatic colic; the pain in the posterior portion of the deltoid region in diseases of the liver; the irradiations of nephritic colic into the testicles and thighs; the brachial and cervical pains of angina pectoris; the costo-xiphoidal pain of diaphragmatic pleurisy and pericarditis. Rectal pain often extends to the thighs, especially in elderly, constipated men, and such pain should always call for a rectal examination. In affections of the colon pain is frequently felt in the precordial region. Chronic colitis causes the arrest of fecal matter at the bend of the intestine between the transverse and descending colon, and the precordial pain

arising from this is a source of frequent errors in diagnosis. Of one hundred persons complaining of heart disease, about seventy have some affection of the colon. Ovaritis often gives rise to intercostal pain, and when the cause of a persistent neuralgia of this region in a woman cannot be found, it is well to consider the possibility of ovarian trouble. Pain upon pressure gives more precise information to the physician than any other. When this exists at the points of emergence of nerve branches only, it indicates a neuralgia. When it exists along the entire course of the nerve the case is one of neuritis. The absence of pain upon pressure in cases of spontaneous pain indicates its reflex nature.

Femoral Cystocele.—Dr. Thierier, of Brussels, reports a case of this uncommon disease. The patient, a man, aged fifty-one, presented himself with a well-marked femoral hernia, which was easily reducible, and he was anxious to have a radical operation performed. On cutting down on the tumor something unusual was recognized, and the protruding sac opened. A free flow of urinous-like fluid followed upon the incision, and by passing a catheter by the urethra it was plainly demonstrated that the tumor consisted of the bladder. Femoral cystocele is one of the least common of tumors. Ruysch, in 1737, reports some cases of inguinal cystocele, and cautions the surgeon that a hernia may contain any of the contents of the abdomen. Baron Haller, in 1755, copies the advice and cases of Ruysch, who, though he appears to have recognized the possibility of femoral cystocele, does not appear to have ever seen one. Pott, whose treatise on ruptures was published in 1756, writes: "A hernia formed by a protrusion of a portion of the urinary bladder through the opening in the abdominal muscle into the groin or scrotum is a disease sometimes, but not very frequently, met with." He describes two cases of inguinal cystocele that came under his own notice. Cystocele, perineal, inguinal, and femoral, is mentioned by Mr. Samuel Sharp (1740), M. C. Verdier (1784), Morgagni (letter 42), Petit, Ponetus, and Bartholin, who credits Dom. I. Sala (1623) with being the first to describe inguinal cystocele.—*Medical Press*.

Typhoid Thymus Extract.—Dr. George B. Henshaw reports, in the *Boston Medical and Surgical Journal*, May 14, 1896, thirteen cases of typhoid fever treated with the typhoid thymus extract. Of these the results in eight were satisfactory, in four the course of the typhoid was not materially shortened, and one death from hemorrhage occurred. One case of typhoid fever was treated with injection of the plain sterilized thymus extract (without inoculation of typhoid bacilli, for control experiment). There was no appreciable change in the chart, or in the condition of the patient at any time, showing that the presence of the typhoid organisms is essential to the success of this treatment. If these cases be added to those previously reported, there will be a total of ninety-eight cases of typhoid fever treated with this extract. Where the treatment has been started reasonably early, the author says there has not been a single death as yet recorded. He believes that this is worthy of further trial, and after two or three hundred cases have been reported some positive conclusions can be reached.

Did he Need it?—

Little Willie from his mirror
Sucked the mercury all off,
Thinking, in his childish error,
It would cure his whooping cough.
At the funeral Willie's mother
Aptly said to Mrs. Brown:
"Twas a chilly day for William
When the mercury went down."

INDEX.

A

- Abbe, Robert, what is amateur surgery? 427.
- Abdomen, massage of the, 203; operative interference in ailments of the, 740; treatment of lesions within the, 159.
- Abdominal operations, prevention of thirst after, 709; section on an infant, 802; surgery, prosecution for damages in, 808; *vs.* vaginal section, 23.
- Abnormality or madness, 756.
- Abortion, artificial, 55; prevention of threatened, 422, 610; rational treatment of, 234.
- Abscesses, aseptic treatment of, 48; retro-peritoneal, following the puerperium, 497; subphrenic, 217, 247.
- Accident neuroses, 719.
- Accidental injuries, 661.
- Acetanilid, poisoning from the external use of, 333.
- Acetylene gas, 166, 282, 310; not explosive, 389.
- Acidity, gastric, in its relation to acidity of the urine, 126.
- Acne, Tenneson's, 158; treatment of, 176, 422, 572.
- Acromegaly, pituitary gland extract in, 299.
- Acting Assistant Surgeons, bill for the relief of, 164.
- Actinomyces, 104; cervico-facial, 265.
- Adami, J. George, on the relationship between inflammation and sundry forms of fibrosis, 361, 397, 469, 505.
- Addison's disease, 314.
- Adenoid vegetations in the naso-pharynx, treatment of, 389; in the nose, resorcin for, 876; universality and antiquity of, 481.
- Adirondacks, 859.
- Advertising, medical, in England, 568, 598, 645; medical, in the daily press, 450, 531; wickedness of, 826.
- African fevers, 277.
- Agramonte, Aristides, infectious vulvo-vaginitis in children, 46.
- Air, taking the, without going out, 718; vitiated, respirability of, 393.
- Albumin in the urine, a test for, 337.
- Albuminuria, cantharides in, 447, 464; during pregnancy, 231; oedema without, 229.
- Alcohol, a word for, 16; action of, on the organs of special sense, 735; and public health, 173; for children, 52.
- Alcoholic beverages, the intoxicating principle in, 232.
- Alcoholism, increase of, 272; influence of, upon resistance to infection, 666; serum-therapy in, 754; study of, at the Moscow Congress, 926; treatment of, by strychnine nitrate, 264.
- Alexander, E., successful treatment of diphtheria without antitoxin, 445, 875.
- Alexander's operation, hernia following, 498; indications for, 358.
- Algiers, climate of, 213.
- Alleghany Mountains, 859.
- Allen, Charles W., congenital occlusion of the urethra—report of operation for its relief, 801; some of the uses of electrolysis in dermatology, 109.
- Almsgiving, 916.
- Alopecia, 286, 390; in children, treatment of, 873.
- Altitudes, high, influence of, on the blood, 265.
- Aluminium, cooking utensils of, 310.
- Ambler, C. P., antiphthisis, 107, 194.
- Ambulance season, the, 127.
- Amenorrhoea, 504.
- American Association of Genito-Urinary Surgeons, officers of, 926.
- American Climatological Association, 807.
- American Gynecological Society, 808.
- American Medical Association, 671, 709; permanent location of the, 711, 854; Section on Dermatology and Syphilography, 781; Section on Diseases of Children, 777; Section on Obstetrics and Diseases of Women, 714, 747; Section on Practice of Medicine, 712, 735; Section on Surgery and Anatomy, 712, 737.
- American Orthopaedic Association, 806.
- American Pediatric Society, 870.
- American Surgical Association, 865.
- Amputation, circular flap for, 321; hip-joint, by the bloodless method, 140; humero-ulnar and metacarpo-radio-ulnar osteoplastic, 304; knee-joint, 612; of the thigh, a new point in, 133.
- Amygdalitis, abortion of, 534.
- Anæmia, nervous disease as a cause of, 735; pernicious, 286; pernicious, condition of the stomach in, 702; treatment of essential, 668.
- Anæsthesia, a new, and alleged safe, mixture to produce, 429; chloroform and oxygen, 273; chloroform, during sleep, 16; deaths during, 452; local, 430, 728; local, Schleich's method of producing, 156, 230; local, from guaiacal injections, 286; risks of, 274.
- Anæsthetic holder, a new, 36.
- Analgesic and antiseptic dressing, 239.
- Anatomical material and preservatives, 95.
- Anderson, Dr. Arthur, death of, 790.
- Anderson, Dr. William, death of, 926.
- Aneurism, calcium chloride in, 321; extirpation of, 430; following gunshot wound of the neck, recovery after deligation of the left common carotid, 373.
- Angina pectoris, treatment of, 423.
- Angio-neurotic oedema treated by pilocarpine, 16.
- Animal extracts, 712.
- Animals, tuberculosis in, 825.
- Ankle, sprained, 64.
- Annals, medical, unnecessary, 59.
- Anthrax in London, 35; nucleinic acid in, 667.
- Antimicrobia, 508, 631.
- Antiphthisis, 106, 194, 215.
- Antisepsis and asepsis in London, 608.
- Antiseptic, mercury oxycyanide as an, 26.
- Antiseptic surgery in Germany, 521.
- Antitoxin of diphtheria, see *Diphtheria antitoxin*.
- Antitoxin or serum therapy, 572.
- Antitoxins, some recent experiences with, 59.
- Antivaccinationists getting vaccinated, 759.
- Antivivisection legislation, 269, 342, 909.
- Antrum maxillare, removal of large neoplasms from the, 141.
- Anus, atresia of the, 315; fissure of the, 426; fistula of the, 924.
- Aphrodisiac, 430.
- Appendicitis, 428; due to traumatism, 248; early operations in, 574; fresh specimens of, 664; medical aspects of, 613, 643, 679, 754, 791, 819, 875; pathology of, 375; statistics of, 643; time to operate for, 289; use of term, 503.
- Appendix, large foreign body in the, 248; mounting the in tubes, 250; technique of removal of the, 743.
- Archives of Clinical Skiagraphy, 807.
- Army, emergency rations in the, 161; medical service, British, 235, 464, 530; sanitation in, 405; titles of surgeons in the, 203.
- Arterio-sclerosis, a new, 791.
- Arterio-sclerosis, a new aid to the diagnosis of, 791.
- Arthritis, painful points in gouty as compared with rheumatic, 669; post-influenzal, 376.
- Arthritis deformans of the jaw, 312.
- Asbestos as a surgical dressing, 196.
- Ascites, collection of fluid behind the liver and spleen, 389.
- Asepsis in country practice, 876; in London, 717.
- Aseptolin, 353.
- Ashby, Henry, notice of book by, 680.
- Asphyxia, 35; neonatorum, treatment of, 429, 464.

 Shoemaker, John V., notice of book by, 680.
 Shoulder-joint, artificial, 249; diagnosis in some common injuries of the, 787.
 Shuttleworth, G. E., notice of book by, 67.
 Sibbett, Dr. R. L., death of, 350.
 Sick, trained attendants on the, 311.
 Siebold centenary in Japan, 562.
 Silver, antiseptic action of, 932.
 Sims, George K., abscess of the lung treated by incision and drainage, 500; myxofibroma of the bladder in a child three years old, 565.
 Singers, lingual tonsil in, 648.
 Sinus over sacrum and coccyx, 351.
 Sinuses, suppurating, tannin in the treatment of, 458.
 Skene, Alex. J. C., a singular case of patency of Gärtner's duct, 692.
 Skiagraph, 344; graduated time exposure, 717.
 Skin, diseases of the, modern treatment of, 642; diseases of the, permanganate of potassium in the treatment of, 302; manifestation of diabetes in the, 508, 540; diphtheria of the, 519; shedding of the, 343; surgery of the, 745.
 Skin grafting, 132; and corn-husk protective dressing, 499; after ablation of the breast, 788; method of obtaining material for, 265, 745.
 Skull, depressed fracture of the, recovery from, 707; exploration and treatment of fissures from fractures of the, 737; some novel methods of description of the, 97.
 Slander, law of, as affecting medical practitioners, 4.
 Sleep, after eating, does it aid digestion? 285; chloroform anaesthesia during, 16; hours of, 684; positions of, 393.
 Slobbering, a characteristic of unhealthy infants, 467.
 Small-pox, epidemic of, at Gloucester, 530, 716; the specific infectious agent of, 677.
 Smell and taste, a case of absolute loss of, 372.
 Smith, Andrew H., prognosis in pneumonia, 640, 670.
 Smith, Donaldson, an African explorer, 59.
 Smith, E. E., notes on urinary analysis, 13, 26.
 Snake bite, cure of, by orrhoterapy, 348.
 Snare, an improvement of Wright's, 36.
 Sneezing, camphor for, 572.
 Sodium chloride, pain relieved by insufflation of, 51.
 Soldiers, sanitary care of, 405.
 South Carolina, new health bill for, 236.
 South, importance of fevers in the, 673.
 Southern Empire State Medical Association, 418.
 Spaeth, Dr. Joseph, death of, 704.
 Spain, medical practice in, 935.
 Specialism, is it on the wane? 486.
 Specialists, unprincipled speculating, 324.
 Specialty, a new, 823.
 Speculum, self-retaining vaginal, 788.
 Spelling reform in England, 243.
 Spinal syphilis, 591; tabes, and general paralysis, relation between, 123.
 Spine, cervical, gunshot wound of the, 227; irritable, management of, 654, 662.
 Spitting nuisance, 127; action against the, 454, 457, 524, 632.
 Spleen, enlarged, 26; ruptured, 386.
 Spoons, varying sizes of, 733.
 Sprains of joints and their treatment, 835; of the ankle, 64.
 Sputum, in malignant tumors of the lung, 700.
 Square, Mr. William, death of, 753.
 Starchy foods, symptoms and diagnosis of indigestion of, 174.
 Stark, Henry S., psychical infection—remarks upon the probability of a mental contagium, 554; should our hospitals extend their facilities for operating to physicians generally? 120.
 Starr, M. Allen, a contribution to brain surgery, with special reference to brain tumors, 145; notice of book by, 681.
 State hospital buildings, new, 853.
 State Hospitals Bulletin, 21.
 Statistics, some general, 316.
 Stedman, Thomas L., notice of book edited by, 419, 776.
 Steers, Dr. Edgar H., death of, 771.
 Stephenson, Sydney, notice of book by, 682.
 Sterility and divorce, 287; causes of, 265, 656.
 Sterilization of the water of Paris, 661; surgical, in private practice, 746.
 Sterling, Dr. John, death of, 560.
 Stethoscope, an articulated Knapp's, 824.
 Stevenson's intermenstrual wave, 808.
 Stewart, Dr. William H., death of, 380.
 Stickler, J. W., effect upon the peritoneum of such substances as are apt to find their way into the abdominal cavity during operations thereon, 156.
 Stinson, J. Coplin, the operative treatment of inguinal hernia, with a series of ninety-seven cases, 329.
 Stirling, William, notice of book by, 67.
 Stitch abscesses, 159.
 Stomach, absorption in the, 670; acidity of the, in its relation to acidity of the urine, 126; and intestine, anastomosis of, with the Murphy button, 374; bacteriology of the, 514; carcinoma of the, 286; chemistry and bacteriology of the, in relation to therapeutics, 736; condition of the, in pernicious anemia, 702; dilatation of the, 668; diseases of the, blood changes in, 90; early diagnosis of cancer of, 736; functions of the, new light on, 125; mechanical causes of interference with the action of the, 741; method of defining the lower limits of the, 569; non-perforating ulcer of the, peritonitis caused by, 207; perforating ulcer of the, successful operation for, 205; physical signs in diseases of the, 339; state of the mucous membrane in secretory disorders of the, 917; stone in the, 158; surgery of the, 741; technique of massage of the, 334; ulcer of the, 533; wounds of, without perforation of the abdomen, 933.
 Stone, R. M., short-sighted medical directors, 388.
 Stover, G. H., graduated time-exposure skiagraphs, 717.
 Stowell, William L., diphtheria with and without antitoxin, 903, 913.
 Strachan, A. Russell, three cases of enuresis successfully treated by similar methods, 338.
 Stradling, Dr. Arthur, death of, 927.
 Straw plaiter's cramp, 201.
 Stricture, urethral, electrolysis in, 802.
 Students, medical, revolt of, 58.
 Styptic, a new, 518.
 Subphrenic abscess in its relation to pyothorax, 713.
 Sugar as a muscular food, 730; in the urine, tests for, 504.
 Suicide in European cities, 144; infectiousness of, 59.
 Sultzbach, Dr. Samuel O., death of, 704.
 Summer health resorts, 850, 855.
 Summers, J. E., Jr., hemophilia, an unrecognized case which terminated fatally after excision of the knee-joint, 336.
 Sunshine and life, 179.
 Suprarenal capsules apparently nervous ganglia, 610.
 Surgery, amateur, 355, 427, 504; microscopy in, 540; some limits to the art of, 674.
 Surgical dilettantism, inherited, 348.
 Susceptibility and immunity, with special reference to surgical cases, 869.
 Suspension in the resuscitation of the newborn, 87.
 Suture, the buried tendon, 304.
 Swan, Dr. Robert Ellis, death of, 383.
 Symphyseotomy, 714; after-effects of, with description of a new method, 210; non-consolidation of symphysis after, 837.
 Syphilis acquired through a flea-bite, 251; antagonism of, to tuberculosis, 228; antitoxin of, 340, 463, 481; as a factor in diseases of the heart and lungs, 319; blood changes in, in relation to therapy, 908; cerebro-spinal, 62; chronic acid with nitrate of silver in, 873; congenital, and tuberculosis, 304; diseases of the liver caused by, 122; early and latent, in infants and young children, 172; in infants, 448; intermittent treatment of, 534; interstitial keratitis from, 610; length of treatment of, 684; of the placenta, 519; pharyngeal and laryngeal adhesions and strictures in, 123; spinal, 591; spinal, tabes, and general paresis, relation between, 123; sulphur baths and mercurial friction in, 340; treatment of, 157; value of mercurial injections in the treatment of, 449.
 Syphilitic osteochondritis, 212.
 Syphiloma, diagnosis of, 374.

T

- Tabes, early symptoms of, 52; general paresis, and spinal syphilis, relation between, 123; syphilitic origin of, 692.
 Tait, Lawson, the evolution of the surgical treatment of the broad-ligament pedicle, 547.
 Tannin in the treatment of suppurating sinuses, 458.
 Taste and smell, a case of absolute loss of, 372.
 Tax on physicians, proposed, in Hawaii, 821.
 Taylor, Dr. Marcus L., death of, 242.
 Taylor, Dr. W. H., death of, 19.
 Tea smoking, 235.
 Teaspoon, the size of a, 822.
 Teeth, transplantation of, 16.
 Tendon grafting, priority of, 71, 133, 246.
 Tents, anaesthetic, 340.
 Testicle, dislocation of the, into the penis, 11.
 Tetany and rickets, 790; hysterical, 400; report of five cases, 44.
 Theobromine, 463.
 Thermometers, dirty, 142.
 Thirst, prevention of, after abdominal operations, 709.
 Thompson, Mr. Thomas William, death of, 502.
 Thomson, W. H., how the facts about the antitoxin treatment of diphtheria should be estimated, 893, 913; some points in the therapeutics of diseases of the heart, 793.
 Thoracic duct, occlusion of the, 211.
 Thoracoplasty, 713.
 Thousand Islands, 864.
 Throat and nose, importance of digital examination in the diagnosis and treatment of diseases of the, 552.
 Thymus gland, a large, 250.
 Thyreo-antitoxin, 37.
 Thyroid cartilage, compound fracture of the, 458.
 Thyroid gland, active principle of the, 37; multiple exogenous adenomata of the, 568.
 Thyroid therapy, 278, 658; in the insane, 705.
 Thyrotomy, 1.
 Tic douloureux, treatment of, 340, 669.
 Tics, classification of, 870.
 Tidey, Stuart, the white throat of the lake, 532.
 Tinea versicolor, treatment of, 422.
 Tinnitus aurium, objective, 157.

- Tongue, carcinoma of the, Kocher's operation, 135; indications in the, 540.
- Tonsil, lingual, in singers, 648; non-recurrence of cancer of the, three years after operation, 204.
- Tonsillar adhesions, knife for, 322.
- Tonsillitis, infectious nature of lacunar, 303; septic, 55; virulence of diphtheria bacilli occasionally in the throat in, 670.
- Tobacco, indications and contraindications for the use of, 199; use of, in disease, 286.
- Tobacco smoke, antiseptic action of, 373.
- Tousey, Sinclair, foreign body in the male urethra removed by internal urethrotomy, 626.
- Toxins, latency of, in the human economy, 30, 31.
- Tracheotomy, a clinical study of, 228; treatment of membranous croup after, 644.
- Trachoma, 422.
- Transvaal, defective sanitation in the, 854; government medical board and american medical degrees, 533.
- Treadway, Wm. A. B., on a monstrosity, 88.
- Trichiasis, 529.
- Trichinosis, some new observations on, 516.
- Tri-State Medical Society becomes a Bi-state, 58.
- Tri-State Medical Society of Iowa, Illinois, and Missouri, 572.
- Trott, Dr. Thomas Henry, death of, 704.
- Trudeau, E. L., antiphthisin, 215.
- Tsetse-fly disease, 600.
- Tubercle bacillus, growth of, in acid media, 105; transmission of, 150; two varieties of, 667.
- Tubercular and tuberculous, 21.
- Tuberculosis, alleged to follow an injury of the knee; 238; and congenital syphilis, 304; and family history, 388; antagonism of, to syphilis, 228; antiseptis in, 282; articular, 675; bovine, at the Norristown hospital, 56; bovine, prevention of, 596, 597; criticism of the "guinea-pig test" for, 726; contagion of, 344; from meat, 238; glandular, 867; hospital for the treatment and investigation of, 130; hydropathic treatment of, 570; in Australia, 324; in domestic animals, 825; in England, 595; insidious origin of, 826; intrathoracic, 866; laryngeal, 429; laryngeal, arrest of, 343; miliary, 610; non-tuberculous ulcers in, 504; of the cæcum, excision of the gut in, 339; of the female genital organs, 866; of the testicle cured by the galvanic current, 693; Paris hospitals as nests of, 351; personal condition is estimating a liability to, 388; prevention of, 344; pulmonary, diagnosis of early, 829; pulmonary, potassium permanganate in, 263, 355; pulmonary, treatment of, 52, 135, 622, 638; renal, 647; renal, surgical intervention in, 924; report of the royal commission on, 502; reward for the discovery of a cure for, 595; serum-therapy in 194, 340, 515, 736; sexual, 104; State control of the spread of, 171; surgical, 574, 824; temperature in, 4; value of family history and personal condition in estimating a liability to, 266.
- Tuttle, James P., prolapse of the rectum with special reference to its obscure forms and some of their reflex phenomena, 38, 60.
